Geological Society, December 19, 1888.—W. T. Blanford, F.R.S., President, in the chair.—The following communications were read :—*Trigonocrinus*, a new genus of Crinoidea from the "Weisser Jura" of Bavaria, with description of new species, *T. liratus* ; Appendix I. Sudden deviations from normal symmetry in Neocrinoidea ; and Appendix II. *Marsupites testudinarius*, Schl., sp., by F. A. Bather. This genus is proposed on the evidence of two calyces in the British Museum (Natural History) which were found among specimens of *Eugeniacrinus* from Streitberg. The species of *Eugeniacrinus*, *Phyllocrinus*, and *Trigonocrinus* may be arranged in a series which is apparently one of evolution. The present genus is, therefore, to be placed with the Eugeniacrinidæ, although its characters are not those of the family as heretofore defined. This is seen from the following diagnosis : *Trigonocrinus*, gen. nov. Calyx roughly triangular or trilobate in section. Basals 4, but one so atrophied as to be almost invisible ; all fused into a basal ring. First radials 4 ; the two on either side of the smallest basal half the size of the others, thus maintaining the triangular symmetry ; all closely united, with each suture-line in a groove. Processes of radials well developed, forming spines homologous with the petals of *Phyllocrinus* ; except the adjacent processes of the smaller radials, which only form a minute ridge. Articular surface of radials curved gently inwards and upwards ; muscular impressions indistinct or absent ; no articular ridge ; no canal-aperture. Arms unknown (? represented by fleshy appendages). Calycal cavity contained in first radials ; with small round ventral aperture, surrounded by a rim, which is the only relic of a muscular attachment. Stem unknown. The two calyces belong to the same species, viz. *T. liratus*, sp. nov. Calyx rather more elongate than in the known species of *Phyllocrinus* ; basals ornamented with minute granules ; radials ornamented with similar granules run into curved ridges, which, owing to their differing intensity, give an imbricated appearance ; spines, triangular in section, with the base of the triangle directed inwards, the apex outwards, the angles often rounded. The differentiation of *Trigonocrinus* from the central Eugeniacrinid type has been effected on the one hand in accordance with the principles of "Degeneration," "Reversion," and "Use and Disuse" ; while, on the other hand, it exemplifies certain methods of change in organic forms, which may be referred to the categories of (1) sport, (2) hypertrophy and atrophy, (3) fusion and fission. Thus considered it is of unique interest among Crinoidea. An examination of the variations in symmetry presented by the Echinodermata suggests the conclusion that the Pentamerous type was originally evolved from another system, or at least that it was selected from among other variations, that it has survived, and that it has been kept true, as being the fittest. Appendix I. Sudden deviations from normal symmetry in Neocrinoidea. A collection of instances from previous authors, with a few additions, the whole illustrating the latter portion of the paper. Appendix II. On *Marsupites testudinarius*, von Schlotheim, sp. A synonymy of the genus *Marsupites* ; it contains but one known species, and all other names must yield to this one. After the reading of this paper the President welcomed a new palæontologist to the Society, and some comments on the author's views were offered by Dr. P. H. Carpenter and Prof. Seeley.—On *Archæocyathus*, Billings, and on other genera allied thereto, or associated therewith, from the Cambrian strata of North America, Spain, Sardinia, and Scotland, by Dr. G. J. Hinde.—On the Jersey brick clay, by Dr. Andrew Dunlop.

PARIS.

Academy of Sciences, December 31, 1888.—M. Janssen in the chair.—Mean elevation of the continents and mean oceanic depths in relation to geographical latitude, by General Alexis de Tillo. Tables are given of the mean elevations and depths, in metres, for every zone of 10° of latitude from pole to equator in the northern and southern hemispheres, based on J. G. Bartholomew's hypsometric chart of the globe. The greatest mean heights and depths are found in the northern hemisphere, between 30° and 40° ; in the southern, between 10° and 30°, which also correspond to the zones of greatest atmospheric action and mean annual pressure. The mean height of the dry land and the mean oceanic depth for the globe are found to be, respectively, 693 and 3803 metres.—Observation of shooting-stars for the period August 9-11, 1888, in Italy, by Père F. Denza. The results are tabulated of the records taken at twenty-nine Italian stations, showing the number of meteors observed in the space of one hour during the periodic showers on the nights of August 9, 10, and 11, 1888. These results differ considerably for the different stations, owing to the varying state of the atmosphere, the experience of the observers, and other causes ; but, on the whole, the meteoric shower was tolerably copious compared with those of previous years.—On the volumes of saturated vapours, by M. Ch. Antoine. From the general relation established by Zeuner between the pressure and volume of aqueous vapour, formulas are here determined for the volumes of the vapour of water, ether, acetone, chloroform, chloride of carbon, and sulphide of carbon.—Propagation of the electric current on a telegraph line, by M. Vaschy. From a consideration of Sir W. Thomson's theory of propagation applied to long submarine lines, it is generally inferred that the currents are propagated along the line *without change of form*, their amplitude alone decreasing in geometric progression. An important practical consequence of this result is indicated for the working of telegraph lines, and this is stated to be also applicable to telephonic messages.—Action of sulphuretted hydrogen on the sulphate of zinc in a neutral or acid solution, by M. H. Baubigny. A current of hydrosulphuric gas passed through a *saturated* solution of zinc causes a portion of the metal to be precipitated ; but the action is arrested when the solution becomes acid to a certain point of intensity. This statement of Berzelius is correct enough, as thus expressed. But the law deduced from its generalization for all cases is here shown to be false, and completely at variance with experience, especially when the solutions are diluted.—Artificial reproduction of chromiferous iron, by M. Stanislas Meunier. After repeated failures, the author has at last succeeded in obtaining this substance (*chromite*) by combining the protoxide of iron obtained from the carbonate with the sesquioxide of chromium obtained by the reduction of the bichromate of potassa.—A chemical study of the Algerian soils, by M. A. Ladureau. A careful analysis of samples from various parts of Algeria shows a general dearth of phosphates, which explains the inferior quality of the cereals grown in that colony.—Combination of the glycol-alcoholate of soda with glycol, by M. de Forcrand. The author has already shown that many alcoholates unite with one or more molecules of a monatomic alcohol to form more or less stable crystalline compounds analogous to the acid salts, and to the numerous hydrates of the salts, bases, or acids. Here, he shows further that glycol may combine in the same way with the glycol-alcoholate of soda at equal equivalents.—On the active crystalline substance extracted from the seeds of the smooth or hairless Strophanthus of the Gaboon, by M. Arnaud. An analysis of this substance, used by the Pahouins (Fans) for poisoning their arrow-heads, shows its close affinity to the wabaine of *Acokanthera Wabaio* from Somali-land, and the strophanthine of *Strophanthus Kombé*, from Senegambia, previously described by the author.—Biological and therapeutic experiments on cholera, by M. W. Loewenthal. A series of experiments undertaken last year with the cholera bacillus seems to show that salol might be advantageously administered both as a prophylactic and a therapeutic during the prevalence of the cholera epidemic.—On a deposit of fossil bones in the Island of Samos, contemporaneous with the Pikermi age, by Mr. Forsyth Major. This find is the result of a scientific exploration of some islands in the Ægean in the year 1887. It comprises some forty species of mammals, some of

which have been identified beyond doubt with members of the Pikermi fauna. Amongst them are the Ictitherium (three species), a mastodon (*M. pentelici*), a rhinoceros, a hipparion (*H. mediterraneum*), *Sus erymanthius*, and seven antelopes. Representatives were also found of the two families of Edentates still living in the Old World; a gigantic Ruminant belonging to the giraffe family, but forming a new genus (*Samotherium boissieri*, Major); and an ostrich (*Struthio karatheodoris*, Major), equal in size to the largest members of the *Struthio camelus* group.

BERLIN.

Physical Society, November 30, 1888.—Prof. Kundt, President, in the chair.—Prof. Neesen spoke on a photographic method of registering the oscillations of projectiles. The conical end of the projectile is hollow, and at the point of it there is a small round opening; a sensitive photographic plate is placed in the cavity of the projectile. If the latter is now fired towards the shining sun, a ray of light must fall on the centre of the sensitive plate as long as the projectile moves horizontally; any deviation in a vertical or horizontal direction must produce an elongated image on the plate, and from this the deviation of the projectile from its true flight may be determined. If the projectile rotates in its flight a spiral will be obtained on the plate. The speaker had made some preliminary observations on rotating and vibrating hollow conical balls, and exhibited the negatives which he had obtained. The rotation of projectiles presents great difficulties, inasmuch as in a series of experiments the sensitive plate must not participate in the rotatory motion. The arrangements necessary for securing this result were described. Experiments as above described must be of the greatest interest in connection with the theory of projectiles, since up to the present time but little is known of the extent of the vertical and horizontal deviation during flight.—Prof. Neesen also gave an account of a stroke of lightning whose effects he witnessed while on a journey last summer. The lightning struck the centre of the roof of a two-storied house, passed along externally for a short distance, then made a round hole through the wall, and came upon the hook from which a mirror was suspended; it then passed over to the glass, fusing it at the upper corner, in the middle where the two halves of the glass joined, and at the lower opposite corner, and finally passed out again through a round hole in the wall below the glass. The way in which the latter was injured by the lightning was especially remarkable, as also was the way in which the lightning, instead of passing straight along the outside of the wall, made its way by one hole to the looking-glass in the room, and then passed out again by another similar opening.

Physiological Society, December 7, 1888.—Prof. du Bois-Reymond, President, in the chair.—Prof. Munk continued the communication which was interrupted at the last meeting of the Society, on the physiology of the thyroid.

December 21, 1888.—Prof. du Bois-Reymond, President, in the chair.—Dr. Barth gave a detailed description of his method of preparing the membranous labyrinth, and exhibited a series of preparations which had been made by this method. He intends to study fully the minute anatomy of the internal ear with the help of these preparations.—Dr. Weyl gave an account of his researches made with a view to determining the toxic or harmless action of the colouring-matters derived from tar. Inasmuch as the German Statute-book only forbids the use of two of these colouring-matters derived from tar as being poisonous, the speaker had made a systematic examination of an extended series of these colours, including such as might possibly be employed for the coloration of food-materials and might hence be a matter of dispute. He first tested the nitroso-and nitro-derivatives of benzol and phenol, and found the first to be non-poisonous, taking phenyl green as a typical representative. The nitro-derivatives which he examined—namely, picric acid, dinitro-kresol, and Martius's yellow—he found to be poisonous; the sulpho-compounds of the last-named colouring-matter, of which two are now articles of commerce—namely, naphthol-yellow S, and brilliant-yellow S—he found to be harmless. This fact points to a relationship between the chemical constitution and physiological action of these bodies. He busied himself further with an examination of the azo-colours, of which many hundred are used commercially. These fall naturally into two groups—namely, one in which the colouring substances contain only one azo-group, and a second in which they contain the azo-group twice, or as it may be called the Congo-group. These groups are distinguished physiologically by the fact that the first does not impart any colour to the urine, while the second does; they are further distinguished technically by the fact that the first group can only be used for dyeing by the help of a mordant, whereas the second does not require the use of any mordant. Dr. Weyl first investigated the action of substances containing one azo-group—namely, aurantia or imperial-yellow of commerce (hektanitro-diphenylamine); this colouring-matter was non-poisonous, and remained so after it had become soluble by the introduction of the sulpho-group (HSO_3) into its molecule. In the above researches the speaker used fibres of wool or silk, either mordanted or not according to the nature of the colouring-matter, for the purpose of determining their presence in the fluids and urine from the animals on which he was experimenting, dipping the threads into the fluids: he found that the commencing coloration of the fibres was the most certain sign of the presence of the colouring-matter.

Note.—In NATURE for December 13, p. 167, column 2, the sixth line from the bottom of the page, instead of "fall" read "rise."

AMSTERDAM.

Royal Academy of Sciences, December 29, 1888.—Mr. J. A. C. Oudemans criticized the value of the retrogradation of the plane of Saturn's ring, determined by Bessel in 1835, and generally adopted also for the plane of the orbits of the inner seven satellites of that planet. He remarked that Bessel's value 3''·848, being exceeded by its mean error, is not trustworthy. He prefers the theoretical value, for which he finds 0''·25.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

A Text-book of Elementary Biology: R. J. H. Gibson (Longmans).—Chance and Luck, new edition: R. A. Proctor (Longmans).—The Photographer's Diary and Desk Book, 1889 (Wyman).—A Text-book of Physiography: E. Hull (Deacon).—The Telephone: W. H. Preece and J. Maier (Whittaker).—Triennial Calendar of the Tungwen College (Peking).—Descriptive Catalogue of the Sponges in the Australian Museum, Sydney: R. von Lendenfeld (Taylor and Francis).—Corona; the Bright Side of the Universe: F. T. Mott (Williams and Norgate).—Manual of Orchidaceous Plants, Part 4, Cypripedium (Veitch).—Explosion of an Air Receiver at Ryhope Colliery (Newcastle-upon-Tyne).—The Anatomy of Megascolides australis (the Giant Earth-worm of Gippsland): W. Baldwin Spencer (Melbourne).—Journal of Anatomy and Physiology, January (Williams and Norgate).—Mind, January (Williams and Norgate).—Quarterly Journal of Microscopical Science, December (Churchill).—Quarterly Journal of Royal Meteorological Society, October (Stanford).—Geological Magazine, January (Trübner).—Journal of Society of Telegraph Engineers and Electricians, No. 75, vol. xvii. CONTENTS.

THURSDAY, JANUARY 17, 1889.

THE HISTORY OF MATHEMATICS.

A Short Account of the History of Mathematics. By W. W. Rouse Ball. (London and New York: Macmillan and Co., 1888.)

THE quaint words addressed "to the great variety of readers" by the editors of the folio Shakespeare of 1623 are equally applicable to the useful compendium of mathematical history which is the subject of our review. "It is now public; and you will stand for your privileges, we know—to read and censure. Do so, but buy it first: that doth best commend a book, the stationer says. Then how odd soever your brains be or your wisdoms, make your licence the same, spare not." But, as goods are usually "bought by judgment of the eye, not uttered by base sale of chapmen's tongues," we produce our samples in the open market by making a few extracts from Mr. Ball's book.

In the opening chapter, on Egyptian and Phœnician mathematics, we become acquainted with an old Egyptian, "a priest named Ahmes," who, "somewhere between the years 1700 B.C. and 1100 B.C.," wrote, on imperishable papyrus, a book entitled "Directions for Knowing all Dark Things," which "is believed to be itself a copy with emendations, of an older treatise of about the time 3400 B.C." Remembering that this work was written certainly five hundred, and probably more than a thousand, years before the time of Thales, the first of the Greek mathematicians, and founder of the Ionian school, it must be regarded as a most remarkable production; for Profs. Cantor and Eisenlohr have shown that Ahmes had some notion of trigonometry. In his problems on pyramids, "Ahmes desires to find the ratio of certain lines, which is equivalent to determining the trigonometrical ratios of certain angles. The data and the results given agree closely with the measurements of some of the existing pyramids." But perhaps the most interesting feature of this ancient treatise is the algebraic notation employed in it, which our author describes in these words:—"The unknown quantity is always represented by the symbol which means a heap; addition is represented by a pair of legs walking forwards; subtraction by a pair of legs walking backwards, or by a flight of arrows; and equality by the sign /∠." Our own + and − first appeared in Widman's "Mercantile Arithmetic" (published at Leipzig in 1489): with him (see p. 186, Ch. XII.) they "are only abbreviations, and not symbols of operation; he attached little or no importance to them, and would no doubt have been amazed if he had been told that their introduction was preparing the way for a complete revolution of the processes used in algebra." The philosophic conception of the nature of algebra (symbolized by the legs walking forwards and backwards; a notion closely related to, if not identical with, Sir W. R. Hamilton's definition of algebra as the science of pure time) perished with its author: the mere abbreviations (+ and −) lived and flourished—but then Widman was able to print *his* book.

The first date that can be assigned with absolute precision is that of Thales. "It is well known that he predicted a solar eclipse which took place at or about the time he foretold: the actual date was May 28, 585 B.C." It marks the real commencement of the history of mathematics; for the science, now revived in Greece, was at this time neglected and completely forgotten by the Egyptians. When we read that Thales, to the utter amazement of the King and all who were present, showed them how to find the height of a pyramid, by a simple application of the theorem that *the sides of equiangular triangles are proportionals*, we may well wonder why Ahmes did not burst his mummy-case and appear in their midst with his book opened at the problems on pyramids.

From the time of Thales to that of Euclid, the knowledge of mathematical facts acquired in one generation was transmitted to the next, almost exclusively by means of oral tradition. That such was the case is mainly due to the Pythagorean secret Society. "Pythagoras himself did not allow the use of text-books, and the assumption of his school was, not only that all their knowledge was held in common, and secret from the outside world, but that the glory of any fresh discovery must be referred back to their founder: thus Hippasus (*circ.* 470 B.C.) is said to have been drowned for violating his oath by publicly boasting that he had added the dodecahedron to the number of regular solids enumerated by Pythagoras. Gradually, as the Society became more scattered, it was found convenient to alter this rule, and treatises containing the substance of their teaching and doctrines were written. The first book of the kind was composed by Philolaus (*circ.* 410 B.C.), and we are told that Plato contrived to buy a copy of it."

Now Anaximander, the immediate successor of Thales as head of the Ionian school, had the honour of teaching Pythagoras; while Eudoxus, Philolaus, and Plato, all of them received their mathematical training from Archytas of Tarentum, who was one of the most celebrated of the Pythagoreans; and "Menæchmus, who was a pupil of Plato and Eudoxus," was alive as late as 325 B.C., which brings us down to about the time of Euclid. Thus the chain of tradition connecting Thales with Euclid is complete. Its successive links can be traced in the second and third chapters of the work before us.

Among the contemporaries of Plato, Eudoxus of Cnidus deserves special notice. His biography is to be found in Diogenes Laertius, who speaks of him as an astronomer, geometer, physician, and statesman; mentions his great works on astronomy and geometry, and his minor treatises on other subjects; and refers to the fact that he *discovered curved lines.* Modern research has found out what the curves of Eudoxus were, though all his writings are lost: in our author's words, "he discussed some plane sections of the anchor ring," among them the curve which ought in future to be named after him, but is "generally called Bernouilli's lemniscate." Thus, Eudoxus (who died in 355 B.C.) anticipated James Bernouilli (d. 1705 A.D.) by more than 2000 years!

The foundation of Alexandria by Ptolemy marks an epoch in the history of mathematics. Alexander himself did little more than choose the site, and it was entirely due to Ptolemy that the city did not share the fate of at least two others of the same name whose foundation

by Alexander is duly recorded by his biographer, Quintus Curtius. What Alexandria actually became, is thus briefly and graphically described :—

"The earliest attempt to found a University, as we understand the word, was made at Alexandria. Richly endowed, supplied with lecture-rooms, libraries, museums, laboratories, gardens, and all the plant and machinery that ingenuity could suggest, it became at once the intellectual metropolis of the Greek race, and remained so for a thousand years. It was particularly fortunate in producing, within the first century of its existence, three of the greatest mathematicians of antiquity—Euclid, Archimedes, and Apollonius. They laid down the lines on which mathematics were subsequently studied, and, largely owing to their influence, the history of mathematics centres more or less round that of Alexandria, until the destruction of the city by the Arabs in 641 A.D."

It would occupy too much space to discuss, or even to enumerate, the writings of the Alexandrian mathematicians. The most precious relics they have left behind them are: the greater part of the numerous works of Euclid, many of the writings of Archimedes, the "Conics" of Apollonius, the "Almagest" of Ptolemy, the "Mathematical Collections" of Pappus, and the "Arithmetic," or, rather, the "Algebra," of Diophantus. These and other valuable pieces of work, which, like them, have reached us in a more or less mutilated condition, are reviewed in the fourth and fifth chapters of Mr. Ball's "History," in which the best editions of these classical authors are mentioned, and other sources of information concerning them are referred to. We owe the preservation of most of them to the Greek refugees at Constantinople, as will be seen from the following quotation :—

"After the capture of Alexandria by the Mohammedans, the majority of the philosophers, who had previously been teaching there, migrated to Constantinople, which then became the centre of Greek learning in the East, and remained so for 900 years. But, though its history covers such an immense interval of time, it is utterly barren of any scientific interest; and its chief merit is that it preserved for us the works of the different Greek schools. The revelation of these works to the West in the fifteenth century was one of the most important sources of the stream of modern European thought, and the history of the school may be summed up by saying that it played the part of a conduit-pipe in conveying to us the results of an earlier and brighter age."

Before the fall of Constantinople in 1453, which is alluded to in the above extract, such mathematics as were known in Western Europe were derived from Arabian sources.

The history of Arab mathematics and their introduction into Europe forms the subject-matter of the ninth and tenth chapters of Mr. Ball's book. The first of these excellent chapters tells us, in the beginning, how the Arabs, by their intercourse with Constantinople and India, in the reign of Al Mamun, the successor of the renowned Caliph Haroun Al Raschid, acquired a knowledge of the principal Greek and Hindu authors; it then gives an account of the works of the three chief Hindu mathematicians, Arya-Bhatta, Brahmagupta, and Bhaskara; and finishes with an analysis of the great treatise of Alkarismi, the first Arab mathematician, and an enumeration of the works of the most prominent among his successors from Tabit-ibn-Korra down to Alhazen and Abd-el-gehl. The account of Bhaskara is very much fuller than that given by M. Maximilien Marie in his "Histoire des Sciences Mathématiques et Physiques" (twelve vols. 8vo, 1883–88), and in other parts of the chapter some very interesting facts are mentioned, which we do not find noticed by M. Marie. Among these we may instance the solution of the cubic by Tabit-ibn-Korra, about 650 years before the time of Tartaglia, and, what is even more remarkable, the enunciation by Alkhodjandi of the proposition that the sum of two cubes can never be a cube.

The next chapter begins with the introduction of mathematics into Europe by the Moorish conquerors of Spain in the eighth century; shows how the Christians gained from them some knowledge of Arab science in the twelfth century, and, before the end of the thirteenth, were in possession of "copies of Euclid, Archimedes, Apollonius, Ptolemy, and some of the Arab works on algebra"; and brings the history of European mathematics down to the middle of the fifteenth century. During this long interval there lived only two great mathematicians in all Christendom, both of whom belonged to the thirteenth century. One was the famous Roger Bacon; the other, Leonardo Fibonacci, of Pisa, was the earliest European writer on algebra that we are acquainted with. Their biographies, though concisely written, necessarily occupy a large portion of the chapter.

The three following chapters contain the history of mathematics from the invention of printing to the year 1637, when the "Géométrie" of Descartes made its appearance. In this brief space of time, barely three-quarters of a century, owing to the labours of Pacioli, Recorde, Stifel, Tartaglia, Cardan, Ferrari, Bombelli, Vieta, Harriot, Oughtred, Stevinus, and others, vast improvements in algebra had been effected; trigonometrical and logarithmic tables had been brought to a high state of perfection by Regiomontanus, Rheticus, Napier, and Briggs; Desargues had invented the modern projective geometry; while, in astronomy, Copernicus, Kepler, and Galileo had replaced the old Ptolemaic system by a still older one (propounded by the Pythagoreans), which was now, for the first time, established on a firm basis.

Our author, as he tells us in the preface, has "usually omitted all reference to practical astronomers, unless there is some mathematical interest in the theories they proposed," and, accordingly, the name of Tycho Brahe does not figure in the above list. It would be better, in our opinion, to treat Copernicus in the same manner, rather than to do him the injustice of speaking of "his conjecture that the earth and planets revolved round the sun." Granting that "he advocated it only on the ground that it gave a simple explanation of natural phenomena," we would ask what other, or what better, proof could he have of it? It should be borne in mind that Copernicus spent the best years of his life in testing his "conjecture" by observations, and that nothing short of a firm conviction of its truth could possibly have induced him to publish it in the face of the fierce opposition which he well knew it would provoke.

With this exception, the short sketches of the lives and writings of all the mathematicians we have named are well drawn, and convey a clear idea of the importance of

their work, and of the amount contributed by each of them to the advancement of the science.

The remaining portion—about half—of the book is divided into six chapters (numbered XIV. to XIX. inclusive), in which the history of modern mathematics is briefly considered. These are so full of great discoveries and illustrious names that they must be read to be appreciated. We can only, in the limited space at our disposal, quote their titles and add some remarks.

Chapter XIV. "Features of Modern Mathematics." In this chapter, which is a sort of summary of the other five, we read that "five distinct stages in the history of this period can be discerned." Turning to the table of contents, we find the five stages thus described: (1) "invention of analytical geometry and the method of indivisibles," (2) "invention of the calculus," (3) "development of mechanics," (4) "application of mathematics to physics," (5) "recent development of pure mathematics." The mere remark that each of these might be made the title of a bulky volume, will show at once the enormous extent and importance of modern mathematics.

Chapter XV. "History of Mathematics from Descartes to Huygens." The principal names in this chapter are Descartes, Cavalieri, Pascal, Wallis, Fermat, Barrow, and Huygens. In many of their writings may be found the germs of those ideas which have since been developed in the infinitesimal calculus. Especially would we mention Cavalieri's *method of indivisibles*, of which our integral calculus is the modified descendant, and Barrow's method of drawing tangents to curves, substantially the same as that given at the beginning of any modern differential calculus. Full explanations of both methods may be found in the present chapter.

The history of modern mathematics dates from the publication of the "Géométrie" of Descartes, and we wish to call attention to a bibliographical point connected with it. M. Marie ("Histoire," &c., t. iv. p. 20) speaks of "quatre traités separés: 'Le Discours de la Méthode,' 'La Dioptrique,' 'Les Météores,' et 'La Géométrie,'" all of them published in 1637; Mr. Ball (p. 241) says that "Descartes's researches in geometry are given in the third section of the 'Discours.'" We cannot positively say which is correct, but our impression is that we have seen a copy of the separately-published "Géométrie." The point is of small importance, but it should be cleared up in subsequent editions.

Chapter XVI. "The Life and Works of Newton." There are two sections—one devoted to the life, the other to an analysis of the works, of our English Archimedes; his three capital discoveries—fluxions, the decomposition of light, and universal gravitation—will occur to most of our readers. Most of the well-known facts relating to Newton's private and public life are mentioned in this chapter, together with some others that have only recently come to light.

Chapter XVII. "Leibnitz and the Mathematicians of the First Half of the Eighteenth Century." The following sentence occurs in the opening paragraph:—

> "Modern analysis is, however, derived directly from the works of Leibnitz and the elder Bernouillis; and it is immaterial to us whether the fundamental ideas of it were obtained by them from Newton, or discovered independently."

It forms a fitting sequel to the tale told in the preceding chapter of the celebrated controversy between Newton and Leibnitz.

The present chapter is in three sections: (1) "Leibnitz and the Bernouillis," (2) "The Development of Analysis on the Continent," (3) "The English Mathematicians of the Eighteenth Century." The two greatest French names in the chapter are those of Clairaut and D'Alembert; the two greatest English ones, those of Taylor and Maclaurin. Matthew Stewart succeeded Maclaurin as Professor at Edinburgh, and was "almost the only other British writer of any marked eminence in pure mathematics during the eighteenth century." After recounting his chief works, our author proceeds to say:—

> "These prove him to have been a mathematician of great natural power, but, unfortunately, he followed the fashion set by Newton and Maclaurin, and confined himself to geometrical methods."

This sentence gives the history, in epitome, of the decline and fall of British mathematics in the last century.

Chapter XVIII. "Lagrange, Laplace, and their Contemporaries." There are four sections: (1) "The Development of Analysis and Mechanics," (2) "The Creation of Modern Geometry," (3) "The Development of Mathematical Physics," (4) "The Introduction of Analysis into England." The greatest foreign name in this chapter (we single it out from a number of others) is that of Euler; the greatest English one is possibly that of Thomas Simpson, who seems to be rather harshly treated by being allotted only three lines in a footnote, when others of less ability are noticed in the text.

In Section 4 we read: "The introduction of the notation of the differential calculus into England was due to three undergraduates at Cambridge—Babbage, Peacock, and Herschel—to whom a word or two may be devoted."

Doubtless the success of the movement was largely due to their efforts, but the initiative was taken by Woodhouse in 1803 (see J. W. L. Glaisher on the "Tripos," Proc. Lond. Math. Soc., vol. xviii. p. 18). The name of Woodhouse is surely as deserving of mention as the other three.

Chapter XIX. "Recent Times." The author begins with a long list of names well known in the mathematical world. This list, however, "is not and does not pretend to be exhaustive." He then classifies the writers he has enumerated "according to the subjects in connection with which they are best known, arranging the latter in the following order: elliptic and Abelian functions, theory of numbers, higher algebra, modern geometry, analytical geometry, analysis, astronomy, and physics."

The section on the theory of numbers is, in our opinion, the best. It contains biographies of Gauss and the late Prof. Smith (about four pages being allotted to each), and mentions the researches of Cauchy, Liouville, Eisenstein, Kummer, Kronecker, Hermite, Dedekind, and Tchebycheff.

We may now say with old Martial—

> "Ohe jam satis est, ohe libelle:
> Jam pervenimus usque ad umbilices."

But we have yet to record the impression left by the perusal of the entire work. The most desirable thing in a book of reference is that the reader should be enabled

to find his way readily to any part of it. In the one before us this want is met by an admirable index, and an equally complete table of contents, and by the liberal use of clarendon type in the body of the book. The printing is clear and generally correct, but we notice the following errata:—

P. x. line 8 from top, for "1885–1888" read "1883–1888."

P. 110, in the heading of Chapter VI., for "641–1543" read "641–1453."

P. 168, line 4 from bottom, for "Act iv. sc. 3" read "Act iv. sc. 2."

P. 358, line 8 from bottom, for "1728" read "1738."

All the salient points of mathematical history are given, and many of the results of recent antiquarian research; but it must not be imagined that the book is at all dry. On the contrary, the biographical sketches frequently contain amusing anecdotes, many of the theorems mentioned are very clearly explained, so as to bring them within the grasp of those who are only acquainted with elementary mathematics, and there is a very interesting account (in a footnote) of the early history of the Universities of Paris, Oxford, and Cambridge. For those who wish to study mathematical history in detail there is a long list of authorities at the beginning, and many references to other works are made in different parts of the book. We would suggest that in future editions reference should be made to "Les Fondateurs de l'Astronomie Moderne Copernic—Tycho Brahé, Képler, Galilée, Newton," by Joseph Bertrand (8vo, Paris, n.d.), and to the article "Viga Ganita" in the "Penny Cyclopædia" (which contains the opinions of Colebrooke, the translator of the "Lilavati," &c., on many points connected with Hindu mathematics).

Finally, we would suggest that the following motto should be printed on the title-page of the second edition:—

"Habetis originis ac progressionis mathematicæ historiam brevem. Ex qua matheseos antiquitas, præstantia, ac dignitas apparet."

The quotation is taken from the concluding paragraph of the "Historica Narratio" prefixed to Andrew Tacquet's "Euclid" (2nd ed., by Whiston, 1710). It describes perfectly the contents of the present treatise.

Mr. Ball promises us a supplementary volume containing a list of mathematicians and their works, which is to be as complete as possible. It will be a most important contribution to mathematical bibliography, and we sincerely hope that the reception that this volume meets with will encourage him to write the supplement.

THE BUILDING OF THE BRITISH ISLES.

The Building of the British Isles: a Study in Geographical Evolution. By A. J. Jukes-Browne, B.A., F.G.S. (London: George Bell and Sons, 1888.)

IT is now thirty-three years since Godwin-Austen, in a paper which glows with the instinctive perception that is one of the marks of genius, suggested to geologists an application of their science which lifts it out of the region of technicalities, gives it a human interest, and attracts all those who care to follow the long chain of events of which the present state of things is the outcome. It was an attempt to go back to Mesozoic and Palæozoic days, and mark out the main outlines of the physical geography of Great Britain and the adjoining parts of Europe during those epochs. To enable its conclusions to be more easily grasped, the paper was accompanied by a map, almost bewildering in its complexity and somewhat hazy in its outlines, but full of the masterly generalization that marshals into one compact body a crowd of isolated facts, and of the intuition that foresees the complete meaning of imperfectly ascertained data.

Many a geologist has since been tempted to try his hand at similar tasks, but few have mustered courage, when it came to the point, to embody their conclusions in a map. And no wonder: everyone who has speculated in this direction knows how easy it is to clothe his conceptions in words, and soon finds out how hard verbal descriptions of physical geography are to follow. So he becomes keenly alive to the fact that, if he wishes to be listened to, he must make the road easy by presenting his restorations to the eye in the pictoral form of a map. But if he be haunted by any sense of accuracy, and any horror of vagueness and hasty reasoning, he finds himself beset on all sides, when he begins to plot out his map, with uncertainties and hesitations that give him pause. It may be easy to say that land lay on this side and sea on that, but when a coast-line is actually to be laid down, though it may be possible to fix the limits between which it must lie, these limits are often so wide apart that the feeling of uncertainty as to the actual position of the boundary becomes unbearable, and the prospect of making a map that shall be even approximately accurate grows hopeless. Worse still is it—and this not unfrequently happens—when there are not even bounding limits, and the coast-lines can be no better than such guess-work as rashness delights in and the logical temperament abhors.

But even those who realize most clearly the difficulties of the task of making maps which show the distribution of land and sea during past geological epochs, welcome with keen delight attempts, such as those in the book before us, which are made in the right spirit; and it would ill become me to carp at the author's restorations, even were they less satisfactory than is the case, for I believe that, in noticing a former work of his, I ventured to take him to task for not having appended maps to his verbal descriptions of the old physical geography of our islands.

Mr. Jukes-Browne has explained, in the introduction, the principles which have been his guide; and the words with which he concludes his opening remarks show how fully he is aware of the difficulties that attend the task he has undertaken, and how much uncertainty hangs over many of his results. Even where we cannot agree with him, we feel sure that he has never been hasty and has spared no pains to arrive at the most probable conclusions.

With commendable caution no attempts are made to depict on a map the physical geography of Archæan and Cambrian times; but preference is given to Prof. Hull's conjecture that the great mass of Cambrian land "lay to the north-west of Europe, and occupied a large part of what is now the North Atlantic Ocean." The words "large part" are vague, but a partiality for filling up the

Atlantic on slight provocation is, I fear, rife among us, and ought not to be encouraged.

The Ordovician and Silurian maps are probably as near approximations as the present state of our knowledge allows—maybe as we shall ever attain to. In the Lower Old Red Sandstone map, the Old Red of South Wales is represented as having been formed in a bay of the Devonian sea. This view does get over some difficulties. If we suppose it formed in a fresh-water lake, we must admit that the barrier separating the lake from the Devonian sea was narrow, and, as our author remarks, there is no independent evidence for the existence of such a barrier. The absence, as far as we know, of any marine fossils tells the other way, but the district is yet geologically almost a *terra incognita*, and we must wait before the question can be settled. In the same way it must be confessed that it is hard to see on what grounds the Glengariff Grits are classed as marine; but here again the "retort courteous" might be, "What reason have you for thinking them fresh-water deposits?" It is too large a question to go into here.

The Carboniferous map I turned to with the greatest curiosity, for it so happens that years ago I was rash enough to try my hand at a similar production. The thing has thrust itself upon me many times since, and each time I have seen something in it that dissatisfied me, and it has been touched up and tinkered till now I hardly recognize my own child; and till I know my own mind, it would be hardly fair, even supposing it possible, to attack another man for differing from me. Really, the two maps have more in common than appears at first sight; and on some points of fundamental importance—the land-locked character of the Carboniferous sea for instance—Mr. Jukes-Browne and I are in complete accord. I should not have ventured on this bit of personal reminiscence, if it had not been that it seemed to me that it may possibly be typical. Put a number of equally qualified men to construct one of these geographical restorations, and the result will probably be this: there will be some few points on which all must agree; but the data for settling details will be so vague, that no two maps will be alike in their minor points. Even if this be so, it by no means proves the work to be unprofitable; but it is as well to bear this in mind when comparing two independent restorations.

Space will not allow of detailed criticism of the series of maps with which the book is lavishly illustrated; but all readers will gratefully thank the author for the pains he has taken to render such effectual help to them in following his reasoning. Every chapter bears the mark of patient and conscientious work; and though in a book of this size no more than an abridged and concise statement of many of its facts can find a place, its suggestiveness will insensibly lead the real student to the original papers of which it is an epitome, and open for him a wide field of reading.

The chapter on the Pleistocene epoch is one on which the author has evidently spent much pains, but it seems to me the least satisfactory in the book. With much that he says I heartily agree. I cannot help feeling that some of our most eminent glacialists have ridden their theories rather hard. That the Scotch Till is a *moraine profonde* seems to me the only hypothesis yet put forward which gives anything like a satisfactory explanation of the origin of that deposit; but I am not prepared to admit a like origin for all the so-called Boulder-clays: most of those who have studied on the ground in detail the Boulder-clays of the plains of Lancashire and Cheshire have come to the conclusion that they are submarine, and that their boulders have been supplied by floating ice. Some of the objections which Mr. Jukes-Browne urges against the ground-moraine theory, however, do not seem to me serious. He cannot understand how it is that an ice-sheet could groove and polish the rocks and form a ground-moraine at the same time. There are many ways out of the difficulty. Ice-scratching is most conspicuous on high ground and steep slopes, where there is little or no Till. It is true that it is far from uncommon on lower and flatter ground, where it is covered and indeed preserved by a coating of Till. Here it may be the first work of the ice-sheet before much *débris* had been dragged down from the hill country; but we must also bear in mind the probable character of a ground-moraine: packed closely by the weight of the ice above and frozen hard, it would be very different from the imperfectly consolidated mass we see now: rather it would act as a solid whole, and, as it was dragged along, would be quite capable of effecting a large amount of abrasion. The alternative which is suggested involves the floating of the ice-sheets bodily over wide extents of sea; but, as far as we know, ice-sheets do not float as a whole when they push their way out to sea, they break up into icebergs. We may picture to ourselves the probable action of an ice-sheet somewhat after this fashion. While descending slopes even moderately steep, it would push before it and drag beneath it any loose *débris* that it found ready made to its hand or that it had itself torn off the surface. But here its motive power would be sufficient to carry with it all the loose matter; consequently here no Till would be formed, unless the sheet happened to encounter a gorge in its path. In such a case the stones and dirt would be driven into the hollow till they filled it up, and the ice would then ride over it. When the ice-sheet reached flatter ground, its dragging power would be seriously diminished: it would probably at first heap up the *débris* into a mound or ridge in front of it: this mound after a time it would override, and flatten and spread out its materials; by a continuance of the process a sheet of Till would be spread over the lowlands. Of course here too any valley that lay athwart the path of the ice would be filled up. Thus would be produced exactly the distribution of the Till which occurs: in the hill-country little or none except as filling in valleys; over the plains a broad sheet, and great thicknesses in the valleys of the low country. So that when our author states that Prof. James Geikie's views might be accepted "if the Boulder-clay was found to fill in lake-like hollows," he is describing very nearly an essential feature in the actual manner of its occurrence.

Having now discharged the functions of the critic, and pointed out what appear to me some weak points, I will only add that if I seem to have been scant of praise, it is because there was no need. The book recommends itself.

A. H. GREEN.

OUR BOOK SHELF.

The Civilization of Sweden in Heathen Times. By Oscar Montelius, Ph.D. Translated from the Second Swedish Edition, by the Rev. F. H. Woods, B.D. (London: Macmillan and Co., 1888.)

EVERYONE who knows anything of archæology is aware that a book on the subject by Dr. Montelius is sure to be worth reading. The work translated by Mr. Woods ranks among the best existing summaries of the antiquities of particular countries. The author begins with the Stone age, and passes on, through the Bronze period, to the various stages of the Iron era. For some reasons it might perhaps have been better if he had reversed the order, taking first a group of antiquities the date of which can be approximately fixed, and working his way back to more remote times. This plan has been adopted, with excellent results, by Mr. Anderson, in his study of Scottish antiquities, and by Dr. Lindenschmidt in the work he is writing on the antiquities of Germany. The method chosen by Dr. Montelius is, however, favourable to clear, popular exposition, and he has made excellent use of the opportunities it has provided for him in this direction. He has a dread of far-fetched, fanciful explanations, and, at every stage of the story he has to tell, is careful to show that his statements are in strict accordance with facts. His account of the Bronze age is particularly interesting, but all that is essential to the comprehension of the remains of the Stone and Iron ages in Sweden he also presents with remarkable conciseness and lucidity. The second Swedish edition, of which the present volume is a translation, was published in 1878. Many additions were made by the author to a German translation, which appeared in 1885; and these additions, with others specially provided for the English rendering, have been incorporated by Mr. Woods in his interesting volume. Mr. Woods has done full justice to the original by his vigorous and lucid style, and the notes he has added—especially those relating to the "Corpus Poeticum Boreale," edited by Dr. Vigfusson and Mr. F. York Powell—will be welcome to all serious students of archæology. The work, we may add, is well printed, and the value of the text is greatly increased by a large number of admirable illustrations.

The "Indispensable" Hand-book to the Optical Lantern. Compiled and Edited by W. D. Welford and Henry Sturmey. (London: Iliffe and Son, 1888.)

THIS is mainly a catalogue of lanterns, accessories, and slides, one section of the book being devoted to each. Each section commences with brief general remarks, and is followed by a price list of the various pieces of apparatus concerned, as manufactured by different firms. The details of each piece of apparatus are described, and in some cases special remarks are made. All the important makers are represented, and their full addresses are given.

The classified descriptive catalogue of the various sets of slides in the market will perhaps be the most useful part of the book, seeing that the possessor of a lantern is likely to be most interested in determining what he shall exhibit. This catalogue is such that one can immediately ascertain full particulars relating to any set of slides, without waiting to see them before purchasing.

The illustrations which crowd the book are of a very high class, notwithstanding the fact that most of them are used for advertising purposes by the firms whose productions they represent.

To anyone about to purchase a lantern, or anything concerned with one, the book is fully entitled to its claim to be indispensable. We can further confidently say that it will interest and prove useful to each one of the ever-increasing number of persons who use the lantern either for purposes of instruction or entertainment.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Alpine Haze.

QUESTIONS of nomenclature are of some importance, and of some difficulty, in subjects not thoroughly investigated. M. Antoine d'Abbadie's last letter (NATURE, January 10, p. 247) is so interesting, and, from the linguistic and bibliographical points of view, so exhaustive, that it is with reluctance that I point out why my opinion slightly differs from his on nomenclature, having already indicated a difference of opinion as to the physical nature of the phenomenon itself. I gave, as a matter of course as well as of courtesy, the title of "Alpine Haze" to my last communication, out of deference to Prof. Tyndall, and shall continue to do so until I know Prof. Tyndall's final opinion, but deference to the highest authority cannot alter my belief that this title is not a fortunate one—a belief confirmed by Antoine d'Abbadie's own evidence. Ludolf's definition is good, but what I required was a simple English term for the use of non-scientific observers, and of some careful scientific observers like Dr. Burder. "Dry haze" (together with the specific term, of which it is the translation) begs a more serious question than is begged by "dust haze."

I am also inclined to think that the un-scientific English "dry haze" may be unfortunately applied to the ordinary haze of comparatively dry weather which Dr. Burder describes. There is, I suppose, little doubt that this latter common haze is composed principally of water-particles (usually with some admixture of smoke and dust), *pace* all the hygrometers in the world. It does not differ from mist, and does not differ from fog, except in amount. W. CLEMENT LEY.

A Remarkable Rime.

DURING cold fogs the accumulation of ice on the branches of trees due to the contact of water particles with solid substances, frequently causes damage to timber in the Continental forests: not often, I think, in this country. No snow has fallen here until to-day since October 2, 1888, but anticyclonic frost has been on several occasions accompanied by fogs of unusual density. During the frost of last week, ice-crystals of about 2 inches in length, at first very hard and adhesive, were formed on the windward (south-south-west) side of all exposed objects, but particularly on metal, even at no greater height than 3 or 4 feet above the earth's surface. This is a common sight on the higher hills even in the British Isles, but at this altitude (460 feet above mean sea-level) appears to be rare. The result has been great injury to timber, and a great "wind-fall," without much wind, to the tenant-farmers. Of deciduous trees, the ash seems to have suffered the most, while little damage, so far as I have observed, has been received by the ornamental conifers which usually suffer so much from snow. It is impossible to estimate, with much approach to accuracy, the amount of moisture drawn from the atmosphere in this rime, but during the thaw we measured $4\frac{1}{2}$ inches of ice-crystals on the ground on the leeward side of a rather spare elm-tree 39 feet in height, while the boughs above this surface, on the leeward side, still retained their exquisite robe of rime. ANNIE LEY.

Ashby Parva, Lutterworth, January 12.

Mass and Inertia.

MR. WORTHINGTON is rather unkind in blaming the chemists for perhaps somewhat pedantically doing that which is right, while he encourages his new friends the engineers in continuing to do that which is wrong.

If he could point to a handy and permanent force, independent both of age and position, which could be boxed up in small compass and handed down to posterity with perfect security against alteration, and with complete certainty of precise accuracy in Auckland, or wherever the future capital of the race may be, there might be something to say for his proposal to adopt force as one of the fundamental units instead of mass. Otherwise, there is practically nothing to be said for it.

Mr. Worthington speaks as if we were anxious to do away with a student's familiarity with force as a push or a pull. This shows that he does not appreciate our position.

I even venture to assert that in what he says concerning mass and inertia he is not so absolutely clear in his own mind as it is desirable for a reformer to be. May I suggest to him that the "inertia" or "inertia-reaction" of a lump or mass of matter—that which is measured in an experiment, and the only thing that can be measured in an inertia experiment—is $m\frac{dv}{dt}$; and that the coefficient of the otherwise measurable kinematic factor in this quantity is properly called "the coefficient of inertia," but is, for brevity, styled "mass," and is taken as a measure of the quantity of matter in the body, because, experimentally, it is found to be absolutely unalterable by every physical and chemical process except those which change the amount of matter in the lump. Fancy making our standard of quantity of matter depend upon the approximately determined gravitative attraction of some arbitrarily selected planet at some arbitrarily selected spot near its present surface!

Sometimes, indeed, m is briefly called merely "inertia," just as the coefficient $\frac{V-V^1}{C}$ in Ohm's law is for brevity styled "resistance"; but the full names of these quantities are "coefficient of inertia" and "coefficient of resistance," respectively. In the case of friction the full name is usually given. With junior students it is clearest to give the full names in every case; just as it is much clearer with them to avoid the misleading abbreviation specific heat, and to use the full phrase specific capacity for heat. OLIVER J. LODGE.

Liverpool, January 14.

A Hare at Sea.

AMONG the notes published in NATURE for December 27, 1888, is an account of a hare swimming across a river; perhaps the following account of a hare taking to the sea may be of interest. In October 1887, I was a member of a shooting party staying near Auchencairn on the Kirkcudbrightshire coast, where for miles the waves of the Solway beat on red sandstone cliffs, broken here and there by small bays, where the burns run down to the sea through little glens. One day I had left the others and was standing among the seaweed-covered boulders of such a bay, when the sounds of a course reached me from a hill-side a quarter of a mile or more away, and presently I saw hare and greyhounds coming down to the shore; they ran close past where I was standing, and then to my astonishment the hare deliberately entered the water and swam out to sea.

I could not persuade the greyhounds to follow, though one was so close that, if she had done so at once, she could have caught the hare without swimming, as the latter was out of her depth directly and swam very slowly. The sun was shining very bright on the water, and it soon became very difficult to keep the hare in sight, as her head only showed now and then on the top of a wave, and about a hundred yards from shore I saw her for the last time, though I stayed about the place a long while.

This hare was perhaps hard pressed, still I could see no reason why she should not have run along the shore to the march dyke, which was close to, and where she would probably have made good her escape. W. J. BEAUMONT.

Sandiway, Northwich, January 13.

THE ARTIFICIAL REPRODUCTION OF VOLCANIC ROCKS.[1]

ORIGINALLY, the study of the crust of the earth was purely utilitarian: it seems to have been at first forced upon man by the necessity of exploring the strata in order to extract metallic ores, constructive materials, and combustible minerals.

To anyone who glances at the history of the sciences, it becomes evident that they all owe their origin to some useful and practical aim, and that from this initial phase they have passed through a regular development: this progress, so far as geology is concerned, I shall proceed to sketch.

Man, then, commences to explore the depths of the earth in order to extract the materials which may minister to his wants. At first he works without rule; but as the miner's art is developed, method is introduced into the search for mineral wealth, and he observes the conditions under which useful minerals and rocks occur in the bosom of the earth. These observations, at first merely empirical and local, gradually become generalized, and thus lead to a recognition of some of the leading features in the architecture of our planet. On digging into the earth, it soon becomes evident that the world was not made at a single stroke, but owes its formation to a succession of epochs.

It follows, therefore, that, in order to interpret the history of the earth, and the operation of the agencies which have taken part in its formation, it is necessary to study the living world, and to investigate the present condition of our planet. In comparing the various strata of the earth with the deposits which are in course of formation under our own eyes, we realize the conditions which have presided at the formation of the stratified rocks of ancient geological periods. It is thus that, by the analysis of facts, and by induction which generalizes the observations, our knowledge of the crust of the earth enters on a new and truly scientific phase. We start by attempting to discover practical rules for the guidance of the miner, and we are gradually led to decipher the history of the earth.

In this reconstruction of the past history of our planet we are guided by a fundamental principle—namely, that the essence of the forces which have acted upon the earth has never changed. We ought, then, to seek in geological epochs for traces of only such phenomena as are of the same nature as those which we can witness to-day, and submit to direct observation.

Since geologists commenced, towards the close of the last century, to apply the inductive method to the study of the mineral masses which form the crust of the earth, to their architecture, and to the organic remains embedded in the rocks, a vast collection of documents has accumulated, bearing upon the history of our planet. During this period, Geology has made such immense progress that she need not envy the older branches of natural science.

Let us see how, in applying this analytical method and relying on induction, geology interprets the formation of the rocks. Rocks, we know, are the solid mineral masses which constitute the earth's crust. Observation teaches us to recognize two groups. The first are characterized by an arrangement in beds or strata: these are the sedimentary rocks. The second group, which does not present this stratified arrangement, comprises rocks of volcanic character, with a massive structure. These differences in the structure and composition of the two great lithological groups lead us to regard them as having been formed under special conditions, which have left their imprint upon each group.

We see the sedimentary rocks in the course of formation when we observe how detrital matter is rolled about by stream and wave, and how such waters deposit pebbles, sand, and mud upon their beds. After the death of the organisms which inhabit these waters, their skeletons or their shells become mingled with the mineral deposits, and with them build up sedimentary masses. The minerals so deposited assume, by successive accumulation, a stratified arrangement. All their constituent particles were originally isolated grains, and still retain traces of their origin: they are either the *débris* of pre-existing rocks or organic exuviæ, which, by physical and chemical processes, may become subsequently consolidated.

Let us now compare these modern sedimentary deposits, characterized by a stratified arrangement, and

[1] A Lecture delivered in French at the Royal Institution, on Friday, May 18, 1888, by M. Alphonse Renard, LL.D., Hon.M.R.S.E., Corr.G.S., Curator of the Royal Museum, Brussels. Translated by F. W. Rudler.

by the detrital nature of their constituents, with certain geological strata. We observe on continental surfaces masses of rock of geological antiquity, which offer close analogy in aspect and structure to the materials which are deposited under our very eyes by fluviatile and marine action. This comparison leads us to regard the old stratified rocks as having been formed by the operation of the same causes, and we hence consider them to be deposits of submarine or fluviatile origin. Water is therefore the agent which is everywhere at work in the formation of sedimentary or detrital masses.

The second group, of which we have specially to treat, includes the massive rocks—those which may be observed in course of formation during volcanic manifestations. The molten matter, vomited from the crater or injected into the sedimentary beds, consolidates on cooling. The constituents of the lavas are crystalline individuals developed at the expense of the surrounding magma. These crystals are not detrital, in the sense in which we have just used that term. Speaking in general terms, we may say that the eruptive masses do not present the stratified arrangement of the sedimentary rocks; but in place of the original horizontality and the regular superposition of the stratified beds, the lavas offer an appearance which indicates the thrust from below upwards, to which they were subjected during eruption. Finally, the massive rocks are destitute of organic remains.

Let us now compare the contemporary volcanic rocks with certain ancient crystalline rocks—granites, porphyries, trachytes, and basalts. We observe that these present close analogy in structure and composition to the products of active volcanoes. From the possession of these common characteristic features, we may conclude that the massive rocks, which traverse the strata, have been, like the modern lavas, injected from below, and share with them an eruptive origin.

But while we see the sedimentary rocks in course of formation under our eyes, and can closely follow the conditions which preside at their origin—the work being accomplished, so to say, in broad daylight—the eruptive masses are elaborated in the depths of the earth; their genesis is to some extent enshrouded in mystery, and our vision fails to penetrate the vast subterranean reservoirs where the molten masses are formed, and whence they are projected in volcanic eruptions.

Here the paths of direct observation are partially closed against us. Neither the finest analysis nor the strictest reasoning can supply the missing data; they are powerless to show us all the causes which are at work in the formation of the eruptive rocks.

In order to resolve our doubts, and to control and complete our observations, we therefore attempt to reproduce the volcanic rocks artificially; to form them synthetically. Armed with the results of observation which must serve as our guide, we endeavour by scientific manipulation to imitate the products of Nature. The science of the earth, previously analytical, enters thenceforth upon its final phase—that of synthetic experiment.

These attempts to imitate Nature, guided by the intelligence of man and executed by his hand, enable him, though limited in resource, to obtain results which offer analogy to that which he desires to investigate; he can direct and regulate the progress of the phenomena, can note with exactitude their relations, and can vary at will the conditions under which they arise. The knowledge acquired by observation, analysis, and reasoning, is thus, according to Bacon's expression, "tested by steel, and by the fire of experiment."

We have now indicated in broad outline the three great steps in the progress of our knowledge of the earth's crust. We have watched it at its birth, when it was limited to utilitarian ends; we have followed it later in its course, when, guided by observation and reasoning, it rose to the dignity of a science. Geology, entered now on its last phase, is transformed into an experimental science.

We shall now show, in studying the artificial reproduction of recent volcanic rocks, how powerfully the resources of the laboratory can assist the direct observation of Nature. But before explaining the methods employed in the synthesis of modern volcanic rocks, we must briefly summarize our knowledge of the constitution and formation of these volcanic masses, as derived from analysis and observation. It is to these natural lavas that our synthesis must be directed; they form the models which we must copy, and it is therefore necessary to become thoroughly acquainted with them in order that we may imitate them in their closest details.

Let us, then, recall what we know about lavas and the conditions of their formation. Without dwelling on these grand manifestations of the internal forces of the earth, or the succession of phenomena in an eruption—those formidable disturbances which shake the volcano to its very base, and eject pulverized vitreous matter and red-hot stones—we may remark that in the midst of such a cataclysm, the crater and the flanks of the mountain, rent by pressure of the matter seeking to escape, allow floods of lava to flow forth, and this matter, rolling down the mountain, slowly solidifies upon its slopes.

The chief feature of an eruption is the emission of lava or streams of molten matter escaping from the crater. We may best compare the lava, in general terms, to a glass liquefied under the influence of the high temperature which prevails beneath the solid crust of the earth. Direct observation of the temperature of the liquefied lava at the moment of its emission from the crater is surrounded by dangers which few observers dare to encounter. Hence we possess on this point only approximate observations. But certain volcanoes, where the outflow of lava is never violent, and which are in a state of moderate and permanent activity, as in the Island of Hawaii, have allowed the intrepid observer to approach sufficiently near to estimate the temperature of the molten mass. It has thus been found that the temperature varies between 1000° C. and 2000° C. But on the outflow of the lava the temperature of the surface is rapidly lowered, the liquid sheet becomes incrusted with scoria, more or less thick, beneath which the fused matter flows like a stream, having a temperature of about the melting-point of steel. It is this mantle of scoria which hinders radiation, and enables the subjacent mass to retain for a long time a certain amount of viscosity.

Further on we shall discuss the observations on the phenomena of crystallization presented by this erupted matter, still liquid or viscous, but ready to congeal. Let us, however, first study some of the essential characteristics of the structure and composition of lavas. These erupted products are in many cases vesicular and scoriaceous; while in others they appear as homogeneous vitreous masses, more or less dark-coloured, in which the naked eye fails to detect any isolated mineral. Sometimes, again, this mass is charged with minerals, more or less numerous, which seem to squeeze aside the vitreous paste which cements them together. These embedded minerals, when perfectly developed, present regular polyhedral forms, constant for each species; they are, in fact, *crystals*—that is to say, perfect individuals of the mineral world. They have drawn from the original vitreous magma the chemical elements of which they consist, and which have grouped themselves according to their affinities; just as we observe that in a liquid saturated with a salt, crystals are developed, consisting of the substance which was dissolved in the mother-liquor.

Mineralogy teaches us to determine the mineral species which crystallize in lavas; chemical analysis, in turn, furnishes us with valuable information respecting the composition of volcanic products. If we subject the eruptive rocks to chemical processes, we find that they all contain

more or less combined silica, which may reach to upwards of 65 per cent. of the mass: these are the acid or light lavas. Thence we pass, by various gradations, to the basic or dense lavas, in which the proportion of silica, gradually diminishing, does not reach more than 55 or even 45 per cent. This silica does not exist in a free state in modern lavas, but is combined, in the form of silicates, with alumina, iron, lime, magnesia, potash, and soda.

In the slags of metallurgical works we find products which present close analogy to those of volcanoes, both in composition and in mode of formation. These artificial scoriæ are, like lavas, formed of silicates; and another point of resemblance between them lies in the fact that we may regard both as the scum of a metallic nucleus, of which they form the upper zones. The differences in composition result from the fact that they are derived from zones of greater or less depth.

Our knowledge of eruptive rocks came to be enriched in an unexpected manner by the application of the microscope to lithology. We need not here recall the almost marvellous results obtained by this method of investigation, inaugurated by H. C. Sorby; but we may say, in a word, that the microscopic analysis of rocks has changed the face of petrography. Let us confine our attention to some of the conceptions relating to modern volcanic rocks, as revealed by these new methods—methods which, in delicacy, in certainty, and in elegance, are unsurpassed in any other branch of natural science. Not only have they enabled us to verify and control hypotheses, but they have led to the remarkable discoveries to which I am about to refer.

The eye, assisted even by the most powerful lenses, could recognize in lavas only those minerals which appeared in rather large crystals; chemical analysis generally gave merely the composition of the total rock, and its mineralogical composition was only suspected. The intimate texture of the rock remained impenetrable; it was impossible to determine with certainty the order in which the constituents of the molten mass had solidified; neither could we trace the various states through which the crystals had passed—their germs, primordial forms, and skeletons—or the aspect of the rock at different stages of its development.

Let us now apply the microscope to the examination of a thin slice of lava, rendered transparent by polishing. The lavas, as we have said, may be compared to vitreous masses; but whilst in our artificial glasses we seek to obtain a pellucid and homogeneous product, the liquefied matter of volcanoes, when it flows forth, already contains certain differentiated products. The glass which contains these bodies may be regarded as the residue of the crystallization, whence the numerous crystalline individuals have extracted their constituent elements. In the black, brilliant, volcanic glasses, apparently opaque and destitute of crystallization, the microscope discovers a world of mineral forms. It shows us their various states of growth, and the arrest of their development consequent on the more or less rapid consolidation of the mass. It is especially in those rocks which, like obsidian, have preserved almost wholly their vitreous character, and are homogeneous to the naked eye, that we find the rudimentary crystals of curious form, representing the first step in the passage of the amorphous matter to the crystalline condition. Owing to the rapidity with which the vitreous paste consolidated, the crystals were unable to grow, and their development was sharply arrested. Hence the origin of these embryonic crystals which abound in natural glasses, and which we designate as *crystallites*. Analogous crystallites are produced in blast-furnace slags, which have close relations to the matter of lavas. Their common origin is betrayed by certain family likenesses which the microscope reveals. The slags, examined in thin sections, exhibit rudimentary crystalline forms, similar to the crystallites of volcanic glasses.

But usually the crystals have not remained in this embryonic state. If the lava has not been too rapidly cooled, the molecular movements are retained, even in a semi-liquid mass, and the paste develops crystals of minute dimensions, called *microlites*. These microscopic crystals are formed in the heart of the vitreous magma during its slow consolidation. Notwithstanding their infinite minuteness, these small polyhedra exhibit with marvellous exactitude all their specific characteristics, such as we are familiar with in much larger crystals, and which we should not expect to find in lavas. They often form, by their interlacement, a beautiful network in the paste, and give to the rock in which they are developed a *microlitic structure*.

The dimensions of these microlites, invariably microscopic, and their arrangement, prove that they may be referred to a period of disturbance; that they were formed, indeed, at a time when the lava, though still in motion, was solidifying. They separated from the magma during the very act of outflow or eruption.

Besides these microscopic crystals and these groups of crystallites, which belong to the last stage of consolidation, the lava contains also a supply of larger crystals, more fully developed, and in many cases recognizable by the naked eye. These have been formed under calmer conditions, analogous to those presented by a tranquil fluid in which crystallization is proceeding slowly. They were formed in the molten magma when it was still inclosed in the subterranean reservoirs. This slow growth is clearly proved by the formation of the crystals in concentric zones and by their size. These large crystals, existing ready formed in the lava at the time of its eruption, are surrounded by microlites or by a vitreous mass. It was after their slow development in the magma, during an intra-telluric period, that the mass in which they floated was upraised. The period of calm was succeeded by one of agitation, and the lava in its violent ejection carried forth the crystals, breaking them, corroding them, and partially fusing them. The microscope offers distinct evidence of these phenomena. We see the large crystals dislocated and their fragments dispersed, their edges rounded and eroded, and their substance invaded and penetrated by the paste.

While the physical and chemical agencies brought into play by the movement of the lava thus attack the ancient crystals to the verge of demolition, the microlites are in course of formation. This vitreous matter, in which the large crystals float, solidifies as a mass of microscopic individuals. The latter are therefore related to a second phase of crystallization: they are developed in a moving viscous magma, and their further growth is arrested by the rapid cooling which induces solidification *en masse*.

The fluidal arrangement of the microlites distinctly shows, too, that the crystalline action was contemporaneous with the movement of the lava-flow. Indeed, we see in microscopic preparations that the microlites are accumulated around the large sections of crystals, forming wavy trains and presenting the arrangement which micrographers designate as *fluidal structure*. It is marked by the orientation of these infinitely small acicular crystals. When these streams of microlites meet the large embedded crystals, they sweep round them, crowding into the spaces between the large sections, accommodating their flow to these outlines, and preserving for us the last movement of the mass at the very moment of solidification.

The microscope therefore proves that crystallization in lavas belongs to two periods: the first, anterior to the eruption, during which the large crystals already found are suspended in a mass that we may regard as entirely vitreous; and the second period, when the microlites and embryonic crystalline forms are separated, dating from the ejection or outflow, and contemporaneous with the solidification of the rock.

From these microscopic observations on the crystals of the second period, we may conclude that they are formed purely and simply by igneous action, without requiring the hypothetical temperatures and pressures formerly considered necessary, and without that absolute repose regarded as needful for the regular crystallization of minerals. We see, indeed, that the microlites are formed after the outflow, at the normal barometric pressure and at a temperature far from being as high as generally supposed, and we witness the birth of the crystals during the very flow of the lava stream. When the cooling is extremely rapid, the microlites have no time to form, and the lava can produce only crystallites.

But the microscope enables us to determine the chronology of the crystals in lava in a still more detailed manner. We have already distinguished two great periods in their history; let us now indicate in a general way how we may establish to some extent the date at which each species of the two groups is separated from the magma. Data leading to the determination of their relative age are afforded by their inclusions.

A crystal developed in a vitreous mass frequently incloses particles of the medium in which it grows. In this way certain sections under the microscope appear penetrated with vitreous grains, imprisoned in the interior of the crystals and frequently arranged along the zones of successive growth. These inclusions prove that the crystals in question were formed in a vitreous mass, liquefied by heat. In other cases the inclusions are mineral species in the form of microlites; and it is clear that they must have been anterior in date to the mineral in which they are inclosed. Finally, in other cases a species will mould itself around sharply defined crystals, conforming to their outlines, and filling up all the spaces between the minerals; thus showing that the crystals are of earlier origin than the surrounding mineral.

From these facts, which speak for themselves, we have been able to draw up chronological lists indicating the relative date of crystallization of each species of the two great periods. I will not stop to cite these lists, but we shall soon see how the law which governs the successive formation of the crystals, and their relative age, is evolved from synthetic experiments.

I have traced in broad outline the history of a lava, but have sketched only a few of the details which modern researches on lithological phenomena have developed with such startling reality: nevertheless, what we have seen is sufficient to show in a striking manner the power of analysis when supported by reasoning. I think I am not wrong in saying that from this point of view the study of a lava presents one of the finest examples of the application of the inductive method to the natural sciences. We hardly know whether to admire most the analytical processes, or the subtlety of observation, or the logical method by which the observed phenomena have been brought into connection.

Microscopic analysis, powerful as a method of investigation, has enabled us to trace with close exactitude the progress of crystallization in a rock where the unaided eye could discover only an indistinct and uniform mass; to penetrate into this marvellous tissue of volcanic products, where millions of polyhedra occur within the volume of a cubic centimetre; to determine with mathematical precision the nature of each of these infinitely small bodies; to track them to their birth, and follow them throughout their development, tracing all the modifications to which they have been subjected under the influence of physical and chemical agents.

Nevertheless, to the conscientious and modest investigator, how much still remains unknown in connection with the history of volcanic products, though the field seems so narrow, and has already been so well worked! What problems remain unsolved, even by the most refined observation! But when observation can no longer aid us, when we have exhausted all the resources of this method of investigation, there yet remains the method of synthetic experiment. This forms one step more on the road which leads to a perfect knowledge of the phenomena, and may conduct us to their definite solution. But, in order that synthetic operations may attain this end, they must be directed with due intelligence and design.

One of the essential conditions of a geological synthesis, as Sénarmont remarked, is, that each of the artificial operations should be compatible with all the circumstances traceable in the products of the natural operation. The slags and scoriæ of our furnaces, which, as we have shown, are related to certain natural products, are, it is true, the results of synthesis, but synthesis made at haphazard; and thus, notwithstanding their high scientific interest, cannot be placed on the same level with the synthesis of which I am about to speak, where the experimentalist, bearing steadily in view the problem which he desires to solve, attempts to realize in the laboratory the identical conditions which have surrounded the formation of the natural products which he wishes to imitate.

In logical order, the synthetic methods follow the progress of observation and of analysis. But even in the very infancy of geology there were certain powerful minds which foresaw, with the glance of genius, the part which experiment was destined to play in that science. Buffon proved by experiment that granite and the principal crystalline rocks are fusible, and that they were transformed by fusion into a vitreous mass. Some years later, Spallanzani performed an extensive series of experiments on the fusion of lavas, in order to overcome the prejudices which prevailed respecting the cause of the heat of eruptive matter.

But it is especially to Sir James Hall that belongs the honour of having, by his celebrated researches, introduced experiment into geology. He demonstrated its application in a masterly manner, and was led to sound generalizations. We have here to notice in Hall's researches only those which relate to the synthesis of rocks. About the time when Spallanzani studied, by laboratory methods, the conditions of the formation of lavas, the illustrious Scottish geologist was busy fusing the eruptive rocks in a vessel of graphite: he observed that the product of this fusion, if cooled rapidly, became an amorphous vitreous mass, while, if cooled more slowly, crystals were formed. James Hall had already observed by experiment the capital fact for future synthesis that, in order to regenerate the crystals of a rock which has been fused, it is necessary to maintain the glass obtained by the fusion at an elevated temperature, but yet a temperature always inferior to that required for the fusion of the rock. During this process, certain minerals crystallize. These facts may be paralleled with the phenomena which lavas display when their temperature is lowered after their emission.

Towards the commencement of this century, Gregory Watt directed his researches in the same direction. He experimented on masses of basalt, 700 pounds in weight: these he fused, and allowed to cool during eight days beneath a layer of charcoal, which was slowly consumed. During this prolonged *recuit*, spherulitic concretions of fibro-radiated texture, 6 centimetres in diameter, separated in the opaque black glass resulting from the fusion: finally, the glass passed into a stony condition, assumed a granular structure, and became charged with very thin crystalline lamellæ. At the same time, its magnetism was increased, while its density rose from 2·743 to 2·949.

One conclusion from the researches of Watt, which are closely related to those of Hall, is, that crystallization may occur during the period when the fused matter commences to solidify.

At the time when the road to the synthesis of rocks

was being thus opened up, analysis and the methods of investigation had not attained to the perfection which they enjoy at the present day; on the other hand, the prejudices which held sway in the infancy of geology increased the obstacles, and these were not surmounted until half a century later. We need not be detained here by the brilliant period of mineral synthesis which followed close on the development of chemistry and mineralogy. It is sufficient to cite the names of Ebelmen, Rose, Mitscherlich, and Sénarmont, to recall those remarkable results in the artifical reproduction of minerals. But the researches of these *savants* related chiefly to the synthesis of isolated species, and not to rocks which are aggregates of mineral species. Speaking generally, it may be said that their researches were essentially mineralogical, and bore but subordinately on lithology. Nevertheless, the researches of these skilful experimentalists shed much light upon geological problems. They also show us that, as the mineral sciences progress, we are led to seek, by experimental methods, the most complete interpretation of the phenomena of Nature. Finally, in 1866, Daubrée led the way to the reproduction of crystalline rocks by simple fusion. This is the method which has been since taken up and developed by MM. Fouqué and Michel Lévy. The researches of Daubrée, to which we refer, are those in which he sought to reproduce by fusion certain meteoric stones characterized by the absence of a felspathic element. By fusing lherzolite, a terrestrial rock which approximates in composition to certain meteorites, he succeeded in obtaining products which, in the details of their structure and composition, resembled the cosmical types which he desired to imitate.

While this eminent geologist thus foreshadowed the researches which some years afterwards shed so brilliant a lustre upon the geological laboratory of the Collège de France, the synthetic methods were still encumbered by hypotheses. It is true we had no longer to struggle against the assumed influence of mysterious forces; but it was held that the reproduction of geological phenomena in the laboratory would be possible only if we had an infinite duration of time at our disposal, and dealt with temperatures and masses far beyond those which we could hope to command in the laboratory. It was still supposed that the mineral associations in Nature were governed by other laws than those which determined the combinations produced by the chemist. Such prejudices would certainly not have hindered Daubrée from proceeding in the path in which he so bravely took the first step by his synthesis of meteorites; for he, indeed, is one of those whose works have largely contributed to banish such prejudices from the realms of geology; but the methods of analysis which then existed did not allow us to probe the nature of the rocks to their very base, and to compare their intimate structure with that of the products of synthesis. Our laboratories were not then in possession of the apparatus by means of which we can command those very high temperatures, maintained during a prolonged period, which such experiments require.

The great improvements in the construction of apparatus, and the application of the microscope to lithology, have at length enabled us to successfully attempt the reproduction of all the modern volcanic rocks. Two French *savants*, MM. Fouqué and Michel Lévy, who introduced into their country the study of micrographic lithology, began in 1877 a series of synthetic experiments destined to be memorable in the annals of science. One of them had already acquired a just reputation by his remarkable researches on volcanic phenomena, carried on in various classical regions; he was familar with all the secrets of the chemical analysis of minerals—a department which he had enriched by the most ingenious and useful methods. The other, prepared by the severe studies of the high French schools, had undertaken, with brilliant success, the examination of minerals by their optical properties: he had carried exact methods into micrography, far beyond what others had done, and he was known by his researches on the eruptive rocks of the older series.

By their joint labours, MM. Fouqué and Lévy have to some extent systematized and co-ordinated the facts relative to the chronological succession of the crystals in eruptive rocks, and have discovered many of the details which we have already noticed in explaining the results of the analyses of lavas. It is to this happy association of talent, to this fruitful collaboration, that we owe those beautiful discoveries which have given such celebrity to the laboratory of the Collège de France, and to which it is an honour for me to render homage before an audience ever ready to welcome scientific progress, and in a place where the immortal Faraday once brought forward, with generous enthusiasm, the admirable researches of Ebelmen in connection with mineral synthesis.

We have already indicated the data upon which these *savants* relied in their researches: they are furnished by chemical and mineralogical analysis. One point, however, not yet touched upon, lies at the base of their general procedure. Theory would predict that the most ancient crystals in an igneous rock should be those which are the least fusible. And this, speaking in general terms, is really what we observe: the minerals of the first period of crystallization are those which occupy the lowest degrees in the scale of fusibility. The constituent mineral species of lavas have appeared at successive periods, as the temperature diminished, according to their relative degrees of fusibility. These facts, proved in detail by microscopic analysis, served as the point of departure in the experiments of MM. Fouqué and Lévy. Their process rests, morever, upon a fact which James Hall foresaw: namely, that the fusion of a rock produces a glass which is more easily fusible than any of the constituent crystalline species of the rock. Now, if we fuse a natural aggregate of minerals and subject the glass produced by this fusion to a series of diminishing temperatures, but always higher than that of the fusing-point of the vitreous mass, the minerals, which can crystallize from this magma should make their appearance one after another, and the less fusible should be the first to separate. These crystals will be united and moulded round by those of which the fusibility is higher, and which will appear in turn as the temperature decreases. Without dwelling on the technical details of the apparatus, it suffices to say that, by aid of the furnaces and bellows, which MM. Fouqué and Lévy employ in their syntheses, we can obtain all degrees of temperature, from a dull red to a dazzling white heat, and can maintain a given temperature constant for an unlimited period.

Into the furnace we introduce a platinum crucible of a capacity of about 20 cubic centimetres, containing the mixture of mineral substances which by fusion and *recuit* are to be transformed into the rock. First, by aid of special arrangements, we subject it for a long time to a glowing white heat, and the mixture is converted into a glass. By regulating the admission of gas and air, and by uncovering the furnace, the temperature is lowered to an orange heat—the fusing-point of steel. By raising the crucible in the furnace, the temperature falls to a cherry-red heat—the melting-point of copper. Finally, if the crucible be completely removed from the furnace, it can still be maintained at a temperature at which copper would fuse with difficulty.

We have thus indicated the broad lines of the operation. These are the successive *recuits* at diminishing temperatures which cause the crystals to be formed in sequence, commencing with the least fusible, and which enable us to impart to the fused matter the texture and the mineral composition of volcanic products.

We proceed to illustrate by examples the method of

lithological synthesis. Let us first explain the manipulations for the reproduction of one of the rocks which plays the principal part in the eruptions of Vesuvius—*leucotephrite*. This rock is composed of leucite, labrador-felspar, and augite.

A mixture is formed of silica, alumina, lime, ferric oxide, potash, and soda, corresponding to one part of augite, four of labrador-felspar, and eight of leucite. This mixture is introduced into the crucible, and fused at a glowing white heat to a homogeneous glass. After fusion, the temperature is lowered, and the vitreous mass is exposed for forty-eight hours to the temperature of fused steel. During this first phase, crystals of leucite separate. They evidently correspond to the first period of consolidation in eruptive rocks.

The matter is then subjected during another forty-eight hours to the temperature of fused copper. All the mass, the residue from which the crystals of leucite first separated, is now transformed into microliths of augite and labrador-felspar, with octahedra of magnetite and picotite.

Let us now compare microscopic preparations of the synthetical product of this double *recuit* with those of the natural lava. Not only have the same minerals been reproduced by this dry fusion, but the order of their appearance and the proportion of the constituent species are identical; and their analogy may be pursued even to the details of the crystallographic forms. The leucite, in large crystals, offers all the features of this mineral in the Vesuvian lavas; and around these crystals are grouped the microlites of the second period—the augite and labrador. Finally, as in the natural rock, the leucite contains inclusions of magnetic iron-ore and picotite, which are the most ancient minerals in the rock.

As a second example, let us take the synthesis of *basalt*—one of the most widely-spread types of rock in the volcanic series, and one which, so far as its origin is concerned, has been the subject of numerous hypotheses. It is known that basalt is composed essentially of three minerals—olivine, augite, and labrador-felspar. The olivine in the natural rock appears in crystals of the first consolidation.

As in the case of the leucotephrite, so here, we form a mixture of the chemical constituents, or of the powdered minerals, corresponding to the mean composition of a basalt rich in olivine. Such a mixture is composed of three parts of olivine, two of augite, and three of labrador. This is first transformed into a homogeneous black glass. During forty-eight hours it is maintained at a white heat. If, after this *recuit* at a high temperature, we examine a thin section of the glass, we observe large crystals of olivine. These are as yet embedded in a vitreous mass, in which small octahedra of massicotite and picotite are isolated, as also a few crystals of augite.

It remains now to produce the microlites of the second consolidation, by which the crystals of olivine developed during the first phase ought to be surrounded. To produce these, the mass is maintained at a cherry-red heat for forty-eight hours. After this *recuit* we obtain a paste composed of microlites of labrador and augite, with magnetite and a vitreous substance which is the residue of the crystallization. We have therefore, in this second phase, reproduced the microlithic structure. These manipulations produce basalts which we can scarcely distinguish from the natural rocks, and thus a few grammes of a substance skilfully manipulated furnish us with the most convincing proof of the purely igneous formation of this rock.

We could go on explainng these remarkable series of experiments by MM. Fouqué and Lévy, in the same way as we have dealt with the two preceding syntheses. All the contemporary eruptive rocks have thus been reproduced: andesites, labradorites, basalts, limburgites, nephelinites, tephrites, leucite rocks, peridotites, and labradorites with ophitic structure. We will, however, confine ourselves, as a last example, to those processes by which they have succeeded in directly explaining, by means of synthesis, the eruptive phenomena of the older periods of the globe.

There are certain ancient crystalline rocks, common in the Pyrenees, which are known as *ophites*. The period at which they were formed, and their mode of origin, had not been definitively established, when in 1877 M. Lévy showed that they were eruptive and that they exhibited under the microscope a remarkable structure which he termed the "ophitic structure," the felspar being surrounded by very large plates of augite. It seemed, then, that the ophitic rocks were igneous rocks, in which the cooling had been more slow than in the ordinary rocks of modern eruptions. It was therefore necessary, in attempting to reproduce the ophitic type by synthesis, to cause the augite to crystallize during a phase sharply separated from that in which the felspar was reproduced; and, moreover, to give to the augite sufficient time to crystallize in large plates. For this purpose, a mixture of one part of anorthite and two of augite was submitted, after fusion, to a first *recuit*, in which it was maintained for forty-eight hours at the melting-point of steel: under these conditions the anorthite separated. A second *recuit* of the same duration as the first, but at the fusing-point of copper, led to the crystallization of the augite in large plates, which were moulded round the felspathic element, and to which were added small octahedra of magnetite and picotite. By this remarkable synthesis the eruptive origin of the ophites, and the cause of their structure, were established beyond all doubt.

It is thus seen how synthesis succeeds in explaining the genesis of rocks, and in settling those discussions which until recently were rife with respect to the principal crystalline types of modern date; those relating, for example, to basalt—a rock in whose formation it was argued that water played an important part. Now, the broad conclusion to be drawn from these experiments is that basalt, and, indeed, modern volcanic rocks in general, have been formed by a fusion purely igneous.

But by the side of these magnificent results the *savants* have had to record many fruitless experiments. It is useful to recall these by way of example, as they serve to indicate the paths to be avoided if we would attain success. These failures circumscribe the field of future experiment, and mark the limits within which hypotheses should have play. They demonstrate, moreover, that the rocks which we have not succeeded in forming synthetically by our methods must have been formed under different conditions from those which prevail in the formation of modern volcanic products. This conclusion, to which observation and analysis had already pointed, without, however, precisely defining the cause, is thus confirmed by the failure of our synthetic researches. If synthesis has succeeded in reproducing all kinds of lava from modern eruptions, it has failed to imitate those rocks which are no longer formed in contemporary eruptions. It may be said, generally, that up to the present time all the acid rocks have withstood our synthetic efforts, and those which contain among their constituent minerals, quartz, mica, orthoclase, and hornblende.

The processes of Nature involve no occult forces, and it may be that by combining those means which are already at our disposal, and in modifying their application, we may be permitted to witness the production of those rocks which have hitherto eluded our efforts. Such a hope is based on the results already attained, which we may regard as only the presage of others perhaps still more surprising. The failures of the past prepare for the conquests of the morrow.

In this rapid review of the progress of lithological synthesis, I have endeavoured to show the high scientific value of the researches instituted in the geological labora-

tory of the Collège de France. I could also have explained the successful syntheses, not less remarkable, of minerals and meteorites made by these experimentalists or by their pupils, among whom M. Bourgeois occupies a special position. But I must limit myself; and, indeed, what I have said is sufficient to show how their methods have advanced our knowledge in a domain to which access had previously appeared shut against investigation.

Wherever the experimental method has hitherto carried its torch, it has brilliantly illuminated the most striking phenomena in the science of the earth. It suffices to mention the name of Daubrée, the direct descendant of the illustrious geologists of the Scottish school, to indicate the extent of the field of the mineral sciences already explored by the method of experiment. It has been successfully applied to the interpretation of metalliferous deposits and of metamorphic rocks, and to the study of the fractures and deformation of the earth's crust, of the schistosity of rocks, and of certain features in mountain structure.

Geology, after having passed through the successive phases of observation and analysis, has therefore entered upon that of experiment and synthesis, in which it strives to imitate the creative power of Nature, thus crowning the scientific edifice by processes which allow us to catch a glimpse of the operation of causes the knowledge of which is the final aim of physical and natural science. It was this crowning of the work which Leibnitz foresaw when he wrote, two centuries ago:—"He will perform, in our opinion, an important work, who shall carefully compare the products extracted from the depths of the earth with those of the laboratory; for then will be brought vividly before our eyes the striking resemblance which subsists between the productions of Nature and those of Art. Although the Creator, inexhaustible in resource, has at command divers means of effecting His will, it nevertheless pleases Him to maintain a constancy in the midst of the variety of His works; and it is already a great step towards a knowledge of things to have discovered even one means of producing them; for Nature is only Art on a large scale."

SOME RECENT ADVANCES IN THE THEORY OF CRYSTAL-STRUCTURE.

THE growth of modern theories concerning the structure of crystals is perhaps not so closely followed by English chemists as might be expected from the inherent interest of the subject, in spite of the attention which is now devoted to all questions of atomic and molecular arrangement in space.

It is in the morphology of crystals that the geometrical arrangement of the atoms or molecules (in the solid) finds, if anywhere, a geometrical expression, and yet little or no account is taken of this subject in text-books of chemistry or physics, so that it is difficult for the student to discover what views are held by modern authors. Moreover, crystallographic observations and theories are generally published in journals specially devoted to mineralogy which are not easily accessible to all who are interested in such questions.

It seems, therefore, advisable to draw attention to the progress which has recently been made in the theory of crystal-structure, and more especially to papers by Prof. Sohncke, of Munich, published in Groth's *Zeitschrift für Krystallographie und Mineralogie*, a journal which is a complete storehouse of information relating to the study of crystals.

Sohncke's theory, which was published in 1879,[1] has now emerged from the purifying fire of recent criticism in an emended form in which perhaps it will more readily excite the interest of chemists.

In order to make it clear in what respects the theory of Sohncke in its latest form differs from those which have been previously advanced it will be necessary to give a brief sketch of the theory of Bravais, of which Sohncke's system is an extension.

The Abbé Haüy,[1] having found that all crystals of the same substance may be reduced by cleavage to the same solid figure, whatever their external form, argued that the cleavage solid has the form of the ultimate particles into which any crystal may in imagination be separated by repeated subdivision, and that this is therefore the form of the structural unit: it is not, of course, necessary or even probable that the latter should be identical with the chemical molecule. Hence a crystal is to be regarded as constructed of polyhedral particles, having the form of the cleavage fragment, placed beside one another in parallel positions. A crystal of salt, for example, which naturally cleaves parallel to the faces of the cube, is constructed of cubic particles.

Upon the relative dimensions of the structural unit depends the form assumed by the crystals of a given substance.

It will be found that this theory not only accounts for the existence of cleavage, but further defines the faces which may occur upon crystals of a substance having a given cleavage figure; for, if once it is assumed that a crystal-face is formed by a series of the particles whose centres lie in a plane, it follows that all such planes obey the well-known law which governs the relative positions of crystal-faces.

A natural advance was made from the theory of Haüy, without detracting from its generality, by supposing each polyhedral particle in Haüy's system to be condensed into a point at its centre of mass, so that the positions of the molecules, and therefore of the crystalline planes, remain the same as before; but the space occupied by a crystal is now filled, not by a continuous structure resembling brickwork, but by a system of separate points.

It will be found that in such a system of points, if the straight line joining any pair be produced indefinitely in both directions, it will carry particles of the system at equal intervals along its entire length; in other words, all the structural molecules of a crystal must lie at equal distances from each other along straight lines. The interval between particles along one straight line will in general be different from those along another, but the molecular intervals along parallel straight lines will always be the same.

Bravais,[2] therefore, following in the steps of Delafosse and Frankenheim, treated the subject as a geometrical problem, and inquired what are the possible ways in which a system of points may be arranged in space so as to lie at equal distances along straight lines—in other words, so as to constitute what may be called a *solid network* (*assemblage*, *Raumgitter*).

The geometrical nature of a network may be best realized as follows. Take any pair ($O\ C_1$) of points in space, draw a straight line through them, and place points at equal distances along its entire length ($C_2, C_3, \ldots$); such a line may be called a *thread* of points (*rangée*). Parallel to this line, and at any distance from it, place a second thread of points ($A_1\ a_1$), identical with the first in all respects; in the plane containing these two threads place a series of similar equidistant parallel threads ($A_2\ a_2$, &c.) in such positions that the points in successive threads lie at equal intervals upon straight lines whose direction ($O\ A_1$) is determined by the points upon the first two threads. Such a system of points lying in one plane may be called a *web* (*réseau*). Now, parallel to this plane, and at any distance from it, place a second web ($B_1\ b_1$), identical with the first.

[1] "Entwickelung einer Theorie der Krystallstruktur." (Leipzig.)

[1] "Traité de Cristallographie." (Paris, 1822.)

[2] "Études cristallographiques." (Paris, 1866.)

Finally, parallel with these, place a series of similar equidistant webs in such positions that the points in successive planes lie at equal intervals upon straight lines whose direction ($O\,B_1$) is determined by the points in the first two webs.

In this way a *network* of points is constructed, in which the line joining any two points is a *thread*, and the plane through any three points is a *web*.

The space inclosed by six adjacent planes of the system having no other points of the network between them is a parallelopiped ($O\,A_1\,B_1\,C_1$), from which the whole system may be constructed by repetition, and which may be taken to represent the structural element (*molécule soustractive*) of Haüy.

The complete investigation of all possible solid networks led Bravais to the conclusion that these, if classified by the character of their symmetry, fall into seven groups, which correspond exactly to the seven systems into which crystals are grouped in accordance with their symmetry.

It follows, then, that two (not, however, independent) features of crystals are fully accounted for by a parallelopipedal arrangement of points in space—namely, the symmetry of the crystallographic systems and the law which governs the inclinations of the faces (law of rational indices).

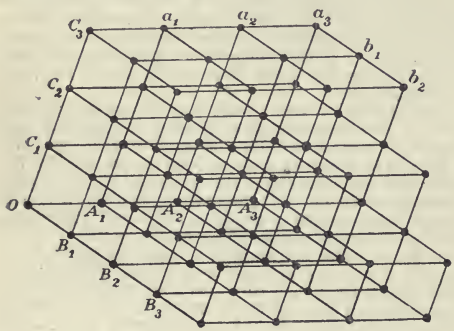

FIG. 1.

There are, however, subdivisions of the various systems consisting of the merohedral or partially symmetrical crystals belonging to them, which are not explained by the geometry of a network; these consequently were referred by Bravais, not merely to the arrangement of the molecules in space, but also to the internal symmetry of the molecule itself.

Hence the theory of Bravais, while able to a certain extent to explain the form of crystals, requires an auxiliary hypothesis if it is to explain those modifications which are partially symmetrical or merohedral.

Sohncke, treating the problem in a different manner, and reasoning from the fact that the properties of a crystal are the same at any one point within its mass as at any other but different along different directions, inquired in how many ways a system of points may be arranged in space so that the configuration of the system round any one point is precisely similar to that round any other. Such a configuration may be called a *Sohncke system* of points in space (*regelmässiges Punktsystem*).

From his analysis of this problem, it appears that there are sixty-five possible Sohncke systems of points, and that these may be grouped according to their symmetry into seven classes corresponding to the seven crystallographic systems; and further that there are within each class minor subdivisions, characterized by a partial symmetry corresponding to the hemihedral and tetartohedral forms of crystallographers.

It may be expected, then, that the theory of Sohncke contains within itself the essential features of a Bravais network of structural molecules, and also the auxiliary hypothesis regarding the arrangement of parts within the molecule which is required to account for merohedrism.

Now, on closer examination the arrangement of Sohncke does prove to be a simple extension of that of Bravais.

Each of Sohncke's arrangements may in fact be regarded as derived from one of the parallelopipedal networks of Bravais if for every point of the latter be substituted a group of symmetrically arranged satellites. It is not necessary that any particle in a group of these satellites should actually coincide with the point of the Bravais network from which the group is derived; and the points of the Sohncke system do not themselves form a network; it is only when all the points in each group of satellites are condensed into one centre that a Sohncke system coincides with a Bravais network.

To any particle of one of the satellite groups corresponds in every other group a particle similarly situated with regard to the point from which the group has been derived. Every such point may be said to be homologous with the first.

It will then be found that each complete set of homologous points is itself a Bravais network in space, and that consequently any Sohncke system may be regarded as a certain number of congruent networks interpenetrating

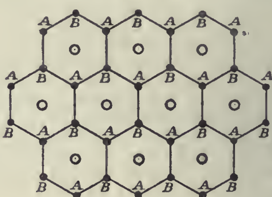

FIG. 2.

one another: the number of such networks is in general equal to the number of points which constitute each group of satellites.

The relation of a Sohncke system to the network from which it is derived may be illustrated by a bees'-cell distribution of points in one plane, *i.e.* by points which occupy the angles of a series of regular hexagons. Thus in the adjoining figure the dots form a Sohncke system in one plane, since the configuration of the system round any one point is similar to that round any other; but they do not form a Bravais web, since the points do not lie at equal distances along straight lines.

If, however, points, represented in the figure by the circles O, be placed at the centres of the hexagons, they will by themselves constitute a web, and the hexagonal system may be derived from this web by replacing each of its points by a group of two satellites, A and B. Or, from the second point of view, the arrangement may be regarded as a triangular web, A, completely interpenetrated by a similar web, B.

It is a remarkable feature of the Sohncke systems that some among them are characterized by a spiral disposition of the particles along the threads of a right- or left-handed screw: now this spiral character, which does not belong to any of the Bravais networks, supplies a geometrical basis for the right- or left-handed nature of some merohedral crystals which possess the property of right- or left-handed rotatory polarization.

The theory of Sohncke as sketched above appeared to

be expressed in the most general form possible, and to include all conceivable varieties of crystalline symmetry.

It has, however, recently been pointed out by Wulff[1] that the partial symmetry of certain crystals belonging to the rhombohedral system—that, namely, of the minerals phenacite and dioptase—is not represented among the sixty-five arrangements of Sohncke.

Other systems of points in space have also been studied by Haag[2] and Wulff, which do not exactly possess the properties of a Sohncke system, and yet might reasonably be adopted as the basis of crystalline structure, since they lead to known crystalline forms.[3] These, however, and all other systems of points which have been proposed to account for the geometrical and physical properties of crystals, may be included in the theory of Sohncke after this has received the simple extension which is now added by its author.

In Bravais's network all the particles or structural elements were supposed to be identical, and in Sohncke's theory also there is nothing in their geometrical character to distinguish one particle from another.

In Fig. 2, the hexagonal series of dots may, as was said above, be regarded as composed of a pair of triangular webs, A and B; now these, although identical in other respects, are not parallel, for the distribution of the system round any point of A is not the same as that round any point of B until it has been rotated through an angle of 60°.

It is possible, however, to conceive similar interpenetrating networks which differ not only in their orientation but even in the character of their particles. The centre of each hexagon, for example, may be occupied by a particle of different nature from A and B to form a new web, O. The three webs are precisely similar in one respect, since their meshes are equal equilateral triangles; moreover, if the *position* of the points alone be taken into account, the whole system would form a Bravais web, *i.e.* if the particles of O were identical with those of A and B. If, however, as is here supposed, the set O consists of particles different in character from A and B, the distribution round any point of O is totally distinct from that round any point of A or B. The points O are geometrically different from the points A B. The web A is interchangeable with B, but O is interchangeable with neither.

Now, it is precisely an extension of this kind which must be given to Sohncke's earlier theory if it is to embrace all the crystalline arrangements which have been alluded to above. The interpenetrating networks are no longer to be regarded as consisting necessarily of identical particles; the structural units of a crystal may be of more than one kind.

The above figure represents a Sohncke system, A B, of particles of one sort interpenetrated by a Bravais web, O, of another sort; but there is no reason why two or more different Sohncke systems, no one of which is identical with a Bravais network, may not interpenetrate to form a crystal structure.

In its most general form, then, the theory may now be expressed—

A crystal consists of a finite number of interpenetrating Sohncke systems which are derived from the same Bravais network. The constituent Sohncke systems are in general not interchangeable, and the structural elements of one are not necessarily the same as those of another.

Or, since each Sohncke system consists itself of a set of interpenetrating networks, the theory may be thus expressed—

A crystal consists of a finite number of parallel interpenetrating congruent networks: the particles of any one network are parallel and interchangeable; these networks group themselves into a number of Sohncke systems in each of which the particles are interchangeable but not necessarily parallel.

The number of kinds of particles which constitute the crystal may therefore be equal to the number of Sohncke systems involved in its construction.

The structural units are no longer, as they were in the theory of Bravais, necessarily identical, but may represent atomic groups of different nature.

The system in Fig. 2 consists of two sets of particles, A B and O; and, if a large enough number of these be taken, any portion of the system (*i.e.* any crystal constructed in this manner) consists of the particles united in the proportion of two of the first group to one of the second. Such an arrangement, then, may represent the structure of a compound, O A_2.

"When, for example, a salt in crystallizing takes up so-called water of crystallization which is only retained so long as the crystalline state endures, the chemical molecule salt + water cannot be said to exist except in the imagination, for the presence of such a molecule cannot be proved. To obtain an easily intelligible example, without, however, pronouncing any opinion as to whether it may be realized, imagine the centred hexagons in the figure to be constructed in such a way that each corner consists of the triple molecule $3H_2O$, and each centre consists of the molecule R. The chemical formula would then be $R + 6H_2O$, and yet a molecule of this constitution would not really exist; on the contrary, the structural elements in the crystallized salt would be of two sorts—namely, R and $3H_2O$."[1]

Hence it is geometrically possible that the structural elements of a crystal may be different atomic groups which are held in a position of stable equilibrium by virtue of being interpenetrating networks.

Whether such systems are chemically and physically possible must be left for future criticism to decide.

Finally, we may call attention to a remarkable declaration of faith which has recently been made in Germany by one who is a recognized leader in crystallographic and mineralogical science.

Prof. Groth[2] has suggested that there may be something more than a chance similarity between the theory of Sohncke and the views of the eminent French crystallographer Mallard, whose classical research upon the optical anomalies of crystals has been the means of dividing the students of this subject into two adverse camps. The explanation of Mallard has up to the present time found little favour among those German mineralogists who have made similar investigations. Prof. Groth has now, however, declared himself in favour of Mallard, being apparently induced to do so by the support which is given to his views by the theory of Sohncke.

Mallard has ascribed the optical anomalies of various substances to a complete or partial intergrowth of two or more crystals which combine in such a manner as to simulate a symmetry of higher order than that which naturally belongs to them. Now, since Mallard regards each crystal as composed of a Bravais network, it is evident that his views are not far removed from those of Sohncke, whose system is based upon the possible intergrowth of two or more networks. THE EARTHQUAKE AT BAN-DAI-SAN, JAPAN.

AS it may interest our readers to know the present state of matters at the scene of the great earthquake which occurred lately at Ban-dai-san, Japan, we think it well to publish the following narrative just received by Dr. George Harley, F.R.S., in a private letter from his son, who has recently visited the locality of the sad disaster.

The letter is dated December 2, 1888, from on board the Peninsular and Oriental s.s. *Verona*, while in the Inland Sea on its voyage back from Japan to China.

Mr. Vaughan Harley says that on October 20 last, having procured the services of an interpreter, he started by train from Yokohama to Tokio, where he obtained a permit from the Japanese Foreign Office to visit the Ban-dai-san valley. From Tokio he went by train to Kuragano, where he engaged, for himself and interpreter, a couple of *jinrickshas*, with two coolies for each. On the following morning he started at 4.45 a.m.,—that is to say, before daylight. It being then early winter in Japan, the day did not break till 6.45. The weather at the time was both cold and rainy; but so long as the roads were good, the coolies, running tandem-fashion, managed to get along at an average rate of from 6 to 7 miles an hour, and accomplished 50 miles a day. On arriving at Inawashiro Lake, after having engaged a guide, he proceeded direct to Ban-dai-san, where the scene that met his eyes, though magnificent, was truly awe-inspiring. It was a veritable valley of devastation. For the whole side of a mountain—3 miles in circumference—had been completely blown away, and hurled as if it had been the mere outside wall of a house, into the valley below, completely burying beneath it four villages and their surrounding farms, along with all their inhabitants. Such was the stupendous force of the explosion, that the mere wind-shock produced by its concussion knocked down, as if they had been nothing more than ninepins, the whole of the trees growing on the opposite mountain-side. The river in the valley, too, was so dammed across by the huge mass of detached mountain as to have formed itself into a small lake, the waters of which now occupy the place where formerly well cultivated crops grew.

The catastrophe which brought about these physical changes appears to have been due to the sudden explosion of superheated pent-up steam, either alone or in conjunction with volatile gases, set free by the decomposing chemical action of heat and water on the constituents of the subjacent mineral strata. The whole surrounding ground is at present full of hot springs, giving forth volumes of steam, while from every crack and crevice in the earth issues, either continuously or spasmodically, clouds of hot watery vapour, so that one has to be very careful where he places his feet. Not only the fact of the presence of these hot springs, but likewise of the still frequent occurrence of earthquakes, shows that the same agent or agents that rent the mountain in twain are still actively at work. Even in the morning of the day following his visit (at 5 a.m.) there was a shock of earthquake, which, although it was strong enough to admit of his feeling the earth quiver beneath him, the people spoke of as being such a mild one as to merit no attention. He says, moreover, that the appearance presented by the standing half of the cleft mountain, with its surrounding clouds of steam, was, to his way of thinking, far grander, and vastly more awe-inspiring, than are either the geysers of Iceland or the yet greater and more numerous ones he had seen in the volcanic district of the Yellowstone Park in North America. For here the scene he witnessed not only plainly pointed to the cause, but gave him ocular demonstration of its stupendous power, and made him feel that, if superheated steam could thus easily, apparently, rend asunder a solid mountain of rock, there could be no difficulty in understanding why the live volcanoes scattered over the globe were looked upon as safety-valves for the effects of the various chemical decompositions brought about by heat and water in the molten minerals within the bowels of the earth. For were there no outlets even to the superheated steam—heated by the vast internal fires up to a point when it possibly resolves itself into its elements—he could readily enough imagine, from what he saw, that its sudden explosion might suffice to shatter the earth's crust into fragments—just, perhaps, as takes place in some of the heavenly bodies, fragments from which ever and anon fall, in the shape of meteorites, upon the surface of our globe. Having got back to the tea-house at 7.15 p.m., leg-tired and foot-sore, but thoroughly satisfied with all he had seen and learned, immediately after a hot bath—a natural one, for there is no need of artificially heating bath-water here, Nature does that amply for them—and supper, he went to bed, the bedstead being the floor, as is usual in Japan. Next morning, he started on his return journey to Yokohama, and arrived in good time for the sailing of the *Verona* on the 25th for Hong Kong, where he immediately posted his letter, in order to catch the homeward mail.

NOTES.

THE Vice-Chancellor of Cambridge University has appointed Prof. Stokes, P.R.S., Rede Lecturer for the present year.

MR. ISAAC ROBERTS, the eminent photographic astronomer, has presented to Dunsink Observatory a photographic reflecting telescope with a mirror by With of 15 inches aperture. The generous donor is erecting the instrument at his own expense, and it will be employed in furthering the study of star parallax—a study with which Dunsink has been so long associated.

ON Thursday evening last, the first meeting of the Institution of Electrical Engineers was held in the rooms of the Institution of Civil Engineers, at George Street, Westminster. Mr. Edward Graves, retiring President, occupied the chair. He opened the proceedings by announcing that the last legal steps had been taken to change the name of their body from "Society of Telegraph Engineers and Electricians," by which name it had hitherto been known, to "Institution of Electrical Engineers." Sir William Thomson, President for the year, then delivered his inaugural address on "Ether, Electricity, and Ponderable Matter."

THE forty-second annual general meeting of the Institution of Mechanical Engineers will be held on Wednesday, January 30, Thursday, January 31, and Friday, February 1, at 25 Great George Street, Westminster, by permission of the Council of the Institution of Civil Engineers. The chair will be taken by the President at 7.30 p.m. on each evening. The President, Mr. Edward H. Carbutt, having been in office for two years, will retire, and will induct into the chair the President-elect, Mr. Charles Cochrane.

THE annual general meeting of the Anthropological Institute of Great Britain and Ireland will be held on Tuesday, the 22nd inst., at half-past eight o'clock p.m. Mr. Francis Galton, F.R.S., will take the chair, and deliver the Presidential address.

AT a meeting of the Council of the Sanitary Institute on January 9, Mr. G. J. Symons, F.R.S., in the chair, it was decided that two courses of twelve lectures for sanitary officers should be held, the first course to begin in March, the second in October.

AT the Central Institution, Exhibition Road, during the spring term, Prof. Armstrong will give about ten lectures on some of the more important current problems in chemistry, on Mondays, at 4.30 p.m., commencing Monday, January 21. The following subjects will be dealt with as far as time permits: the nature of chemical change; the interdependence of chemical change and electrolysis; the molecular composition of gases, liquids, and solids; the nature of solutions; physical constants; laws of substitution and isomeric change as bearing on the problem of the nature of chemical change; valency; geometrical isomerism and allo-isomerism.

ZOOLOGISTS will regret to hear of the death of Dr. Heinrich Alexander Pagenstecher. His "Allgemeine Zoologie," in four volumes, the first of which appeared in 1875, the last in 1881,

is well known. For a good many years he was a Professor of Zoology at the University of Heidelberg. In 1882, after having retired from public life, he was persuaded to accept the post of Director of the Museum of Natural History at Hamburg. His death—which occurred on January 5—was due to heart disease. He was in his sixty-fourth year.

THE death is announced from Southsea, after a very short illness, of Sir William O'Shaughnessy Brooke, F.R.S., in the eightieth year of his age. From 1852 till 1862 he was Director-General of Telegraphs in India. He was created a Knight Bachelor in 1856 for his distinguished services in establishing the electric telegraph service in our Indian possessions.

THE Rev. Churchill Babington, D.D., F.L.S., died on Sunday morning last at Cockfield Rectory. He was well known as a botanist, and contributed to Sir J. Hooker's *Journal of Botany and Kew Miscellany*. Dr. Babington was one of the honorary Fellows of St. John's College, Cambridge.

AT a meeting of the Royal Botanic Society, held last Saturday, the Secretary reported that the recent fogs had done much damage to the plants in the conservatories, causing many of them to shed both leaves and flower-buds. More especially had this been the case with Australian plants, which, from enjoying in their own country a large amount of sunlight, were found less capable than any others of contending against the vicissitudes of London weather. Mr. G. J. Symons, F.R.S., said he believed that fogs were increasing not only in London, but generally. Plants, however, suffered not only from the absence of light, but from the pores of their leaves becoming filled up with the sulphurous, sooty matters contained in London fogs.

INTELLIGENCE received at San Francisco from Hawaii states that Kilauea, the largest volcano in the island, is in a state of eruption.

A NEW mineral of exceptional chemical interest has been discovered by Mr. Sperry, chemist to the Canadian Copper Company, of Sudbury, Ontario, Canada. It is an arsenide of platinum, $PtAs_2$, and is the first mineral yet found containing platinum as an important constituent, other than the natural alloys with various metals of the platinum group. A considerable quantity of the mineral, which takes the form of a heavy brilliant sand composed of minute well-defined crystals, has been thoroughly investigated by Prof. Wells, who names it "sperrylite," after its discoverer; and the crystals have also been measured and very completely examined by Prof. Penfield. The sand is generally found to contain fragments of chalcopyrite, pyrrhotite, and silicates, which may be removed by treatment first with aqua regia to remove sulphides, and afterwards with hydrofluoric acid to remove silicates. After this treatment the sperrylite sand is seen to have remarkably increased in brilliancy, every grain showing extremely brilliant crystal faces, of a tin white colour, resembling that of metallic platinum itself. It is very heavy, possessing at 20° a specific gravity of 10·6. Strangely enough, however, although so heavy, the sand shows a marked tendency to float upon water, owing to its not being easily wet by that liquid; even when the grains do sink, they almost invariably carry down bubbles of air along with them. This peculiar property is retained even after boiling with caustic potash and washing with alcohol and ether, and cannot therefore be attributed to any surface impurities. Sperrylite is only slightly attacked by the strongest aqua regia, even after boiling for days, and it also remains unchanged when heated in a bulb tube to the temperature of melted glass. Heated in an open tube, however, it gives off a portion of its arsenic as a sublimate of the trioxide, the residue then fusing. When dropped upon a piece of red-hot platinum foil it melts, evolving white fumes of inodorou arsenious oxide, and forming a porous excrescence in colour resembling metallic platinum upon the surface of the foil. Analyses show that sperrylite contains 52·5 per cent. of platinum; mere traces of rhodium and palladium, in quantity less than 1 per cent., being also present. Prof. Penfield shows that the crystalline form is cubic, the habit being of the pyritohedral type of hemihedrism, very similar to the various members of the pyrites group, in which an atom of iron, nickel, or cobalt, is united to two atoms of sulphur, arsenic, or antimony. The forms generally developed are the cube {100}, octahedron {111}, pyritohedron π {210}, and occasionally the rhombic dodecahedron {110}. It is very curious that in the treatment with aqua regia, the cube and octahedron faces remain unattacked, while the acids exert a decided action upon the pyritohedral (pentagonal dodecahedral) faces, entirely destroying their power of reflecting light. This similarity between sperrylite and the pyrites of the iron group is rendered all the more important in view of the fact that the platinum and iron groups both occur in the same vertical row (the eighth) in Mendelejeff's periodic classification.

WE referred last week to a proposal for a Meteorological "Congress," to be held in Paris during this year. It should be clearly understood that the meeting in question has originated with the French Meteorological Society, in connection with the Exhibition of 1889, and is quite distinct from the meetings organized by the Committee appointed by the Congress of Rome. This Committee, as stated in Mr. Scott's letter (NATURE, vol. xxxviii. p. 491), has decided to convene a meeting of directors of the meteorological services, at some future time, instead of an official Congress, such as those held at Vienna and Rome; but no such meeting has been arranged by the Committee for the year 1889.

THE Weekly Weather Report issued by the Meteorological Council has been enlarged and considerably improved with the new year. The statistical pages remain unaltered: they refer exclusively to the temperature, rainfall, and sunshine within the United Kingdom. The other portion, which until the end of last year consisted of a brief summary of the weather for each day, accompanied by copies of the daily charts of pressure and temperature over North-Western Europe, has undergone a great change. The area of the charts has been extended so as to cover the whole of Europe, the Mediterranean, Tunis, and Algeria, the hours represented being 8 a.m. for temperature and weather, and 8 a.m. and 6 p.m. for barometer and wind. The enlargement has necessitated the addition of two pages to the Report, the whole forming a most interesting record of the weather over this wide area. The first number is chiefly remarkable for the view it gives us of the Continental anticyclone which spread from Moscow, where the barometer exceeded 31 inches, westward to the Atlantic; the changes in position and intensity being in sympathy with the movements of cyclonic disturbances in the Mediterranean and in the Arctic regions. Towards the close of the week the decreasing intensity of the high-pressure system became favourable to cyclonic weather on our own shores, which afterwards completely dispelled the thick fogs and severe frost. The great cold felt in this country belonged to the same area as that which spread over the Continent, the thermometer being as much as 20° below zero at zero, and gradually rising thence to the shores of the Atlantic.

THE Report of the Smithsonian Institution for the year 1887-88 has been issued. The Secretary, Prof. Samuel P. Langley, refers, as was to be expected, in terms of the highest appreciation, to the character and work of his predecessor, Prof. S. F. Baird. The Institution, as usual, has been doing much excellent work, but Prof. Langley complains that the funds at its disposal are not adequate to its wants. The amount bequeathed by Mr. Smithson, and accepted by Congress, is no longer so valuable as it was half a century ago. "I do not

now refer," says Prof. Langley, "merely to the fact that we measure all things by another scale in 1888 from what we did in 1836; or that, owing to the immense increase of public wealth, the capital of the original bequest, which then was greater than any but a few private fortunes, has become relatively so inconsiderable to-day. More than this is meant. It is meant that the actual purchasing power of each dollar is, for our purposes, notably less; that it is being forced upon us that we cannot print as many books, or pay as many *employés*, or make as many researches, as when the scheme of expenditure was first fixed, and that, consequently, a scheme which was wise then, because not only desirable but feasible, is not necessarily so now." Prof. Langley expresses a hope that an increased income may be provided by the Government and by private benefactors.

We have received the "Bibliography of Astronomy for the Year 1887," compiled by William C. Winlock, and published by the Smithsonian Institution. As a reference list it will be found to be very useful. Most of the various contributions to astronomy published during the year 1887 in the many scientific journals and Transactions of Societies, as well as many more elaborate publications, have been inserted. A few of the titles, as the author says, have been taken from reviews or book-catalogues, and, by means of an alphabetical arrangement of the different subjects of astronomy, references to them can be very easily obtained.

Two weeks ago we printed a brief account of a method employed by Prof. Pickering for enumerating nebulæ photographed in a given part of the heavens, and comparing them with those given in pre-existing catalogues, and by this means increasing the number of known nebulæ. The following is a rather more detailed account of the subject. The region selected for these experiments extends from 5h. 10m. to 5h. 50m. in right ascension, and from $-10°$ to $5°$ in declination. The instrument employed was a Bache telescope, having a photographic doublet, with an aperture of 8 inches and a focal length of 44 inches; and, by means of this, negatives 10° square were obtained, the definition included in a central circular area of 7° in diameter being very good. The work of examining the plates very carefully was intrusted to Mrs. Fleming. Each plate was laid on an inclined plane similar to a retouching desk used in photography, and, by means of a strong magnifying glass, thoroughly studied. Whenever a marking on the negatives appeared to resemble a nebula, the co-ordinates of it were accurately noted, but great care was taken to make sure that the marking was not due to a piece of dust or a defect in the film. The approximate right ascensions and declinations of these objects were next determined from the configuration of the adjacent stars on the charts of the *Durchmusterung*. Then, by comparing the measurements obtained on the plates, and those on the charts, several of the markings coincided, thereby showing that they had been both photographed and catalogued, while in some cases those which had been catalogued had not been photographed, and in other cases some not catalogued were photographed. From the twenty-seven negatives taken fourteen of the objects on them were contained both in the photographs and in the catalogue. Four in the catalogue were not photographed, while twelve, which were not catalogued, were detected on the negatives, and so were probably new. In some instances the back of the plate was covered with a film of shellac and lampblack so as to absorb the light from the rear surface of the plate. The region covered in the above experiments was about four thousandths of the entire sky, so that by photographing the whole heavens a great number of new clusters and nebulæ would be brought to light. From these experiments a very interesting result is disclosed, especially as regards the four nebulæ which were in the catalogue and were not photographed, which suggests that these nebulæ gave different spectra in the ultra-violet from those that were photographed and not catalogued

We have received Part 4, vol. ii., of the Journal of the College of Science, Imperial University, Japan. It contains papers on the determination of the thermal conductivity of marble, by Kenjirō Yamagawa; on the combined effects of torsion and longitudinal stress on the magnetization of nickel, and on the magnetization and retentiveness of nickel wire under combined torsional and longitudinal stress, by H. Nagaoka; and on the specific volume of camphor of borneol, by Mitsuru Kuhara.

A descriptive Catalogue of the Sponges in the Australian Museum, Sydney, by Dr. R. von Lendenfeld, has been printed by order of the trustees of that institution. Dr. Lendenfeld was intrusted with the compilation of this work in 1885. Early in the following year he changed his residence from Sydney to London, so that some delay was rendered inevitable. He considers, however, that the loss of time was amply made up by the advantage he enjoyed of being able to study the collections in the British Museum, and to compare the types of other authors with the Australian Sponges.

The Executive Committee for the reception of the British Association on their visit to Bath met on Thursday last, when it was announced that, after paying all expenses, there remained a surplus of £950. It was decided, with one dissentient, to recommend to the subscribers that the balance be retained intact to form the nucleus of a fund for building an art gallery in Bath.

A few weeks ago (says the *Cheltenham Examiner*), Mr. Francis Day, of Kenilworth House, Pittville, presented a fine collection of Indian birds to a Museum at Cambridge. Mr. Day has now given the remainder of his zoological collection to the British Museum. The gift consists of about 1500 specimens of Indian fishes, 500 of which are stuffed, and the remainder preserved in spirit. There are also a large quantity of English fishes, both stuffed and in spirit; about 1000 specimens of Crustaceans, collected from all parts of India and Burmah, and some British Crustacea, including some from the collection of Prof. Malm. Among the Indian fishes are specimens from the celebrated collection of Dr. Jordan, and the British fishes include especially interesting hybrid *Salmonidæ*, from Sir James Maitland's fish-farm at Howietoun in Scotland, in which Mr. Day takes great interest. There is, in addition, a miscellaneous collection of zoological specimens from the East, including a large crocodile.

The following arrangements have been made at the Royal Institution of Great Britain:—On Tuesday next, January 22, Prof. G. J. Romanes will begin the second part of his course of lectures entitled "Before and after Darwin," the subjects being "The Evidences of Organic Evolution and the Theory of Natural Selection." On Thursday next, January 24, Prof. J. W. Judd, F.R.S., will begin a course of four lectures on "The Metamorphoses of Minerals." At the first Friday evening meeting of the season, January 25, at 9 p.m., Prof. G. H. Darwin, F.R.S., will give a discourse on "Meteorites and the History of the Stellar Systems."

The evening lectures at the Royal Victoria Hall for the next few weeks are arranged as follows:—January 22, Mr. J. D. MacClure, "Shooting Stars"; January 29, Mr. F. W. Rudler, "Coal"; February 5, Prof. Reinold, "Torpedoes"; February 12, Commander Cameron, "Africa and the Horrors of Slavery."

The additions to the Zoological Society's Gardens during the past week include a Vulpine Phalanger (*Phalangista vulpina* ♂)

from Australia, presented by Mr. F. Buckland; a Common Paradoxure (*Paradoxurus typus* ♀) from India, presented by the Rev. J. De Gruchy; a Tawny Owl (*Syrnium aluco*), European, presented by Mr. T. Gunn; a Stump-tailed Lizard (*Trachydosaurus rugosus*) from New Holland, presented by Mr. C. Elliot; a Grey Ichneumon (*Herpestes griseus*) from India, presented by Mr. C. L. Curtis; a Bonnet Monkey (*Macacus sinicus* ♀) from India, two Red-backed Pelicans (*Pelecanus rufescens*) from West Africa, a Masked Parakeet (*Pyrrhulopsis personata*, yellow var.) from the Fiji Islands, deposited; five Clotbey's Larks (*Ramphocorys clotbeyi*), five Algerian Shore Larks (*Otocorys bilopha*), two Rosy Bullfinches (*Erythrospiza githaginea*) from Algeria, purchased.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 *JANUARY* 20–26.

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on January 20

Sun rises, 7h. 56m.; souths, 12h. 11m. 24·4s.; sets, 16h. 26m.: right asc. on meridian, 20h. 11·7m.; decl. 20° 1′ S. Sidereal Time at Sunset, 0h. 27m.

Moon (at Last Quarter January 24, 16h.) rises, 19h. 0m.*; souths, 2h. 29m.; sets, 9h. 45m.: right asc. on meridian, 10h. 27·3m.; decl. 13° 31′ N.

GEOGRAPHICAL NOTES.

The following letter from Mr. Stanley to Tippoo Tib has been received in Brussels:—"Boma of Banalya-Murenia, August 17, to the Sheik Hamed Ben Mahomed [Tippoo Tib] from his good friend, Henry Stanley. Many salaams to you. I hope you are in good health, as I am, and that you have remained in good health since I left the Congo. I have many things to say to you but I hope I shall see you face to face before many days. I reached this place this morning with 130 Wangwana, and three soldiers and sixty-six natives belonging to Emin Pasha. This is now the eighty-second day since we left Emin Pasha on the Nyanza, and we have only lost three men all the way. Two of them were drowned, and the other ran away. I found the white men whom I was looking for. Emin Pasha was quite well, and the other white man, Casati, was quite well also. Emin has ivory in abundance, cattle by thousands, and sheep, goats, fowls, and food of all kinds. We found him to be a very good and kind man. He gave numbers of things to all our white and black men, and his liberality could not be exceeded. His soldiers blessed our black men for their kindness in coming so far to show them the way, and many of them were ready to follow me at once out of the country. But I asked them to stay quiet a few months that I might go back and fetch the other men and goods I had left at Yambunga, and they prayed to God that he would give me the strength to finish my work. May their prayer be heard. And now, my friend, what are you going to do? We have gone the road twice over. We know where it is bad and where it is good, where there is plenty of food and where there is none, where all the camps are and where we shall sleep and rest. I am waiting to hear your words. If you go with me it is well. If you do not go it is well. I leave it to you. I will stay here ten days, and then I go on slowly. I move from here to a big island two hours' march from here, and above this place there are plenty of houses and plenty of food for the men. Whatever you have to say to me my ears will be open with a good heart, as it has always been towards you. Therefore if you come, come quickly; for on the eleventh morning from this I shall move on. All my white men are well; but I left them all behind, except my servant William, who is with me.—(Signed) Stanley.' This letter, which was brought by a messenger to Stanley Falls, reached Brussels by post on Tuesday evening, and is the only one from Mr. Stanley which has reached the coast. The remainder of the letters brought by the messenger remain at Stanley Falls, and will arrive in Europe two or three months hence.

Another of the few remaining mysteries of African geography has just had a little light shed upon it. For many years a lake has been conjecturally placed upon our maps some 15° to the east of the Cameroons, under the name of Liba. No white traveller has ever seen it. Quite recently, however, Dr. Zintgraff, who has been exploring in the Cameroons interior, has obtained information from some natives of the region in which Lake Liba is placed, that leads him to the conclusion that the so-called Lake Liba is probably only a lake-like expansion of a river of that name which exists in the country of his informants. Should the statements of the natives be confirmed, it would seem that the lake, or rather river, to which it belongs is connected neither with the Congo nor the Shari.

Further light has been thrown upon the important question of the supposed waterway between Macluer Inlet and Geelvink Bay, in New Guinea, the existence of which was reported by Captain Strachan. It appears that Dr. A. Meyer's explorations, the results of which seem incompatible with Captain Strachan's conclusions, have recently received important confirmation from the investigations of certain Dutch officials. Lieut. Ellis, who explored the north and north-east coast of New Guinea from May to November 1887, was unable to find the reported water connection, or to gain any information about it from the natives. His own investigations and the inquiries instituted by him force him to the certain conclusion that no such connection exists; and in this he is supported by the opinion of Dr. Host, another explorer.

Dr. Schweinfurth is at present engaged in exploring the little-known region of the Menakha Mountains. Towards the end of last year he left Aden for Hodeida, on the Red Sea, for the purpose of visiting these mountains and the town of Sana. Dr. Schweinfurth carried letters from the Porte recommending him to the care and protection of the authorities; and as he is liberally supplied with funds from Berlin, he hopes to make a thorough exploration of the district, which has been but little visited by Europeans.

The number of the *Zeitschrift* of the Berlin Geographical Society containing the geographical bibliography of the past year has just been issued. As usual it contains a practically exhaustive list of all publications, papers, and maps that have appeared in the various departments of geography.

THE STRASSBURG BOTANICAL INSTITUTE.

IN the American *Botanical Gazette* for December 1888 (vol. xiii. No. 12) there is a paper by Mr. William R. Dudley on the Botanical Institute at Strassburg. This paper is valuable and interesting as showing the sort of provision for botanical study that is thought right and necessary in Germany. The Institute forms part of the new University buildings of Strassburg. Mr. Dudley gives plans of the ground floor and first floor, and from these it appears that a considerable portion of the building is reserved as a residence for the Director and his family, and that two rooms are allotted to the Director's assistant, usually a young man who has recently taken his degree as a doctor. On the ground floor, besides the living-rooms, are a larger and smaller lecture-room, a "*Lehrsammlung*" or illustrative museum, and a "preparation-room," which is used in the preparation of lectures, and is also found useful by those who wish to carry on work in connection with the museum. On the first floor a large part of the space is given up to laboratories. It includes also an herbarium, a library, a weighing-room, a chemical-room, a dark room, and a small greenhouse.

After some introductory statements, Mr. Dudley continues as follows:—

No doubt the architect who designed this building is accountable for cutting it up into symmetrical squares; any German architect who failed in this would be sure to die unhappy. Nevertheless, for the sequence of the rooms and for the details, De Bary was responsible, and, taking everything into consideration, it is considered in Germany their best single laboratory for botany.

Its chief characteristics are the abundance of all necessary appliances and apparatus, cleanliness and orderly disposition of all its supplies, good light from huge windows and white wall-surfaces. Wall-cases are numerous, and the contained glassware, reagents, &c., nicely arranged. Drawers are abundant—this one containing only reagent tubes, that glass plates, another pipettes, burettes, &c. Running water is convenient, of course, and distilled water and three grades of alcohol where they can be readily obtained by students if necessary. There are several sterilizing boxes in the large laboratories; also constant-temperature boxes provided with thermostats. The chemical-room is provided with a hood for fumes and for the steam generated by the steam sterilizing cylinders. Gas is provided at each table, and a separate room is set apart for delicate instruments, such as balances. Indeed the association and dissociation of rooms and apparatus, the conveniences, the absence of unnecessary things and showy effects, indicate the intelligence and discernment of a worker and a master.

The tables are broad, very heavy, and designed so as to prevent warping or seaming. They are convenient for two beginners or a single special student. Each person is provided, at the outset, with about a dozen common reagents and fluids. The microscopes for laboratory use are chiefly Hartnack. Most of the private microscopes in the laboratory at the time I was there were from Seibert, an excellent Wetzlar manufacturer, not well known in America, and one or two from Zeiss. The stock of reagents in the cases is large, and, if necessary, new ones will be cheerfully ordered. The University requires of special students working every day in the laboratory, a payment of fifteen dollars, which covers all necessary expenses.

Strassburg University had about 1000 students during the winter semester of 1887–88, and 104 professors, *privat-docents*, and assistants. It is, therefore, neither one of the largest, nor one of the smallest, of Germany's twenty-one Universities.

The Botanical Laboratory had six advanced and five beginning students, and I do not think the number was affected by De Bary's illness. To instruct or counsel these were four instructors: the Professor; the associate Professor, Dr. Zacharias; the *privat-docent*, Dr. Wortman; and the assistant, Dr. Jost—all contributors, in a greater or less degree, to science, and of course well-trained men. At least three of the advanced students were working quite independently during De Bary's illness, although it was the latter's custom to inquire nearly every day after the work of the advanced students, when he was in health. But the German Government, which employs and pays these instructors, is not afflicted with that particular kind of malaria which enters into the management of almost every American institution, and gives it alternate chills and fever over fall and rise in numbers. Numbers are a matter of indifference to it. A very distinguished German Professor once said to me: "The truth is, we teach whatever we please, we do as much or as little as we please, and the Government does not interfere with us." Yet these men teach enthusiastically, and accomplish in scientific research ten times as much as the American Professor, who is "personally conducted" by a whole Board of Trustees. The German Government *does* "personally conduct," however, in certain very important matters. In the first place, it provides a suitable *corps* of assistants, and makes it sure, therefore, that the Professor has *not* too great a burden of teaching on his hands. It provides ample appropriations; it appoints its Professors for merit, and it sends up its students from the secondary schools with an excellent and uniform training.

The advanced students were mostly engaged in bacteriological investigations, although one was working out certain biological questions of fern development. Prof. Zacharias was engaged in histological work, Dr. Wortman in physiology, and Dr. Jost completed a paper during the winter on the morphology of certain mistletoes.

In the "*Lehrsammlung*" are numerous beautiful preparations, some made by De Bary, and at once recognizable as the originals of well-known figures in his published works; and some by former pupils, some of whom are now famous men. These preparations are frequently used in illustrating the lectures, all of which were held late in the afternoon or in the evening.

The herbarium collection is not relatively large, and is situated rather remote from the other rooms. Had De Bary been a systematist, he would, no doubt, have placed his herbarium centrally. Instead, the large laboratories, the rooms which have seen so many distinguished investigators, and witnessed so many scientific discoveries under the guidance of the great Director, are the rooms around which the others are clustered.

The library, stocked with a fairly good number of the important serials, together with a few standard works in the principal departments of botany, is placed nearer the laboratory; and in this, every Monday evening, meets the "Botanical Colloquium," made up of the advanced students of the laboratory and the instructors. Certain members give carefully prepared abstracts and reviews of the current botanical literature, which are followed by spirited discussions. After an hour or more of arduous and profitable labour of this kind, by means of which each member is enabled to keep quite abreast of advanced lines of work, they adjourn to a more convivial place, and spend the remainder of the evening in the relaxation natural to the German. By eleven o'clock all their vast learning, and especially the hard facts of the recent Colloquium, are in a state of saturated solution, and by next morning are quite ready for use.

INDUSTRIAL EDUCATION.

MAY I ask you to publish and invite criticism on the inclosed Bill, which has been read a first time in the Kensington Parliament? It is put forward as not antagonistic to, but rather as including (see Clause 8), the academic schemes of technical education with which we are familiar. I write as one who was at a primary school, who has worked at the bench, who has great reason to be grateful to the Science and Art Department, who has been a master at a public school, a manager of works, and an employer of labour. JOHN PERRY.

10 Penywern Road, South Kensington, S.W.,
December 28, 1888.

A Bill for Technical Industrial Education.

Whereas it is expedient to make provision for Technical Industrial Education in England and Wales:

Be it therefore enacted, &c.

(1) This Bill may be cited as the Technical Education Bill 1889, and shall not extend to Scotland or Ireland.

(2) "Apprentice" means any boy of less than 18, or any girl of less than 17 years of age employed, whether under indentures or not, in any place which, under the Factories or Workshops Acts, is denominated a factory or workshop, or in any warehouse, shop, office, or other place of business, or for wages, or other remuneration, in any place of employment. But apprentice so defined shall not include any menial or

domestic servant. "Master" means the employer of any apprentice as hereinbefore defined.

"School Authority" means the School Board exercising jurisdiction in the district in which the place of employment is situated, or any elected body which may take over the powers o such School Board; and in places where there is no School Board, it means the County or Borough Council under the Local Government Act, 1888, or the Municipal Corporations Acts.

"Technical Education" is an education in the scientific and artistic principles which govern the ordinary operations in any industry.

"Technical School" means a place for technical education, whether established and maintained—

(*a*) By the School Authority, and open to all apprentices;

(*b*) By voluntary effort, and open to the apprentices of more than one master;

(*c*) Or by a master for his own apprentices.

"Inspector" means the Inspector of Factories in whose district the place of employment is situated, or if there be no such inspector, then the School Board Visitor for such district.

(3) The Education Department shall forthwith and from time to time prescribe regulations in conformity with the rules for the time being of the Science and Art Department, in the subjects in respect of which Parliamentary grants are made by the Science and Art Department, for the formation and instruction of classes of elementary school children who have passed the Fourth Standard, and thereupon the School Authority may form such science and art classes, and provide such instruction accordingly, and earn such grants, and may assign such grants to the teachers of such classes, or may otherwise provide for their remuneration.

(4) Every master shall provide each of his apprentices with technical education at a technical school.

(5) Every apprentice shall devote at least two hours a day, five days in the week, during working hours, to study at a technical school.

(6) The School Authority shall annually in January prescribe the time for such study, having regard to the usual working hours in places of employment in their district, and shall publish a table of the times so prescribed. A printed copy of such table shall be conspicuously exhibited by the master in every such place of employment in such positions for such times and in such type and form as the School Authority shall prescribe.

(7) The School Authority shall have power to establish and maintain such technical schools as may be necessary to accommodate and provide technical education for all apprentices in their district whose masters do not otherwise efficiently provide for the technical education of their apprentices. The master of each apprentice shall pay the prescribed fees for his tuition at such schools.

(8) The technical schools established and maintained by the School Authority may provide technical education for persons other than apprentices.

(9) The course of studies at such schools, and fees payable for the same, shall be prescribed from time to time by the School Authority, subject to the sanction of the Education Department.

(10) The inspector shall inform himself as to the sufficiency of the technical education given to apprentices in his district, and report thereon to the School Authority and the Education Department at such times and in such manner as they shall respectively prescribe.

The duties, powers, and penalties relating to the office of inspector, specified in the Factories and Workshops Act, 1878, shall be applicable to any inspector under this Act, and to any place of employment within the provisions hereof.

The inspectors shall be paid by the School Authority such remuneration for their services under this Act as the Education Department shall approve.

(11) All offences under this Act shall be prosecuted, and all fines under this Act shall be recovered on summary conviction before a Court of Summary Jurisdiction in manner provided by the Summary Jurisdiction Acts.

The provisions of the Factories and Workshops Act, 1878, and the Acts amending the same as to legal proceedings and appeals, shall be deemed to be incorporated in, and made applicable to, this Act.

The punishment for any offence under this Act shall be a fine not exceeding £5.

(12) The expenses of carrying this Act into execution shall be defrayed by the School Authority, who shall have power to provide for such expenditure by moneys raised, precepts issued, or rates levied under their powers. Separate statements of such expenditure shall be furnished annually to the Education Department.

ZOOLOGICAL NOTES FROM TORRES STRAITS.

Caudal Respiration in Periophthalmus.—At the Birmingham meeting of the British Association, in 1886, Dr. S. J. Hickson pointed out that the species of Periophthalmus which he had observed in the Celebes always rested with its tail immersed in water, although the body was out of the same. I do not know whether any experiments have been made on this fish, but I have made a few which tend to show that this remarkable animal largely respires by means of its caudal fin. The experiments were made on specimens obtained from a Mangrove swamp on the Island of Mabuiag (Jervis Islands), and may be summarized as follows:—A specimen totally submerged in the sea was perfectly well and lively after forty-two hours. A second specimen lived a day and a half in a vessel containing just sufficient water to keep the tail-fin submerged, but not enough for respiration by means of the gills. (It is possible that the fish would have lived longer, if the sea-water had been continually renewed.) Fish with the caudal fin coated over with gold size, when put in a vessel of sea-water, only lived, on an average, from twelve to eighteen hours, although they could utilize their gills for respiration; others kept under similar circumstances, but not anointed with gold size, lived a day or two, apparently in perfect health. On submitting the caudal fins to the microscope, the circulation of the blood appeared to be exceptionally vigorous. I hope to be able to further test these observations on a future occasion.

The Employment of the Sucker-fish (*Echeneis*) *in Turtle-fishing.*—The only two references to the employment of the sucker-fish in turtle-fishing which I have by me are those in Dr. Günther's "Introduction to the Study of Fishes," and the "Narrative of the Voyage of H.M.S. *Rattlesnake*," by J. Macgillivray. The latter (vol. ii. p. 21) states that he was informed that the natives of Morulug (Prince of Wales Island), Torres Straits, catch a small species of turtle in the following manner:—"A live sucker-fish (*Echeneis remora*), having previously been secured by a line passed round the tail, is thrown into the water in certain places known to be suitable for the purpose; the fish while swimming about makes fast by its sucker to any turtle of this small kind which it may chance to encounter, and both are hauled in together!" Dr. Günther (*l.c.* p. 461) throws doubt upon the habitual utilization of the *Echeneis* for this purpose. In the Straits there are two periods for turtle-fishing, the one during October and November, which is the pairing season, and when turtle are easily speared owing to their floating on the surface of the water; the other, during the remaining months of the year when the turtle frequent the deeper water and the channels between the reefs. It is then that the sucker-fish—or, as the natives term it, "Gapu,"—is utilized. I have, at present, no means of determining the species of *Echeneis* common in the Straits. I believe it to be *E. naucrata*, as the species here attains a greater length than *E. remora*. When going out turtle-fishing, a Gapu is caught, and the more experienced natives have no great difficulty in procuring one when it is required. A hole is made at the base of the caudal fin by means of a turtle-bone, and the end of a very long piece of string is inserted in the hole and made fast. The end of a second, quite short, piece of string, is passed through the mouth and out by the gills. By means of these two strings the fish is retained, while slung over the sides of the canoe, in the water. When a turtle is sighted deep down in the water, the front piece of string is withdrawn, plenty of slack being allowed for the hind string. The Gapu on perceiving the turtle immediately swims towards it, and attaches itself to the reptile's carapace. A man, with a long rope attached to an upper arm, dives into the water and is guided to the turtle by the line fastened to the Gapu's tail. On reaching the turtle, the man gets on its back, and passes his arms behind and below the fore-flappers, and his legs in front and below the hind-flappers. The man is then rapidly drawn up to the surface of the water bearing the turtle with him. On the arrival of the

diver the Gapu usually shifts its position from the carapace to the plastron of the turtle. At the end of the day's fishing the Gapu is eaten. The natives have a great respect for the Gapu, and firmly believe the fish possesses supernatural powers. For example, when there is something the matter with the bow of the canoe, the Gapu is said to attach itself to the neck or the nuchal plate of the turtle; when the lashings of the outrigger to the thwart poles are insecure, the Gapu is believed not to stick fast to the turtle, but to continually shift its position; if the strengthening ties in the centre of the hold of the canoe are faulty, the Gapu is stated to attach itself to the turtle and then immediately to swim away. More than once I was told, "Gapu savvy all the same as man; I think him half devil." The sucker-fish is not used to haul in the large green turtle. I was repeatedly told that it would be pulled off, as the turtle was too heavy. The above information was gathered from several sources, and checked by means of much questioning.

Amphioxus.—A species of Amphioxus, apparently very similar to *A. lanceolatus*, was not uncommon at one spot at Mabuiag, at a depth of from 3 to 4 fathoms. A species of this animal is catalogued as follows by Mr. Krefft, in his list of "Australian Vertebrata, Fossil and Recent": "*Branchiostoma lanceolatum*. Dredged in Bass's Straits, by H.M.S. *Herald*, at a depth of from 10 to 12 fathoms." I am not aware whether it has been found elsewhere in Australian waters.

ALFRED C. HADDON.

Thursday Island, November 12, 1888.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Sedgwick triennial prize has been awarded to Mr. Alfred Harker, Fellow of St. John's College. The subject of the essay is "The Petrology of the Igneous Rocks associated with the Cambrian (Sedgwick) of Carnarvonshire."

SCIENTIFIC SERIALS.

IN the number of the *Journal of Botany* for December 1888, Mr. S. Le M. Moore has an interesting article on photolysis in *Lemna trisulca*, in which he contests some of Stahl's conclusions as to the effect of day and night on the relative positions of the chlorophyll-grains on the cell-walls. The remaining articles, both in this number and in that for January 1889, are chiefly of interest to geographical or systematic botanists. Messrs. Britten and Boulger's "Biographical Index of British and Irish Botanists" has now advanced as far as the letter G.

IN the *Botanical Gazette* for November 1888, Miss E. L. Gregory completes her account of the development of cork-wings on certain trees, the trees described in the present instalment being species of *Acer* and *Liquidambar*.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 22, 1888.—"Report of Researches on Silicon Compounds and their Derivatives. Part I." By J. Emerson Reynolds, M.D., F.R.S., Professor of Chemistry, University of Dublin.

The present investigation was undertaken some years ago with a view to examine the action of the silicon haloids—but more especially of silicon tetrabromide—on various compounds containing nitrogen, as our knowledge of the relations of silicon and nitrogen is extremely limited.

It was ascertained at an early stage of the inquiry that the bromide of silicon is much superior to the chloride as a reagent with nitrogenized compounds, but since the bromide had apparently not been obtained in any quantity even by its discoverer, Serullas, considerable time had to be devoted to working out a method for the production of a sufficiently large supply of this material. The method adopted is described in the full paper.

In the purification of the crude tetrabromide a new *chlorobromide*[1] *of silicon* was discovered, which boils at 141° C. This proved to be the compound $SiClBr_3$, which was required to complete the series of possible chlorobromides of silicon.

The first group of nitrogen compounds subjected to the action of silicon tetrabromide included the primary thiocarbamide or sulphur urea, obtained by the author in 1869, and the allyl-, phenyl-, and diphenyl-thiocarbamides.

All these are shown to unite with silicon tetrabromide, and afford the highly condensed compounds—

$$(H_4N_2CS)_8SiBr_4,$$
$$(C_3H_5,H_3N_2CS)_8SiBr_4,$$
$$(C_6H_5,H_3N_2CS)_8SiBr_4,$$
$$((C_6H_5)_2H_3N_2CS)_8SiBr_4.$$

These are more or less vitreous solids, with the exception of the allylic compound, which is a transparent and singularly viscous liquid. All are dissolved and decomposed by water and by alcohol.

The action of alcohol on the compound $(H_4N_2CS)_8SiBr_4$ was studied in detail, and it was shown that not only do ethyl bromide, thiocyanate, and diethylic silicate result, but that the representatives of two new classes of thiocarbamide derivatives are formed.

The first of these is a beautiful *tetrathiocarbamide* compound whose formula proved to be—

$$(H_5N_2CS)_4NBr,$$

which may obviously be written—

$$(H_4N_2CS)_4H_4NBr.$$

This body separates from alcohol in fine masses of crystals resembling sea anemones in appearance, which melt at 173°–174°, and begin to decompose at 178°–180°. The synthesis of this substance was effected by heating ammonium bromide with thiocarbamide.

Several homologues of the above *tetrathiocarbamidammonium bromide* were produced by synthetic methods; some of these contain chlorine or iodine instead of bromine. The following are examples of the compounds found in the course of this part of the investigation:—

$$(H_4N_2CS)_4H_4NBr,$$
$$(H_4N_2CS)_4H_4NCl,$$
$$(H_4N_2CS)_4H_4NI,$$
$$(H_4N_2CS)_4(CH_3)H_3NBr,$$
$$(H_4N_2CS)_4(C_2H_5)_2H_2NBr,$$
$$(H_4N_2CS)_4(C_2H_5)_3HNCl.$$

By the action of silver nitrate on the tetrathiocarbamidammonium bromide the crystalline *dithiocarbamide* compound with silver bromide was obtained—

$$(H_4N_2CS)_2AgBr.$$

This was subsequently produced by the direct union of thiocar bamide with the pure silver haloid. The compound—

$$(H_4N_2CS)_2AgCl$$

was also obtained in fine crystals, as were other similar substances.

A *trithiocarbamide* compound is also formed during the action of ethyl alcohol on $(H_4N_2CS)_8SiBr_4$, but it is much more soluble than that which first separates. It is also crystalline, and its analysis and reactions lead to the formula—

$$(H_5N_2CS)_3Br,C_2H_5Br.$$

Hitherto only mono- and di-thiocarbamide derivatives have been known, but the results above stated in outline prove that tri- and tetra-thiocarbamide compounds are formed in presence of silicon tetrabromide and certain other agents, which latter form addition products with the condensed amide.

So far, cases were only dealt with in which silicon tetrabromide combined with nitrogenized groups without loss of its halogen. The next stage of the inquiry involved the investigation of certain interactions in which the tetrabromide loses all its halogen. One of the chief results obtained in that direction forms the subject of a separate communication.

[1] The chlorine required for the production of this compound was derived from the crude bromine (which always contains chloride of bromine) used in preparing the tetrabromide.

Mathematical Society, January 10.—J. J. Walker, F.R.S., President, in the chair.—Mr. Basset made a few remarks on the steady motion and stability of dynamical systems.—Dr. Glaisher, F.R.S., gave several forms of expression of Bernoulli's numbers derived from the consideration of lemniscate functions.—The President (Sir J. Cockle, F.R.S., in the chair) read a paper on results of ternary quadratic operators on products of forms of any orders.—Mr. Jenkins communicated a note by Mr. R. W. Christie on a theorem in combinations.

EDINBURGH.

Royal Society, December 3, 1888.—A restatement of the theory of organic evolution, by Prof. Patrick Geddes. In the introduction to this paper Prof. Geddes gives to the four customary divisions of biology more general meanings. He considers that morphology, besides being a description of individual forms, deals with specific and generic ones. Taxonomy is thus the higher and more generalized morphology. Embryology includes the description of the development of species and genera in addition to that of individuals. Morphology and embryology, then, deal with the descriptions of the form, and the development of the form, not only of individuals but of races. Similarly, physiology is applied to the description of the functions of the individual, and also to those of species, genera, and higher groups. As the description of the relations of organs characterized the physiology of the individual, so that of interspecific adaptations is the physiology of the race. As morphology and embryology are related, so are physiology and ætiology. Ætiology gives the laws of variation of individual and race. It deals not merely with functions in a balanced state in the individual, and perfected adaptation between races, but also with the origin of both of these in the temperament of the unit organism, and of the sum of organisms. This question has to be separated from the deeper one of the origin of organismal temperament in the influence of environment or otherwise. The following diagram shows these relationships:—

	Structure.		Function.	
	Embryology.	Morphology.	Physiology.	Ætiology.
Group ...		Linnæus	Darwin	
Class ...				
Order ...				
Genus ...				
Species ...				
Species unit (pair, &c.)			....	......>
Individual				
Organ ...				
Tissue ...				
Cell ...				

From this division of the field of biology, a clearer and more exact estimate of Mr. Darwin's position can be had. It is plain that the theory of natural selection, which Mr. Romanes rightly describes as rather that of "the origin of adaptations," is part of the higher physiology, or the relation of races to one another. It is thought by many that Mr. Darwin dealt with problems of ætiology—that he described the origin of the functions in the individual. But he openly deferred the consideration of the laws of variation, and confessed entire ignorance of them. He, indeed, at different times, had two impressions of the import of natural selection. Like others, he sometimes makes the mistake of thinking that an account of adaptations, which species acquire, explains their origin. At other times he clearly sees that there must be a science of variation—an ætiology—which shall tell of the origin of variations acted on by natural selection to form the raw material of adaptations. Both pre- and post-Darwinian writers have dealt with the explanations of variations as arising from temperament. The former have theorized in a general way; the state of their knowledge not allowing them to prove that variation is definite. This point of view must again be taken, and all recent results read from it. The object of the present paper is to show how this may be accomplished throughout the organic world, as the author has already done in finding a definite *rationale* of sex and reproduction. Prof. Geddes then took up the matter in detail for the vegetable world, under such headings as: inflorescence; floral structure; floral colour; the antithesis between floral and grassy types; variations in the leaf; thorns and spines; evergreens; corelations between the reproductive and vegetative systems. The classes of the animal kingdom were treated *seriatim*, the definite lines of variation being traced from the synthetic types in each. He next showed, and illustrated with masses of detail, that throughout a great number of species there are individuals with vegetative and others with reproductive diathesis; and similarly in every genus. Some species are more vegetative, some more reproductive in character; and so, further, of orders and large groups. The vegetative or self-maintaining activities are opposed to, and balanced by, the reproductive or species-maintaining ones. The history of the individual life, or of the development of the race, is a series of alternations between predominating vegetation with subordinate reproduction, and prevailing reproduction with diminished vegetation. The differentiation of sex, the development of parental care and of sociality, are the most obvious results of the reproductive, the race-maintaining diathesis; and these play at least as important a part in organic progress as struggle for individual advantage. In conclusion, Prof. Geddes contrasted his own views of the process of nature, as a materialized ethical process, with that of Prof. Huxley, expressed in his *Nineteenth Century* article, where he considers organic evolution an intellectual but not a moral process. A second paper is to follow, carrying out the argument into the ethical, social, and economic relations of humanity.

BERLIN.

Meteorological Society, December 4, 1888.—Dr. Vettin, President, in the chair.—Dr. Andries developed an original theory as to the constitution of the sun, by which he explained a large number of phenomena. During the discussion which ensued, the theory was attacked from various sides.—Prof. von Bezold made a report on Prof. Kiessling's book, "Untersuchungen über die Dämmerungserscheinungen" ("Researches on the Phenomena of Twilight"), after he had briefly alluded to the recent and more comprehensive work of the English Commission on the Krakatão eruption, which had appeared simultaneously with that of Prof. Kiessling. He pointed out that these two works complement each other, inasmuch as Prof. Kiessling had confined himself entirely to the optical phenomena arising out of the eruption, describing them fully, and illustrating them by physical experiments, while the Commission had dealt comparatively briefly with these phenomena.—Dr. Less spoke on falls of snow during high temperatures. On the morning of November 20 the temperature was 9° C.; it reached a maximum of a little over 11° between 9 and 10 a.m., and then fell irregularly with repeated showers of rain to about 3° C. At 9.45 a.m., when the temperature was above 11°, one of the watchers in the Meteorological Institute announced that he had observed some few flakes of snow falling with the commencing rain. Since the speaker could not find anybody from among his acquaintances who could confirm the above observation, he addressed himself to the public at large by means of the newspapers: he thus obtained very valuable and reliable reports, not only from various parts of Berlin, but also from outlying districts, of snow having fallen, either in solitary large flakes or in larger quantities, at temperatures as high as 9° to 11° C. Dr. Less had once before in this year (1888) observed the same phenomenon, on May 8, when the temperature of the air was 12° C. On going over the literature of this subject in the synoptic weather reports for Germany for the years 1876 to 1888, he came upon twenty-eight cases in which snow had fallen, either in larger quantities or as solitary flakes, when the temperature was above 5° C. He explained the formation of the snowflakes as the result of low-lying currents of air whose temperatures were much lower than those at the earth's surface. Out of the twenty-eight cases quoted above, eleven were accompanied by marked and wide-spread thunder during the ensuing twenty-

four hours. This circumstance may be taken as supporting Sohncke's theory of aërial electricity, according to which the electricity during a storm results from the friction of drops of ice and water, and this can only take place when cold currents of air at comparatively low levels flow over warm, moist masses of air.

Physical Society, December 14, 1888.—Prof. von Helmholtz, President, in the chair.—Dr. Thiessen gave an account of experiments which he had carried out in order to measure the amount by which gravity varies at different heights. The method he employed was that of Jolly, but with the introduction of a modification, in order to eliminate the irregularities due to differences of temperature at the higher and lower stations. Scale-pans were attached to each arm of the balance—one close up to the beam, the other some distance below it—and the weight was interchanged between the pans, both at the upper and lower stations, thus eliminating the influence of differences of temperature and of any inequality of the balance. The upward force of the air had no influence on the results, notwithstanding the varying volumes of the weights used. The distance between the upper and lower scale-pans was 11·5 metres, and the weight used was 1 kilogramme. Twenty-four determinations were made, which gave as a result that the kilogramme, when in the lower pan, weighed 2·8 milligrammes more than when it was weighed in the upper pan. After making some corrections, and, among these, one necessitated by the fact that the weight in its lower position was 4 metres below the general surface of the earth, it was found that the weight of 1 kilogramme varies by 0·28 milligramme for each 1 metre of difference in altitude.—The President gave an account of a paper by Prof. Hertz, which he had yesterday communicated to the Berlin Academy. It contained a description of further experiments on electrodynamic waves, and their analogy with waves of light. Weak induction-discharges between small metallic cylinders with rounded ends were employed, and a similar apparatus for the detection of the electrodynamic waves. The action was not propagated more than 2 or 3 metres through space; when it fell on a metallic surface it was reflected, interference phenomena were observed, and from these the length of half a wave was found to be 30 centimetres. When a metallic parabolic mirror, 1 metre across its opening, was placed behind the apparatus used to produce the discharge, the action was propagated to a distance of 8 metres; and the action was greatly increased when a second concave mirror was placed behind the receiving apparatus. When a conductor was interposed, the action ceased, while non-conductors allowed the waves to pass. By interposing perforated metallic screens, it was found that the waves are propagated in straight lines; the waves passed through a dry wooden partition. Polarization of the waves could be determined in several ways. When the receiver was placed at right angles to the apparatus producing the waves, no action between them could be detected, the vertically-produced waves not being picked up by the horizontally-placed receiver. When the two pieces of apparatus were placed parallel to each other, and a wooden cube, with a number of insulated metallic wire rings wrapped round it, was placed in the path of the electrodynamic waves, it produced the same effect as does a tourmaline plate on polarized light. When the wires were vertical—that is to say, parallel to the exciting apparatus—the action was not propagated through the cube; but it was, on the other hand, when the wires were horizontal. When the receiver with its mirror was placed horizontally, so that it did not record any action as reaching it, and the wire arrangement, described above, was placed in the path of the waves, no change took place in the receiver when the wires on the cube were either vertical or horizontal, but the receiver was affected when the wires were placed at an angle of 45°. The laws of reflection of electrodynamic waves at metallic surfaces were found to be the same as those for the reflection of light at plane mirrors. Finally, Prof. Hertz has determined the refraction which the waves undergo in a prism made of pitch, and finds that the refractive index of this substance for electric waves is 1·68.—Dr. Ritter demonstrated by experiments the action of the ultra-violet rays of light on electric discharges in accordance with the experiments of Hertz, Wiedemann, and Eberts.

STOCKHOLM.

Royal Academy of Sciences, January 9.—On the researches and studies made at the zoological station of the Academy at Christineberg in Bohuslan, during the past year, by Prof. S. Lovén. He gave an account of papers by Dr. Aurivillius on the disguise amongst the Oxyrhynchous Crabs, by Dr. Virén on a Nereid Annelid (*Nereis fucata, forma inquitina*), by Herr Lönnberg on cestodes in marine fishes and birds.—Researches on the periodic system of the elements, by Dr. T. R. Rydberg.—Baron Nordenskiöld exhibited some uncommonly large crystals of magnetic iron from the Nordstjerne mine near Vestanfors, and gave an account of some remarkable Swedish localities with crystallized magnetite. He also showed four meteorites, for the collection of the State Museum, received from the British Museum. Amongst these were (1) a sample of a small, highly-interesting block of iron, which fell near Rowton, in Shropshire, August 20, 1876; (2) a fragment of a meteorite which fell in Hisen, in Japan.—On some transcendents, which appear at the repeated integration of rational functions, by Dr. A. Jonquière, of Bern.—On natural etching figures and other phenomena of solution on beryllium, from Muovinsk, by Herr W. Peterson.—Researches on minerals from Fiskernæs, in Greenland, by Herr N. V. Ussing.—Mineralogical notes, II., 3-4, by Herr G. Flink.—Anatomical studies on Echidna, by Miss C. Westling.—On the dimorphism of the *Rhizopoda reticulata*, by Dr. A. Goës.—The insect fauna of Greenland; I. Lepidoptera and Hymenoptera, by Prof. Chr. Aurivillius.

THURSDAY, JANUARY 24, 1889.

MR. GRANT ALLEN'S NOTIONS ABOUT FORCE AND ENERGY.

Force and Energy: a Theory of Dynamics. By Grant Allen. Pp. 161. (Longmans, Green, and Co., 1888.)

THERE exists a certain class of mind, allied perhaps to the ancient Greek Sophist variety, to which ignorance of a subject offers no sufficient obstacle to the composition of a treatise upon it. It may be rash to suggest that this type of mind is well developed in philosophers of the Spencerian school, though it would be possible to adduce some evidence in support of such a suggestion.

In the volume before us Mr. Grant Allen sets to work to reconstruct the fundamental science of dynamics, an edifice which, since the time of Galileo and Newton, has been standing on what has seemed a fairly secure and substantial basis, but which he seems to think it is now time to demolish in order to make room for a newly excogitated theory. The attempt is audacious, and the result—what might have been expected. The performance lends itself indeed to the most scathing criticism; blunders and misstatements abound on nearly every page, and the whole structure is simply an emanation of mental fog.

Thus much it is necessary to say in order to give an adequate idea of the nature of the book; but, having said as much as this, it is possible to speak quite otherwise of the friendly tone and apparently candid modesty in which the preface has been written. The preface, indeed, almost disarms a critic, or at any rate it causes him to use the blunt end of his lance; and were it not necessary to call attention to the erroneousness of such of the doctrines as are new, and expose their hollowness to a number of unlearned persons who are always eager to see some flaw found in a universally accepted theory the difficulties of which they have never mastered, and which they therefore vainly hope will turn out incorrect, one would gladly accept the apology and explanation of the preface and let the work sink into oblivion unnoticed.

Its pretentious form, however, renders criticism necessary; and indeed criticism is expected by the author, though, as he naïvely confesses, it will not undermine his own opinion of the truth and value of his work.

The book is in two parts: Part I. "Abstract or Analytic"; Part II. "Concrete or Synthetic." The second part consists of more or less popular illustrations of the doctrines inculcated in the first part: it need not therefore much concern us. The first part starts with chapters on "Power," "Force," "Energy"; later on it has three chapters called respectively, "The Persistence of Force," "The Conservation of Energy," "The Indestructibility of Power." These last headings are not very promising; and the performance does not belie the promise.

Chapter II. leads off with the following definition:—

"A Force is a Power which initiates or accelerates aggregative-motion, while it resists or retards separative motion, in two or more particles of ponderable matter (and possibly also of the ethereal medium)."

In other words, the author agrees to limit the term "force" to that which is commonly known as attraction. Very good. Now take Chapter III.:—

"An Energy is a Power which resists or retards aggregative motion, while it initiates or accelerates separative motion, in two or more particles of ponderable matter, or of the ethereal medium."

In other words, he is going to denote that which is commonly known as repulsion by the name "energy." He by no means always adheres to the limitations imposed by this definition, and frequently he means by the term energy the same as is ordinarily understood by the term, though he does so most happily in cases where the result can be looked upon as a separation of some bodies.

Thus, for instance, the upward motion of a cannon-ball he would style an energy, because it separates the ball from the earth; the strain in a bow he would call an energy, because it can separate the arrow from the bow; heat he would call energy, because it usually expands things; but the *horizontal* motion of a cannon-ball or a railway train he will have a difficulty in calling an energy, and, in fact, is unable to do so without a flagrant mistake of principle in the case of the ball, and some manifest special pleading in the case of the train. Still more unable is he properly to apply the term energy to the *downward* motion of a falling body. We shall see what he makes of this obvious difficulty shortly. Nevertheless, this is the main doctrine in the book—viz. that anything tending towards aggregation is a force, while anything tending to disgregation is an energy.

Passing, then, to the next chapter, "The Species of Force," he subdivides force into attraction between large masses, or gravitation—between molecules, or cohesion—between atoms, or chemical affinity—and, lastly, between electric charges. It may as well be said, once for all, that throughout the book there are many lame and hesitating references to electricity and ether, which are so vague as to be quite harmless, and which it will be the most charitable plan to simply ignore. We had better ignore most of the chemical and molecular statements also, for the same reason, and attend only to those which deal with ordinary lumps of matter. But even here it will not do to criticize the language too closely, or one would have enough to do. This, for instance, is one of the first sentences about gravitation: "When an aërolite comes within the circle of the earth's attraction, it is Gravitation which makes them leap towards one another." "The circle of the earth's attraction" and the sudden "leap" of the aërolite when it comes within this circle, are phrases which scarcely express quite accurately the facts of the case!

The next sentence throws a flood of light upon the state of the writer's mind when he formed his conception of the difference between force and energy, and explains also, I venture to surmise, why his doctrine found so blithe an acceptance with Mr. Edward Clodd, as Mr. Clodd's own book and the preface to this one inform us. It is the orbital energy of the moon which counteracts the aggregative power of gravity. "If the moon were to lose its orbital Energy, Gravitation would pull it to the earth."

This sentence is not indeed untrue, but it is significant as showing that it is the old puzzle of centrifugal force or

of radial acceleration that is at the bottom of this whole "new theory." The puzzle was solved completely long ago, in the clearest possible manner, and the "Principia" is the witness to it; but it is still felt to be a difficulty by beginners, and I suppose there is no offence in applying this harmless epithet to both Mr. Grant Allen and Mr. Clodd, so far as the truths of dynamics and physics are concerned.

"Energy" and "Force" are always opposed to one another, and the meaning of the author is well illustrated by the following quotation:—

"Again, when two masses are in a state of aggregation, the Force of gravitation resists any attempt to sever them. If a cannon-ball lies upon the ground, it cannot be raised without an expenditure of Energy, and the amount of the Energy required to lift it to a given height is the measure of the resistance offered by Gravitation."

That is to say, the energy required to lift a body to a given height is a measure of the force of gravitation. This reminds one of some of the sentences in Tyndall's "Heat."

The next chapter, "The Species of Energy," classifies energy as molar, molecular, atomic, and electrical, just as in the case of force. "Of Molar Energies employed in resistance to aggregation, the most familiar instance is that of orbital movement"—moon and earth, &c.

Now we come to the *crux* of how horizontal motion can be an "energy" in the sense defined by Mr. Allen.

"On a smaller scale, the Energy of a bird in flying, or of a cannon-ball fired horizontally, is largely employed in counteracting gravitation"!!

May I inform the author of an elementary fact? A cannon-ball fired horizontally falls just as quickly, and reaches the ground (if flat) in precisely the same time, as if it were merely dropped; its energy of motion has no power of counteracting gravitation. The same is really true of the moon: it falls towards the earth just as much in each second as if it had no orbital velocity; in no case does motion influence the effect produced by a given force. But this is just the fact which, if he had been able to recognize it, would have saved him the trouble of writing this treatise.

I said I would charitably omit reference to the molecular, chemical, and electrical statements, but I cannot resist one quotation from the next page: "Large masses of water before freezing part with their Energy in the visible form of heated mist."

Chapter VII. is headed "The Kinds of Kinesis," by which is meant apparently the varieties of motion. Motion is subdivided, not into rotation and translation, but thus:—

"Motion has three Kinds; . . . it may be separative, or it may be aggregative, or it may be continuous and neutral. Each species of Kinetic Energy has a form of each kind."

The author now finds it necessary to grapple with the difficulty which we guessed he would sooner or later feel, viz. how it is possible to bring falling motion, or motion of bodies towards one another, under his category of "Energies or separative Powers." A body thrown up, and a body thrown horizontally, he has already tackled by simply committing some convenient errors of fact. He surmises that such bodies fall less than they would if dropped, and thus that their energy of motion counteracts gravitation; but the case of a body thrown down is not to be thus managed, so he proceeds to get over the difficulty in three ways. First, by raising a cloud of words; second, by asserting that when a body strikes the earth, although its potential energy of separation has disappeared, yet the heat of its collision separates atoms just as much, and results in the same ultimate amount of separation again (a statement which in no sense can be considered true), so that the motion which intervened between the start and stop of the falling body "we are justified in regarding as essentially a transitory form of separative Power."

"Throughout we see that aggregative Energy" (*i.e.* energy apparently aggregative) "is merely Potential Energy in course of transformation to another form. While the really aggregative Power of Force is causing these bodies to combine, the Energy of their motion represents for a while their original separateness, and is finally transformed into a similar separateness between other bodies."

So, while motion *from* the earth is true kinetic energy, motion *towards* it is a transitory form of potential energy, and represents for a while the original separateness of the bodies!

When a doctrine requires a statement like this to bolster it up, it is wise to take the need as a sure indication that we are somewhere off the track, and had better get back to the turning whence the path which has led us into such a jungle diverged. It is a pity the author did not take the hint thus clearly vouchsafed to him. His difficulties about understanding normal acceleration and the generality of Newton's second law were natural and excusable, though hardly the subject to write a book about; but after encountering and being worsted by this last thicket, it was very unwise to go on plunging madly forward, and exhibit his scratches as signs of victory.

But he has not yet made his last struggle into still more hopeless entanglement. Here is his third attempt at extrication:—

"We see that the Energy of a falling body does not consist in its mere downward movement, but rather in that accelerating motion which is capable of being transformed into heat when the masses aggregate."

If this statement means anything, it means that the kinetic energy of a down-moving body consists, not in its velocity, as is the case with an upward-moving body, but in its acceleration, and that it is this acceleration which ultimately gets turned into heat!

"So the Energy of Kinesis is seen to be a mere transferential mode from one kind of separation to another." "Motion is the redistribution of Separations."

One may at least acknowledge the ingenuity as well as the gallantry with which the author endeavours to get clear of his impenetrable jungle.

In passing, here is a curious definition of friction, given in an explanatory note.

"From the point of view of the Force involved, friction means the cohesion which must be overcome; but from the point of view of the Energy employed, friction means the separative power of heat which overcomes."

Next we come to the extraordinary but fortunately short chapter entitled "The Persistence of Force," which

"must be carefully distinguished from the opposite principle of the Conservation of Energy."

From the examples given it appears that the author means by "the persistence of force" the universal prevalence and unalterable character of gravitation. This, if you please, is a principle "opposite" to the "conservation of energy."

It may be asked how on earth the author manages to make out any doctrine of conservation for what he is pleased to style "Energy." It may be asked, but scarcely answered. First, there is a momentous difference of language to be attended to, a difference of which we are told the concrete and practical results are enormous. "While Forces *persist*, Energies are *conserved*." This is a most satisfactory beginning, and makes one feel quite smooth and comfortable. But unfortunately the author is not original in the rest of this chapter, and his illustrations of conservation of energy do not flow from his definition, but are quite common-place. I cannot resist one little extract from this chapter wherein the property of "inertia" has an altogether new light thrown upon it, a light even more brilliant than that just thrown upon "friction."

> "Two molecules of water vapour are prevented from aggregating under the relatively feeble attraction of cohesion at a distance, by their inertia—that is, by the relatively strong cohesion of surrounding or intervening matters (just as a mass on a table is prevented from aggregating with the earth by the cohesion of its boards). Two atoms having affinities for one another are similarly prevented from aggregating by inertia. . . . So also two electrical units are prevented from aggregating in the Leyden jar by the electrical neutrality of the glass partition."

Chapter X., "The Indestructibility of Power," asserts that

> "the total amount of Power, aggregative or separative, in the Universe is constant, and no Power can ever disappear or be destroyed. This sums up the two preceding generalizations of the Persistence of Force and the Conservation of Energy in one still wider generalization."

Chapter X. is very short.

The chapter on "Liberating Energies" is a dissertation on pulling a trigger, and quite mistakenly supposes that some expenditure of energy is essential to the performance of this act.

> "A ball suspended by a thread is released by the separative Energy of a knife or scissors."

The separative Energy of a knife is a good phrase.

> "The stronger Force necessarily outweighs the weaker, and as Forces cannot increase or decrease in intensity, the only manner, &c."

Forces cannot increase or decrease in intensity? No, certainly not; this is proved by the existence of the phrase "persistence of force." Well, this is logical; at any rate, after the bookish manner of argument, and that is some comfort.

> "Electrical Liberating Energies are those which release Electrical Units from the interference of a Force antagonistic to Electrical Affinity."
>
> "They are such as close the circuit of a battery, or bring a discharging tongs to a Leyden jar."
>
> "The usual vagueness of electrical science prevents any definite treatment of these phenomena."

Are we, then, to conclude that the author, in all this treatise, has hit on no germ of truth—nothing but what was well known before, or what is erroneous? I fear that, with the possible exception of the idea of classifying energies by reference to the sizes of the bodies concerned, this must be our conclusion. He has regarded the universe from the point of view of action at a distance, and has been struck with one or two salient features: (1) the universality of gravitation at great distances, and of cohesion at small; (2) the existence of what has been styled "repulsive motion"—that is, a motion which simulates the effects of repulsion, as when two particles or two molecules, rushing together, swing each other round and separate again; or when a heated gas expands. One knows that, in old text-books, heat was often spoken of as a repulsive force. And a sufficient velocity imparted to a satellite *does* keep it clear of the earth.

Struck with these facts, he has proceeded to take gravitative separation as the typical and fundamental form of energy; motion being a form of energy only because it tends to separation (in some cases, at any rate), so that he defines motion, in the last chapter of Part I., as "the redistribution of separations," while energy he defines as "a Power which separates." On the other hand, he has taken gravitation and cohesion as his typical forms of force; and, because these tend to pull bodies together, he has defined force as "a Power which aggregates," and has proceeded to write a treatise on the subject, showing how force and energy are opposed to one another.

The thing which strikes one most forcibly about the physics of these paper philosophers is the extraordinary contempt which, if they are consistent, they must or ought to feel for men of science. If Newton, and Lagrange, and Gauss, and Thomson, to say nothing of smaller men, have muddled away their brains in concocting a scheme of dynamics wherein the very definitions are all wrong; if they have arrived at a law of conservation of energy without knowing what the word energy means, or how to define it; if they have to be set right by an amateur who has devoted a few weeks or months to the subject, and acquired a rude smattering of some of its terms,—what intolerable fools they must all be!

But this does seem the attitude of many literary men, and that must be one reason why they dislike and despise science. If such a view were just or true, dislike and contempt would be the only reasonable attitude.

A scientific man may often feel harassed by being unable to express in literary form what he has to say; but, though this is an evil, it is surely a lesser evil than to have the knack of writing and no matter to write. It is as when the Sophists proceeded to teach rhetoric, heedless of whether either their pupils or themselves possessed any real knowledge about which to be eloquent.

Mr. Grant Allen has apologized for his Mistake in the preface, and one has no quarrel with him. One might, if it were worth while, have a quarrel with a certain class of literary men for the shallow and flippant way in which they occasionally refer to Science; but it is not worth while.

The disciple is not above his master in this respect.

Here is one quotation of many which might have been chosen from Mr. Herbert Spencer:—

"Newton described himself as unable to think that the attraction of one body for another at a distance could be exerted in the absence of an intervening medium. But now let us ask how much the forwarder we are if an intervening medium be assumed. This ether, whose undulations, according to the received hypothesis, constitute heat and light, and which is the vehicle of gravitation,—how is it constituted? We must regard it in the way that physicists do regard it, as composed of atoms which attract and repel each other—infinitesimal, it may be, in comparison with those of ordinary matter, but still atoms. And remembering that this ether is imponderable, we are obliged to conclude that the ratio between the interspaces of these atoms and the atoms themselves is incommensurably greater than the like ratio in ponderable matter; else the densities could not be incommensurable. Instead, then, of a direct action by the sun upon the earth, without anything intervening, we have to conceive the sun's action propagated through a medium whose molecules are probably as small relatively to their interspaces as are the sun and earth compared with the space between them; we have to conceive these infinitesimal molecules acting on each other through absolutely vacant spaces which are immense in comparison with their own dimensions. How is this conception easier than the other? We still have mentally to represent a body as acting where it is not, and in the absence of anything by which its action may be transferred; and what matters it whether this takes place on a large or a small scale?" ("First Principles," chap. iii. § 18).

Omitting any reference to the absurd reasoning about "incommensurable" densities in this quotation, and about the ether being "imponderable," as if Mr. Herbert Spencer or anyone else knows anything whatever on the subject, I wish to call attention to the words regarding the structure of the ether "in the way physicists do regard it"! If they do, if they are unable to see that action at a distance across a small space is just as inexplicable as action at a distance across a large one, and if the ether they imagine is not thought of as in some sense or other a *continuum* for this very reason; if, in fact, they are unable to appreciate, in all the years they have been thinking on the subject, what is obvious on the face of it to someone who steps in, so to speak, for the first time, —what singularly incompetent persons they must be!

That seems to be the real upshot and natural meaning of many of these criticisms of science from the outsider's point of view. O. J. LODGE.

ROCKS AND SOILS.

Rocks and Soils: their Origin, Composition, and Characteristics. By Horace Edward Stockbridge, Ph.D., Professor of Chemistry and Geology in the Imperial College of Agriculture, Sapporo, Japan; Chemist to the Hokkaido Cho. (New York: John Wiley and Sons. London: Trübner. 1888.)

CHEMIST to the Hokkaido Cho! It is not the least striking feature of our time that there should be an Imperial College of Agriculture at Sapporo whose Professors publish researches in New York and London. This is not exactly a novel experience, for events crowd upon us thick and fast in these days; but those of us who can look back forty years must be struck when confronted with the Chemist of the Hokkaido Cho. Dr. Stockbridge is not, be it understood, the alchemist to an Eastern potentate, nor yet one of the astrologers, Chaldæans, or soothsayers of a modern Belshazzar, but an agricultural chemist and geologist discoursing upon rocks and soils, nitrates and microbes, and suggesting processes by which atmospheric nitrogen is fixed in the soil by the action of living organisms. The great Mikado, "virtuous man," has, we know, transplanted full-grown and fully-equipped knowledge from the West to his remote dominions; and so successfully, that it has rooted, and now is become an article for exportation—as witness the volume before us. To some of our readers it may appear unnecessary to dilate upon a fact which springs naturally out of the most recent developments of civilization. We need not now despair of openings for aspiring young chemists under the protection and pay of the King of Dahomey or of Ashantee, or of an Imperial Institute at Khartoum or some other part of the Dark Continent; and truly the missionaries of science are in a fair way to rival those of religion in their ubiquity.

The volume before us is of attractive appearance. It is, however, hard upon the reader who takes it up in order to learn something about rocks and soils to be carried through the entire history of the planet on which his lot is cast. Deeply interesting as are the cosmic questions bearing upon the original nebulous mist, "in glowing gaseous condition," they scarcely affect even scientific agriculture. Besides, it is open to doubt whether an agricultural chemist and geologist is within his province in explaining the differences between white stars, red stars, and habitable planets which have gone through phases thus indicated. Such information belongs to the domain of the astronomer and the physicist, and the agricultural study of rocks and soils should be taken up at a later date of the earth's history. It is not our object to criticize Dr. Stockbridge's book severely, but it appears to us that if he had cut out 100 pages at the beginning, and added 100 pages at the end in harmony with his concluding sections, his work would have been more useful.

The two features of this book which seem to us the most important are, first, Dr. Stockbridge's views as to the "fixation of atmospheric nitrogen independent of ammoniacal condensation and of nitrification." The compounds thus formed in the soil are, we are told, complex insoluble amides resembling those existing in living organisms, and must have resulted through the vital activity of the micro-organisms present in the soil. If soils have the power of fixing atmospheric nitrogen through the action of living organisms, they possess a means of recruiting fertility independent of plant action, and of so fundamental a nature that, supposing such action to take place, the question of the source of nitrogen and the supply of nitrogen in soils would be set at rest. Another novel view is that propounded with reference to dew-formation. Here, we have a subject which is not very clearly related to that of rocks and soils. So far as the soil is a vehicle of plant nutrition, its conditions as related to moisture are of course important, and it is in this connection that the theory of dew as propounded by Dr. Stockbridge finds a place in his work. It is not necessary here to explain Dr. Wells's explanation of the fall of dew.

It is sufficient to state that it is unsatisfactory to our author, who holds that dew on the leaves of plants is (we presume he means occasionally and not universally) derived from the plant itself rather than from condensation from the atmosphere. Dew on growing vegetables is produced by the condensation of the transpired moisture from the plant on its own leaves. This explanation is proved by direct experiment, and we are not disposed to deny its truth. It is probable, and, in fact, more than probable, that plants which are giving off large quantities of water into a cold or overcharged atmosphere should have a portion of their own moisture thrown back upon them. This fact is asserted in Marshall Ward's translation of Sachs's "Physiology of Plants," when he says, "Much of the water we find early in the morning on the margins of the leaves of many field and garden plants in the form of large drops, and which are generally taken for drops of dew, is really water excreted from the plants themselves." That the air is really the cooling medium by which the moisture rising from the warm soil or the growing plant is condensed is no doubt often true. The mist which stretches over the meadows at sundown is moisture condensed in the cool air, and thus becomes precipitated upon vegetation, and not only on vegetation, but upon everything else. Where we think Dr. Stockbridge has overstated his case is when he writes in italics, "*The declaration is here made that dew is the condensed exhalation of the plant.*" The statement is too general, and the assertion has too much of the character of a supposed new discovery on the part of the author. The real facts of the case are, that dew is produced in some cases from condensed exhalations from the plant, or from condensed moisture rising from the soil; but also from the precipitation of moisture from higher sections of the air during the night; especially when the sky is clear. The collection of water in the form of hoar frost upon leafless trees or lawns must be derived from the condensation of atmospheric moisture upon the tree, or upon the grass, cooled by radiation; and we have no doubt that grass radiates heat on a moonlight night more rapidly than does bare ground. Dr. Stockbridge lays too much stress on the fact that the earth is warmer than the air when dew is falling. This he asks us to believe is fatal to the theory that the earth condenses or can condense atmospheric moisture. The radiating power of the earth is very great, and exceeds that of the air, which, in fact, absorbs and retains much heat which otherwise would be immediately lost in space. Dr. Stockbridge argues that the surface of the earth is invariably warmer than the air at the dew point, but this is not likely to be the case. Even the temperature of grass land is affirmed to be always warmer than the air, and hence it is contended that in no instance can the earth or vegetation be the condenser. We are disposed to think that observation will throw more light on this point than such experiments as are quoted or were made by Dr. Stockbridge.

It is probable that dew may be precipitated at times by a colder air on a warmer surface, and at other times by a cold soil or cold expanse of leaf from a warm atmosphere. Whether the leaf of a grass or the air above it acts the part of "the cold pitcher" is not always to be predicated. but in either case dew would be the result. We may point out that, while Dr. Stockbridge is disposed to assert that the soil is always warmer than the air, other authorities are of opinion that the surface, especially of grass, is colder by many degrees than the air. A thermometer laid upon grass would, we believe, recede further and record a lower minimum than one suspended 2 feet above the grass. The freezing of dew on grass during summer nights, which is always an unpleasant sight to gardeners and farmers, appears to be accounted for by radiation of heat from the grass surface, while the substance of the grass cuts off radiated heat from below. The absence of dew under shade also is apparently due to radiation from the earth being checked, and the cooling process of the surface of the earth or its vegetable covering being prevented.

Dr. Stockbridge's book suffers from careless reading of the proofs. This work, the author tells us, he was compelled to depute to others. In one place (p. 183) the word "soil" is evidently used instead of air, thereby reversing the author's obvious meaning, and the word "not" is interpolated, which further confuses the sentence hopelessly. Names of authors quoted are mis-spelt in several cases. The book, especially in the earlier pages, is somewhat bombastic and provincial in its style, and, as we have before stated, many of the earlier pages might have been omitted with advantage. The tone of the writing becomes more modest, precise, and student-like as the author approaches the topics which we are informed upon the title-page he professes.

JOHN WRIGHTSON.

OUR BOOK SHELF.

The Kingdom of Georgia. By Oliver Wardrop. (London: Sampson Low, 1888.)

THE author of this work sees no reason why Georgia should not become as popular a resort as Norway or Switzerland. Perhaps he takes rather too sanguine a view of the energy even of the British tourist, but everyone who reads his book will certainly wish to have a chance of visiting the country he describes. A brighter or pleasanter book of the kind we have not seen for many a day. The style is fresh and sparkling, and Mr. Wardrop has the secret of awakening and maintaining the interest of his readers without any attempt at picturesque fine-writing. He conveys a remarkably vivid impression of the splendid natural scenery of Transcaucasia; but it is in describing the Georgian people that he displays most effectively his powers as an observer. He has the warmest appreciation of the intelligence, bravery, and generosity of the Georgians, and, in the course of his narrative, the extent to which these and other qualities affect their social life is shown with much force and animation. There are valuable chapters on the history, the political condition, and the language and literature of Georgia; and an excellent bibliography of works relating to the country is given as an appendix. The book is also supplied with good maps and illustrations.

The British Journal Photographic Almanac for 1889 Edited by J. Traill Taylor. (London: Henry Greenwood and Co., 1889.)

THIS work, as a compendium of photographic art science, could scarcely be more complete. It contains about 300 closely-printed pages, consisting of articles written by men who are eminent in connection with photography in its various and ever-increasing branches. Great ad-

vance has been made in this year's volume, both as regards size and the number of articles included; the pages of the calendar which were formerly devoted to the dates of meetings of Societies have here been left blank for the sake of persons desiring to make notes or memoranda.

Valuable hints on all topics are given both to amateurs and professionals, no single department of the work, as far as we can find, having been neglected.

A brief summary of the year's work is given by e editor, touching upon the gradual merging of the brown and purple tones into those of darker and more engraving-like type, the advancement made in flash-light photography, and the new method of platinum-printing. The summary concludes with an obituary of those who have passed away since the last issue.

Next follow series of articles, commencing with one on "Iron Printing," by the editor, and continuing with those contributed by Abney, Burton, Perry, Piazzi-Smyth, and many others.

Twenty pages are devoted to an epitome of progress during the year 1888, and then are added a list of useful receipts, standard formulæ, reference tables, &c.

The Photographer's Diary and Desk-book for 1889. Compiled by the Editor of the *Camera*. (London: Published at the Office of the *Camera*, 1889.)

OF the various diaries brought out for the present year, that issued by the proprietors of the *Camera* will be sure to give great satisfaction to photographers, both amateur and professional. This differs from other photographic diaries in two respects: in the first place, it is much larger, there being plenty of room for notes on experiences of various kinds, results of manipulating, developing difficulties, and many other details well worth recording, which are often so useful and valuable for reference. In the second place, there is a great amount of useful information condensed in the first fifty pages. Besides various tables and processes of developing, printing, &c., information similar to that included in almanacs and other diaries is inserted; the tables and standard formulæ relating to photography being printed in larger type, to enable the worker, when in the dark room, to refer to them. This diary is a very complete and useful publication, and, as a book of reference, is most handy.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Climate of Siberia in the Mammoth Age.

A SHORT time ago I was discussing with my friend Mr. Henry Seebohm the various problems connected with the distribution and migration of birds in Siberia, about which he has collected so many facts. One fact which he mentioned to me seemed to have a much wider interest than a merely ornithological one, and to illustrate from an unexpected quarter a conclusion which you have allowed me to urge in your columns, and which forms a notable postulate in my recent work on "The Mammoth and the Flood." I mean in reference to the climate of Siberia during the Mammoth age. The views I have advanced on this subject are not my own. I have merely followed in the footsteps of almost every recent Continental authority, especially the authorities with the greatest claims to attention—namely, the Russian naturalists who have visited Northern Siberia. They maintain—and I think the position is unassailable—that during the Mammoth period that district which is now a bare *tundra*, on which neither in summer nor winter could herds of pachyderms find food or shelter, was marked by a temperate climate, and was probably occupied by forests to the very borders of the Arctic Ocean.

This view, which is supported by so many facts, was finally established when it was shown by Schmidt and others that rooted trunks of trees are found in the beds containing Mammoth remains far north of the present range of trees, and that southern forms of fresh-water mollusks, such as the *Cyrena fluminalis*, are also found preserved in the same beds in Siberia far to the north of any place where they will now live. These facts are consistent only with the former existence of a temperate climate in Siberia.

It is interesting to meet with support for this position from the present avifauna of the Palæarctic region. Mr. Seebohm, who has an unrivalled collection of skins, illustrating the ornithology of this region from Britain to Japan, assures me (and, in fact, he showed me the evidence) that certain birds—notably the jay, the nuthatch, the marsh-tit, coal-tit, and long-tailed tit, the great and little spotted woodpecker of England and Japan, and in one case of Northern China—are virtually undistinguishable. Similarly, the hazel grouse of Japan resembles that of the Pyrenees, and the nutcracker of Japan and China is like that of Western Europe. While this is so, the forms of these same birds found in the intervening district of Siberia differ very materially, and have, I believe, in almost every case, been treated as specifically distinct. This is assuredly a very interesting fact. Both Britain and Northern Japan are in the same zoological province—namely, the Palæarctic region, over which there is a singular constancy of types and forms, and yet we find that in certain birds the forms at either extremity of the province are closely allied, while the intermediate form differs. This is at one with the fact that the climate of the two extremities is very similar, and that of the intervening district is very much more severe in the winter. We can hardly doubt that the general adherence to a normal type which marks the fauna and flora of the Palæarctic region (and which was even more marked, and amounted, so far as we know, to identity, in the Mammoth period) is due to the fact that formerly, and in every probability in the Mammoth period, an equality of conditions prevailed throughout. This equality has been maintained at the extremities of the region, with the result of maintaining the old forms and types unaltered; while it has changed and grown more severe in the intervening region, with the corresponding result of altering the types there. The conservatism of forms at either end of the province proves unmistakably a conservatism of conditions. This is assuredly a very interesting independent proof, if proof be now needed, that the climate of Siberia was once much more temperate throughout, and like that of Britain and Japan, and this doubtless in the Mammoth age.

I may add that it seems to me very nearly certain that this change of climate in Siberia was the cause of the conversion of what were once sedentary birds there into birds that migrate to South Africa and elsewhere—a migration which has been very well illustrated by Mr. Seebohm. That the date of the commencement of this migratory tendency is not very remote in time is shown by the fact that the birds have not been more differentiated, notwithstanding the very various conditions prevailing in their several winter-quarters. I believe myself that in the Mammoth period, when the climate of Siberia was temperate, there was no need for these tremendous migrations, which were, no doubt, originally induced by the necessity for finding food in winter; but that most, if not all, of these migratory birds were then either stationary in Siberia, or were only local migrants, like so many of our own birds are now.

Mr. Seebohm, in his recent work on the Charadriidæ, has invoked the Glacial epoch to account for the facts presented by that singularly distributed genus. I know of no Glacial epoch in Siberia before the present. The last epoch there, as we can test and prove by the presence of the undecayed carcasses in the frozen ground, was the period when the Mammoth lived. It was when that period closed (and as I claim to have proved closed very rapidly) that the present Arctic conditions of the Siberian climate were introduced, and I would urge it was from this date that the *present* laws controlling the migration of Siberian birds arose.

This seems an inference of some importance; and when the ornithological history of the eastern half of the Palæarctic region is written in detail, it will very probably be shown that the

peculiar sub-specific types found there are many of them *new* forms, which have arisen since the Mammoth age, having been altered from the old ones, which live on under old conditions in the West of Europe and the Japanese Archipelago.

I should like to specify one particular bird in regard to which this notion seems to point a special moral. This is the British red grouse, the only peculiar bird of these islands. Its nearest ally on the Continent, and a very near ally, is the willow grouse. I have little doubt that the willow grouse of the Continent is an altered form, and that our red grouse is the parent, since the evidence we have, and it is not slight, goes to show that England has preserved better than Scandinavia the climatic conditions of the Mammoth period. The white marks and other characteristics of the willow grouse are evidences of the effect of colder winter-quarters, as they are in the case of the ptarmigan.

Lastly, I cannot avoid emphasizing once more the conclusion which I have pressed in my book that this milder climate in Siberia during the Mammoth age entirely does away with the necessity for invoking quite transcendental seasonal migrations for the fauna there which have been postulated by Prof. Dawkins and others. That the Mammoth, with its immature young, should be able to pass to and fro between the south of Siberia and the New Siberian Islands and Kamchatka, between summer and winter, has always seemed to me incredible. If they could compass the journey they would either find a temperate conditions of things, which is alone consistent with their finding food, when there would be no occasion for them to migrate, or they would find the conditions which prevail now, when no pachyderms could find food *even in summer*, since they are physically incapable of browsing the short herbage of the *tundra*. Nor could the trees and the southern mollusks, like the *Cyrena*, migrate, even if the young Mammoths could. This theory of migrations finds no support, so far as I know, among those who have studied the problem on the ground; and it is put entirely out of court when we realize that, Siberia having had a temperate climate, there was no necessity to migrate.

A similar argument applies to the theory invoking the transport of the Mammoth carcasses by means of the Siberian rivers, which has always seemed to me untenable when the conditions are faced. I would mention that in Baron Toll's recent journey to the New Siberian Islands, situated a long way north of the Siberian coast-line, and entirely out of the reach of any possible river portage, he not only found remains of a carcass of a Mammoth preserved in the flesh, but found them in a bed situated to the north of a ridge. This fact may be put beside those already mentioned by Wrangell and others long ago, that the carcasses and skeletons and *cachés* are found chiefly on the hillocks and higher ground of the *tundra*, out of the reach of river-floods altogether, and found most frequently near the small rivulets and feeders of the greater streams, which could not float them, and found also near those flowing south. This theory of portage and that of seasonal migrations have been nursed and maintained in this country in spite of evidence of every kind, because they are supposed in some way to buttress the theory of uniformity, as taught by Lyell and Ramsay. An appeal to them and to similar complicated physical causes becomes not merely unwarrantable, but unscientific and illogical, when we realize that from one end of Siberia to the other the climate was sufficiently temperate when the Mammoth lived there to enable trees to grow and vegetable food to be found everywhere, and the physical surroundings of the country were probably such as may be measured by those still prevailing in Britain or Japan.

HENRY H. HOWORTH.

Bentcliffe, Eccles, January 10.

The Crystallization of Lake Ice.

ON returning recently from North Wales, I was very pleased to meet with a description, by Mr. James C. McConnel (NATURE, December 27, p. 203), of the elaborate experiments performed by himself and Mr. Dudley A. Kidd on glacier and lake ice at St. Moritz. An experiment I had made on the ice of Llyn Creigenen, a small lake to the north-west of Tyrau Mawr, seems to me to be, in some measure, confirmatory of the results obtained in connection with the crystallization of lake ice.

By sharply striking the ice, which was only about half an inch thick, with the rounded end of a stick, fractures were produced, which invariably adopted the form of a six-rayed star-like figure. The beautiful regularity of these figures, in regard to the number, position, and perfect straightness of their rays, at once reminded me of the well-known percussion- and pressure-figures produced in mica plates by Reusch and Bauer. Mr. Grenville Cole, who was with me at the time, repeated the experiment, and obtained precisely similar results. We found that over a certain area a large number of these figures could be produced, in each of which there were corresponding parallel rays—that is to say, every percussion-figure was similarly disposed with regard to a fixed line. Outside this area, the figures produced, although preserving the characters of those first made, exhibited a change in the direction of the rays. In this way we could determine the boundaries of a number of adjacent areas, separated from one another by definite lines of demarcation. These areas averaged about two feet across.

We were unable to conceive of any conditions of stress which would, in a homogeneous solid plate, give rise to such phenomena—fractures of such beautiful regularity, and so constant in character. Consequently, we thought of crystallization; but this would necessitate the recognition of ice-crystals of very large dimensions—a conclusion obviously at variance with the existing notions concerning the crystalline characters of ice. We thought, however, that the matter might be worthy of investigation, and, on returning to town, were pleased to find that large crystals of lake ice had been found at St. Moritz by Messrs. McConnel and Kidd, which, however, did not attain the size of those we noticed on Llyn Creigenen. But the fact that on the St. Moritz Lake the ice attained a thickness of over one foot shows that the temperature must have been lower, and the conditions more rigorous, than in North Wales at the time of our visit.

If it is possible at all to obtain large crystals of ice, I should say the conditions for such on Llyn Creigenen were of the most favourable character. For three days previously, the temperature varied very little from zero C., and, from the slight wind that prevailed at the time, the lake was well sheltered by the hills which rise abruptly around; indeed, the lake was unusually free from disturbing influences of any kind.

If these sheets of ice were gigantic crystals, it is in the highest degree probable that the surface of the ice coincided with the basal plane, as was the case with the columnar crystals observed by Prof. Heim in the lake ice of the Swiss lowlands. For want of a polariscope we were prevented from investigating the matter further in the field; but in some small well-sheltered pools on Tyrau Mawr we found it easy to produce the same phenomena of percussion-figures, whilst the ice in the marshy places amongst the grass gave fractures of a most irregular kind. We found, in several places, skeleton-crystals like ornamented equilateral triangles, measuring some inches across.

Normal School of Science, South Kensington.

Use of the *Remora* in Fishing.

WITH reference to Mr. A. C. Haddon's interesting account of the use of the *Remora* or sucker-fish by the natives of Torres Straits in fishing for turtles (NATURE, January 17, p. 285), I may call attention to the paper on this subject read by our corresponding member, Mr. Frederick Holmwood, C.B., late H.B.M. Consul at Zanzibar, before the Zoological Society of London, on June 17, 1881 (see P.Z.S., 1881, p. 411), which Mr. Haddon does not seem to be acquainted with. Mr. Holmwood has fully described the mode of the use of the *Remora* by the native fishermen of Zanzibar in catching turtles and fishes. It is curious to find a somewhat similar method of employing the *Remora* practised by the islanders of Torres Straits.

P. L. SCLATER.

3 Hanover Square, London, W., January 19.

A Remarkable Rime.

UNDER this heading a letter appears from Lutterworth (p. 270), but no mention is made of the colour of the water obtained on melting some of the rime collected from the trees. In the neighbourhood, far removed from any large town, the rime crystals, on melting, gave water tasting very sooty, and looking as though the liquid had been used to wash Indian ink brushes in, it being quite black with sooty particles.

M. H. MAW.

Barrow-on-Humber, Hull, January 22.

HUMAN VARIETY.[1]

IT would have been a pleasure to me in this address, given at the conclusion of my office as your President, to have cast a retrospect over the proceedings of our Institute during the four years that I have had the honour to hold it. But the subjects that have come before us are so varied that it seemed difficult to briefly summarize them in a manner that should not be too desultory.

On the whole, I thought it might be more useful if I kept to a branch of anthropometry with which many inquiries have made me familiar, and took the opportunity of urging certain views that seem to be worthy the attention of anthropologists.

Before entering upon these more solid topics, let me mention that the laboratory of which I spoke in my last address has been in work during the past year, and that about 1200 persons have been already measured at it in many ways, some more than once. I lay on the table a duplicate of one of the forms of application to be measured, and of one of the filled-up schedules. It will be observed that I now have the impressions made in printers' ink of the two thumbs of each person who is measured, being desirous of investigating at leisure the possibilities of employing that method for the purpose of identification, not forgetting the success that attended Sir W. Herschel's use of it in India, but conscious at the same time of practical difficulties. There is no doubt that the thumb or finger marks vary so much that a glance suffices to distinguish half a dozen varieties, while a minute investigation shows an extraordinary difference in small, though perfectly distinct, peculiarities. Neither is there any room for doubt that these peculiarities are persistent throughout life; nor, again, that so satisfactory a method of raising a very strong presumption of identity would be valuable in many cases. It will suffice to quote the following. A newspaper was lately sent me from the distant British settlement of North Borneo, where, owing to the wide and rapid spread of information nowadays, attention had been drawn to an account of a lecture I gave on one of the Friday evenings last spring, at the Royal Institution. It was on "Personal Description and Identification," and a writer in the *British North Borneo Herald* commented upon the remarks there made on finger imprints. He spoke of the great difficulty of identifying coolies either by their photographs or measurements, and that the question how this could best be done would probably become important in the early future of that country. I also am assured that the difficulty of identifying pensioners and annuitants has led to frequent fraud from personation, involving in the aggregate a very large sum of money annually, as there is good reason to believe. If finger imprints could be practically brought into use, such frauds would be extremely difficult. I am still unable to speak positively as to the best way of making them, but the plan adopted at the laboratory is as follows. A copper plate is smoothly covered with a very thin layer of printers' ink, a printers' roller being used, and the plate being cleaned every day. When the layer is thin, no ink penetrates into the delicate furrows of the skin, but the ridges only are inked, and these leave their impression when the inked thumb is pressed on paper. In this way a permanent mark is registered. A little turpentine cleans the fingers effectually afterwards. But for purposes of identification a simpler process is necessary, one by which a person suspected of personation could furnish an imprint for comparison with the registered mark without having recourse to the troublesome paraphernalia of the printer. Such a process is afforded by slightly smoking a piece of smooth metal or glass over the candle, pressing the finger on it, and then making the imprint on a bit of gummed paper that is slightly damped. The impression is a particularly good one, and is sufficiently durable for the purpose. The iron used for the ironing of clothes is excellent for the purpose; even a smooth penny can be used. As for the gummed paper, luggage labels can be used; even the fringe to sheets of postage stamps is broad enough to include as much of the impression as is especially wanted—namely, where the whorl of ridges takes its origin.

[1] Address delivered at the anniversary meeting of the Anthropological Institute, on Tuesday, January 22, by Mr. Francis Galton, F.R.S., President.

I hope at some future time to recur to this subject.

Correlation.—The measurements made at the laboratory have already afforded data for determining the general form of the relation that connects the measures of the different bodily parts of the same person. We know in a general way that a long arm or a long foot implies on the whole a tall stature—*ex pede Herculem;* and conversely that a tall stature implies a long foot. But the question was as to whether that reciprocal relation, or correlation as it is commonly called, admitted of being precisely expressed. Correlation is a very wide subject indeed. It exists wherever the variations of two objects are in part due to common causes; but on this occasion I must only speak of such correlations as have an anthropological interest. The particular problem I first had in view was to ascertain the practical limitations of the ingenious method of anthropometric identification due to M. A. Bertillon, and now in habitual use in the criminal administration of France. As the lengths of the various limbs in the same person are to some degree related together, it was of interest to ascertain the extent to which they still admit of being treated as independent. The first results of the inquiry, which is not yet completed, have been to myself a grateful surprise. Not only did it turn out that the expression and the measure of correlation between any two variables are exceedingly simple and definite, but it became evident almost from the first that I had unconsciously explored the very same ground before. No sooner had I begun to tabulate the data than I saw that they ran in just the same form as those that referred to family likeness in stature, and which were submitted to you two years ago. A very little reflection made it clear that family likeness was nothing more than a particular case of the wide subject of correlation, and that the whole of the reasoning already bestowed upon the special case of family likeness was equally applicable to correlation in its most general aspect.

It may be recollected that family likeness in any given degree of kinship—say that between father and son—was expressed by the fact that any peculiarity in the father appears in the son, reduced on the average to just one-third of its amount. Conversely, however paradoxical it might at first sight appear, any peculiarity in a son appears in the father, also reduced on the average to one-third of its amount. The regression, as I called it, from the stature of the known father to the average son, or from the known son to the average father, was here from 1 to $\frac{1}{3}$; from the known brother to the unknown brother it was $\frac{2}{3}$; from uncle to nephew, or from nephew to uncle, it was $\frac{2}{9}$; and in kinship so distant as to have insensible influence, it was from 1 to 0. Whether the peculiarity was large or small, these ratios remained unaltered. The reason of all this was thoroughly explained, and need not be repeated here. Now the relation of head-length to head-breadth, whose variations are on much the same scale, is of the same kind as the above. They are akin to each other in the same sense as kinsmen are. So it would be in the closer relation between the lengths of the corresponding limbs, left arm to right arm, left leg to right leg. The regression would be strictly reciprocal in these cases. When, however, we compare limbs whose variations are on different scales, these differences of scale have to be allowed for before the regression can assume a reciprocal form. The plan of making the requisite allowance is perfectly

simple, but I cannot explain it without using technical terms. In some cases this allowance is large; thus the length of the middle finger varies at so very different a rate from that of the stature that 1 inch of difference of middle-finger length is associated on the average with 8·4 inches of stature. On the other hand, 10 inches of stature is associated on the average with 0·6 inch of middle-finger length. There is no reciprocity in these numerals; yet, for all that, when the scale of their respective variabilities is taken into account as above mentioned, the values at once become strictly reciprocal. I shall be able to explain this better later on.

In every pair of correlated variables the conditions that were shown to characterize kinship will necessarily be present—namely, that variation in one of the pair is on the average associated with a proportionate variation in the other, the proportion being the same whatever may be the amount of the variation. Again, when allowance is made for their respective scales of variability, the proportion is strictly reciprocal, and it is always from 1 to something less than 1. In other words, there is always regression.

Variety.—The principal topic of my further remarks will be the claims of variety to more consideration from anthropologists than it has hitherto received. They commonly devote their inquiries to the mean values of different groups, while the variety of the individuals who constitute those groups is too often passed over with contented neglect. It seems to me a great loss of opportunity when, after observations have been laboriously collected, and been subsequently discussed in order to obtain mean values from them, the very little extra trouble is not taken that would determine other values whereby to express the var ety of the individuals in those groups. Much experience some years back, and much new experience during the past year, has proved to me the ease with which variety may be adequately expressed, and the high importance of taking it into account. There are numerous problems of especial interest to anthropologists that deal solely with variety.

There can be little doubt that most persons fail to have an adequate conception of the orderliness of variability, and think it useless to pay scientific attention to variety, as being, in their view, a subject wholly beyond the powers of definition. They forget that what is confessedly undefined in the individual may be definite in the group, and that uncertainty as regards the one is in no way incompatible with statistical assurance as regards the other. Almost everybody is familiar nowadays with the constancy of the average in different samples of the same large group, but they do not often realize the way in which the same statistical constancy permeates the whole of the group. The Mean or the Average is practically nothing more than the middlemost value in a marshaled series. A constancy analogous to that of the Mean characterizes the values that occupy any other fractional position that we please to name, such as the 10th per cent., or the 20th per cent.; it is not peculiar to the 50th per cent., or middlemost.

Greater interest is usually attached to individuals who occupy positions towards either of the ends of a marshaled series, than to those who stand about its middle. For example, an average man is morally and intellectually a very uninteresting being. The class to which he belongs is bulky, and no doubt serves to keep the course of social life in action. It also affords, by its inertia, a regulator that, like the fly-wheel to the steam-engine, resists sudden and irregular changes. But the average man is of no direct help towards evolution, which appears to our dim vision to be the primary purpose, so to speak, of all living existence. Evolution is an unresting progression; the nature of the average individual is essentially unprogressive. His children tend to resemble him exactly, whereas the children of exceptional persons tend to regress towards mediocrity. Consider the interest attached to variation in the moral and intellectual nature of man, and the value of variability in those respects. For example, in the Hebrew race, whose average worth shows little that is worthy of note, but which is mainly of interest on account of its variety. Its variability in ancient and modern times seems to have been extraordinarily great. It has been able to supply men, time after time, who have towered high above their fellows, and left enduring marks on the history of the world.

Some thoroughgoing democrats may look with complacency on a mob of mediocrities, but to most other persons they are the reverse of attractive. The absence of heroic gifts is a heavy set-off against the freedom from a corresponding number of very degraded forms. The general standard of thought and morals in a mob of mediocrities must be mediocre, and, what is worse, contentedly so. The lack of living men to afford lofty examples, and to educate the virtue of reverence, would leave an irremediable blank. All men would find themselves at nearly the same dead average level, each as meanly endowed as his neighbour.

These remarks apply with obvious modifications to variety in the physical faculties. Peculiar gifts, moreover, afford an especial justification for division of labour, each man doing that which he can do best.

The method I have myself usually adopted for expressing and dealing with the variety of the individuals in a group, has been already explained on more than one occasion. I should not have again alluded to it had I not had much occasion of late to test and develop it, also to devise an unpretentious little table of figures, that I call a "table of normal distribution," which has been of singular assistance to myself. I trust it may be equally useful to other anthropologists. It is appended to these remarks, and I should like after a short necessary preface to say something about it. The table and its origin, and several uses to which it has been applied, will be found in a book by myself, that will be published in a few days, called "Natural Inheritance" (Macmillan and Co.). All the data to which I shall refer will be found in that book also, except such as concern correlation. These accompanied a memoir read by me only a month ago before the Royal Society, and will be published in due course in their Proceedings.[1]

It has already been said that the first step in the problem of expressing variety among the individual members of any sample, is to marshal their measures in order, into a class. We begin with the smallest measure and end with the greatest. The object of the next step is to free ourselves from the embarrasment due to the different numbers of individuals in different classes. This is effected by dividing the class, whatever its size may be, into 100 equal portions, calling the lines that divide the portions by the name of grades. The first of these portions will therefore lie between grades 0° and 1°, and the hundredth and last portion between grades 99° and 100°. We have next to find by interpolation the values that correspond to as many of these grades as we care to deal with. It is of no consequence whether or no the number in the class is evenly divisible by 100, because we can interpolate and get the values we want, all the same. This having been done, the value that corresponds with the 50th grade will be the middlemost. It is practically the same for ordinary purposes as the mean value or the average value; but as it may not be strictly the same, it is right to call it by a distinctive name, and none simpler or more convenient occurs than the letter M. So I will henceforth use M to denote the middlemost or median value, or, in other words, that which corresponds to the 50th (centesimal) grade.

The difference between the extreme ends of a marshaled

[1] For abstract, see NATURE, January 3. p. 238. For tables of percentiles, see vol. xxxi. p. 223. For hereditary stature, see vol. xxxiii. p. 295.

series is no proper measure of the variety of the men who compose it. However few in number the objects in the series may be, it is always possible that a giant or a dwarf, so to speak, may be among them. The presence of either would mislead as to the range of variety likely to be found in another sample taken from the same group. The values in a marshaled series run with regularity only about its broad and middle part; they never do so in the parts near to either of its extremities. In a series that consists of a few hundreds of individuals, the regularity usually begins at about grade 5°, and continues up to about grade 95°. Therefore it is out of this middle part, between 5° and 95°, or better, in a still more central portion of it, that points should be adopted between which variety may be measured. Such points are conveniently found at the 25th and the 75th grades. Just as the grade 50° divides the class into two equal parts, so the grades 25° and 75° subdivide it into quarters, and the difference between those values affords an irreproachable basis for the unit of variety. The actual unit is half the value of that difference, because the value at 25° tends to be just as much below that at 50°, as the value at 75° is above it. Therefore the average of these two values is a better measure than their sum. Briefly, if we distinguish the measure at 25° by the letter Q_1, and that at 75° by Q_3, then the unit of variety is $\frac{1}{2}(Q_3 - Q_1)$, and this unit we will henceforth call Q. As M measures the average, so Q measures the variety, and they are independent of one another. In strength, for example, the relation of Q to M in the particular group of adult males on which I worked was as 1 to 10; in the statures of the same group it was as 1 to 40; in breathing capacity as 1 to 9; in weight as 1 to 14.

The arithmetic mean or average is a muddle of all the values in the series; it is by no means so clear an idea as the middlemost value M. Therefore, although the peculiarities of an individual are commonly considered in the light of deviations from the average value, I prefer to reckon them as deviations from M. Practically the two methods are identical, but I find the latter more convenient to work with, and believe it to be the better of the two in every way.

Deviation is identical with variation, and the well-known law of frequency of error gives data whence the *relative* values of the deviations at the several grades may be calculated for any normal series. If we know the deviation at any one grade, then the *absolute* value of those at every other grade can be calculated; consequently the variety of the whole series is thereby expressed.

The small table of distribution, of which I spoke, gives the values at each grade when Q is equal to 1. Then the value at 25° is − 1, and that at 75° is + 1. If we desire to determine Q in any such series, the only required datum is the deviation at some one known grade, since, by dividing that deviation by the tabular value, we get Q at once. Or, conversely, if we know the Q of the series, and wish to calculate the deviation at any given grade, we multiply Q by the tabular deviation. Thus, in stature, which varies in an approximately normal manner, the value of Q is about 1·7 inch, therefore to find the deviation in stature at any grade, we multiply 1·7 inch by the tabular value.

If we know the *measures* at any two grades of a normal series, we are easily able to calculate both Q and M, and can thence derive the measures at any other desired grades. I have long since pointed out the possibility of a traveller availing himself of this method; but, for the want of a table of distribution, the calculation would probably puzzle him. With the aid of this table the calculation is made most readily. Let us suppose that the traveller is among savages who use the bow, and that he desires to learn as much as he can about their strengths. He selects two bows; the one somewhat easy to draw, and the other somewhat difficult, and at leisure, either before or after the experiment, he ascertains exactly how many pounds weight they severally require to draw them to the full. Then by exciting emulation, and by offering small prizes, he induces a great many of the natives to try their strengths upon them. He notes how many make the attempt, and how many of them fail in either test. This is all the observation requisite, though common-sense would suggest the use of three and not two bows, in order that the data from the third bow might correct or confirm the results derived from the other two. Let us work out a case, not an imaginary one, but derived from tables I have already published, and of which I will speak directly. Let the problem be as follows:—

30 per cent. of the men failed to exert a pulling strength of 68 pounds; 60 per cent. failed to pull 77 pounds. What is the Q and the M of the group?

Consider this 30 per cent. to be the exact equivalent of grade 30°, and the 60 per cent. of grade 60°. The reason why the percentage of failure, and the number of the grade are always equivalent will be found in a footnote to the table, and I need not stop to speak of it. Now, the tabular value at grade 30° is − 0·78; that at 60° is + 0·38; the difference between them being 1·16. On the other hand, the difference between the two test values of 68 pounds and 77 pounds is 9 pounds. Therefore Q is equal to 9 pounds divided by 1·16; that is, to 7·8 pounds. M may be obtained by either of two ways, which will always give the same answer. We may subract 0·38 × 7·8 pounds from 77 pounds, or we may add 0·78 × 7·8 pounds to 68 pounds. Each gives 74 pounds. Observation gave precisely these values both for Q and for M. The data were published in the Journal of this Institute as a table of "percentiles," and were derived from measures made at the International Health Exhibition. The value of M is given directly in the table, but that of Q happens not to be given there; it may easily be found by interpolation. That table affords excellent material for experimental calculations on the principle of this test, and for estimating its trustworthiness in practice.

It contains a variety of measures referring to eighteen different series, all corresponding to the same grades—namely, to 5°, 10°, 20°, and onwards for every tenth grade up to 90° and ending with 95°. The measures refer to stature, height sitting above seat of chair, span, weight, breathing capacity, strength of pull, strength of squeeze, swiftness of blow, keenness of eyesight, in each case of adult males and of adult females separately. I have since found that when the deviations are all reduced in terms of their respective Q values, by dividing each of them by its Q, that the average value of all the deviations at each of the grades in the eighteen series closely corresponds to the normal series, though individually they differ more or less from it, some in one way, some in another. On the whole, the error of treating an unknown series as if it were a normal one can rarely be very large, always supposing that we do not meddle with grades lower than 5° or higher than 95°.

It will be of interest to put the comparison on record. It is as follows:—

Grades	5°	10°	20°	30°	40°	50°
Observed	− 2·44	− 1·87	− 1·24	− 0·77	− 0·40	0
Normal − below 50° + above 50° ...	2·44	1·90	1·25	0·78	0·38	
Observed	+ 2·47	+ 1·92	+ 1·21	+ 0·75	+ 0·38	0
Grades	95°	90°	80°	70°	60°	50°

The "observed" are the mean values, made as above described, of the eighteen series; the "normal" are taken from the table of distribution given further on.

An ingenious traveller might obtain a great number of approximate and interesting data by the method just described, measuring various faculties of the natives, such as their delicacy of eyesight and hearing, their swiftness in running, their accuracy of aim with spear, arrow, boomerang, sling, gun, and so forth, either laterally or else vertically, distance of throw, stature, and much else. But he should certainly use three test objects, and not two only.

It should be remarked that, if the distribution of deviation was constant throughout any large class of faculties, though the Q might differ in different sub-classes of it, then, even though the distribution of that faculty was very far indeed from being normal, an appropriate table of distribution could be drawn up to solve such problems as those mentioned above. I have as yet no accurate data to put this idea to a practical test.

There are three convenient stages of expressing the variety of the various measures in a series, each reaching considerably nearer to precision than the one before. The first is to give only Q and M; the second is to record the measures at the grades 10°, 25°, 50°, 75°, and 90°; the third is the more minute method, adopted in the table of percentiles—viz. to give the measures at 5°, 10°, 20°, &c., 80°, 90°, and 95°. It may in some cases be found worth while to go further, say to 1° and 99°, or even also to 0° and 99°·9. So much for the expression of variety.

The use of Q is by no means limited to the objects just named. It is a necessary datum wherever the law of frequency of error has to be applied, and the properties of this law are applicable to a very large number of anthropological problems, with more accuracy of result than might have been anticipated when the series are only approximatively normal. This has been practically shown by the agreement among themselves of several inquiries to which I will shortly allude, and it is theoretically defensible by two considerations. The one is that the law of frequency supposes the amount of error or of deviation to be the same in symmetrically disposed grades on either side of 50°, their signs being alone different, *minus* on the one side of 50° and *plus* on the other. Now, in an observed series there may be, and often is, a want of symmetry, but if the deviate, say at 70°, is as much greater than the normal as the deviate at 30° is less than the normal, then the effects of these two upon the final result will be much the same as if there had been exact symmetry at those points. The other consideration is that any nonconformity of the observed deviates with the theoretical ones towards the end of the series has but a small and perhaps insensible effect on the broad general conclusions We need care little for any vagaries outside of the grades 5° and 95°, if the intervening portion gives fairly good results. The latter portion forms nine-tenths of the whole series, and even considerable irregularities in the remaining tenth are of small relative importance.

One great use of Q is to enable us to estimate the trustworthiness of our average results. We require to know both Q and the number of observations before we can estimate the degree of dependence to be placed on M. If there was only one observation, then the degree of dependence would be equal to Q; in other words, the error of M would be just as likely as not to exceed Q. If there were two, two hundred, two thousand, or any other number of observations, the error of M would then be reduced, but not in simple proportion. It would be as likely as not to exceed a value equal to Q divided by the square roots of those numbers. When we desire to ascertain the trustworthiness of the difference between the M values of two series, as between the mean statures of the professional and artisan class as derived from certain observations, the properties of the law of frequency of error must again be appealed to. Anthropologists are much engaged in studying such differences as these; but from their disregard of the simple datum Q, and from not being familiar with its employment, there is usually a lamentable and quite unnecessary vagueness in the value to be attached to their results. This is especially the case in comparisons between the average dimensions of the skulls of various races, which often depend upon the measurement of only a few specimens. An almost solitary exception to this needless laxity will be found in a brief but admirably-expressed memoir by Dr. Venn, the well-known author of the "Logic of Chance." It is upon Cambridge anthropometry, and was published in the last number of the Journal of this Institute. It deserves to be a model to those who are engaged in similar inquiries.

Another class of investigations in which a knowledge of Q is essential was spoken of some time back—namely, questions of correlation in the widest sense of the word. These problems have nothing to do with the relations of the M value, but are solely concerned with those of the deviations from M at the various grades. It is true that a knowledge of M is requisite in order to subtract it from the measures, and so to get at the deviations. But after this is done, M is put aside. It has no part in the work of the problem; it is only after the results have been arrived at without its use that it is again brought forward and added to them. Numerous properties of the law of frequency of error in which Q is the datum were utilized in my inquiries into family likeness in stature, and in all cases they brought out consistent results. An excellent example of this was seen in the success of the methods employed to determine the variety in families of brothers. Four different properties of the law had to be applied to partly different samples of the same group in order to determine the value of the Q of stature in fraternities, and they respectively gave 1·07, 0·98, 1·10, and 1·10 inch, which, statistically speaking, are much alike. Certain properties of the law of frequency of error were also applied to family likeness in eye colour, with results that gave by calculation the total number of light-eyed children in families differently grouped according to their parentage and grandparentage, and according to three different sets of data, as 623, 601, and 614 respectively, the observed number being 629. Other properties of the same law have been applied to determine the ratio of artistic to non-artistic children in families whose parentages were known to be either both artistic, one artistic, one not, or neither artistic. They gave to 1507 children the ratios of 64, 39, and 21, respectively, as against the observed values of 60, 39, and 17.

Lastly, as regards the correlation of lengths of the different limbs. It has already been shown that the correlation lies between the deviations, and has nothing to do with the values of M. Now, to express this relation truly, so that it shall be reciprocal, the scale of deviation of the correlated limbs, say, for example, of the cubit and of the stature, must be reduced to a common standard. We therefore reduce them severally to scales in each of which their own Q is the unit. The Q of the cubit is 0·56 inch, therefore we divide each of its deviations by 0·56. The Q of the stature is 1·75 inch, so we divide each of its deviations by 1·75. When this is done the correlation is perfect. The value of regression is found to be 0·8, whether the cubit be taken as the "subject" and the mean of the corresponding statures as the "relative," or *vice versâ*.

The value of the regression has been ascertained for each of many pairs of the following elements, and a comparison was made in each case between the correlated values as observed and those calculated from the ratio of regression. The coincidence was close throughout, quite as much so as the small number of cases under examination, 350 in all, could lead us to hope. The elements were nine in all, viz. head-length, breadth of head, length of right leg below the knee, of left cubit, of left middle finger, of the height sitting above the chair, of

stature, of the differences between the two foregoing (which indicate the total length of the lower limbs), and of the span. Anthropologists seem to have little idea of the wide fields of inquiry open to them as soon as they are prepared to deal with individual variety and cease to narrow their view to the consideration of the average.

Enough has now been said to justify the claims with which I started, and which take this final form. First, wherever it is likely to be of use, that, in series of which the M is calculated, the measures at a certain number of selected grades should also be calculated and given, sufficient to enable the rest of the series to be found with adequate accuracy by interpolation. Secondly, that the value of Q should always be given, as well as that for M, for two reasons. The one is, that they suffice between them to give an approximate determination of the whole series, more closely approximate as the series is more closely of the normal type; and, secondly, because Q is an essential datum before any application can be made of the law of frequency of error. The properties of this law are, as we have seen, largely available in anthropological inquiry. They enable us to define the trustworthiness of our results, and to deal with such interesting problems as those of correlation and family resemblance, which cannot be solved without its help.

Table of ordinates to normal curve of distribution, in which the unit = the probable error, and the grades, which are the abscissæ, run from 0° *to* 100°.

Grades.	0	1	2	3	4	5	6	7	8	9
0	∞	−3·45	−3·05	−2·79	−2·60	−2·44	−2·31	−2·19	−2·08	−1·99
10	−1·90	−1·82	−1·74	−1·67	−1·60	−1·54	−1·47	−1·42	−1·36	−1·30
20	−1·25	−1·20	−1·15	−1·10	−1·05	−1·00	−0·95	−0·91	−0·86	−0·82
30	−0·78	−0·74	−0·69	−0·65	−0·61	−0·57	−0·53	−0·49	−0·45	−0·41
40	−0·38	−0·34	−0·30	−0·26	−0·22	−0·19	−0·15	−0·11	−0·07	−0·04
50	0·00	+0·04	+0·07	+0·11	+0·15	+0·19	+0·22	+0·26	+0·30	+0·34
60	+0·38	+0·41	+0·45	+0·49	+0·53	+0·57	+0·61	+0·65	+0·69	+0·74
70	+0·78	+0·82	+0·86	+0·91	+0·95	+1·00	+1·05	+1·10	+1·15	+1·20
80	+1·25	+1·30	+1·36	+1·42	+1·47	+1·54	+1·60	+1·67	+1·74	+1·82
90	+1·99	+1·99	+2·08	+2·19	+2·31	+2·44	+2·60	+2·79	+3·05	+3·45

This table is an inverse rendering of the values derived by interpolation from the ordinary table of the probability integral, but its unit is changed from that of the modulus to that of the probable error, Q. and the (centesimal) grades are reckoned from 0° to 100°. In the usual way of reckoning, the 50th grade should have been reckoned as 0°, and the deviations should have run on the one side down to − 50°, and on the other up to + 50°.

Referring to what was said some way back, that if 30 per cent. fail to pull 60 pounds, then 60 pounds must be taken as the measure corresponding to grade 30°, the reason is as follows. The 30th grade separates the man who ranks 30th in a class of 100 men from his neighbour who ranks 31st. It does so for the same reason that grade 1° separates the man who ranks 1st from the man who ranks 2nd. Now, the 30th man failed in the test, and the 31st succeeded. Therefore the grade corresponding to bare success lies between them, and is the same as grade 30°.

SUPPOSED FOSSILS FROM THE SOUTHERN HIGHLANDS.

ON Monday, the 14th instant, the Royal Society of Edinburgh held a special meeting for the purpose of hearing a discussion on the crystalline rocks of the Scottish Highlands. The subject was brought forward by the Duke of Argyll, who had found in the quartzite beds which cross Loch Fyne near Inveraray certain markings which he believed to be of organic origin. His attention was first called to some ferruginous stalk-like incrustations on the surfaces of fragments of quartzite, his impression being that these markings were the remains of plants, and were embedded in the rock. The importance of the discovery of organic remains in any of the rocks that form the Central and Southern Highlands of Scotland will at once be recognized by geologists. Since the recent work of the Geological Survey in Sutherland and Ross, and the demonstration thereby afforded that the apparent upward succession on which Murchison relied, from the base of the lowest quartzite up into the upper or eastern or younger gneisses, is deceptive, there has been, perhaps, a tendency to assume that the extraordinarily complicated structure that supervenes to the east of the quartzites and limestones of Sutherland extends across the whole of the rest of the Highlands, and that the crystalline schists of these regions are made up of all kinds of crushed and sheared igneous or sedimentary masses, out of which it may be impossible to make anything like intelligible order. But those observers who have themselves examined the schists of the central and southern counties of the Highlands are tolerably confident that such assumptions have no warrant in the actual structure of the ground. On the contrary, they regard the greater proportion of the schistose and altered rocks of these districts as unquestionably of sedimentary origin. They feel persuaded that sooner or later they will be found to yield fossils, and that any day may bring to light a series of corals, shells, graptolites, or trilobites, which will furnish a palæontological basis for settling the geological age of the rocks, and placing them in their true position with regard to the Palæozoic formations of the rest of the country.

The announcement that the Duke of Argyll had found what seemed to be organic remains in the Inveraray quartzites awakened accordingly much interest among geologists. His Grace soon discovered, however, that what he had at first believed to be fossils were only external markings due to the precipitation of hydrous peroxide of iron round the decaying stems of mosses, heaths, or other plants. These markings occurred indifferently on pieces of quartzite, mica-schist, gneiss, &c., and in no instance were found within the stone, but always on the surface. But in turning over the exposed blocks of quartzite the Duke found numerous ferruginous markings which undoubtedly occurred all through the interior of the rock. After quarrying away portions of the solid rock, collecting a large series of specimens, and comparing them with others obtained from the quartzite of Sutherland, he deemed himself in a position to announce the probably organic nature of these markings; and the paper which he communicated last week to the Royal Society of Edinburgh gave the results of his inquiries. The bodies which he regards as fossils are compared by him to the "annelid burrows" which form so prominent a feature in the quartzites of Sutherland and Ross. He recognizes in the Inveraray rock similar ovate sections, the position and form of each tube being marked by a ferruginous ring, which is well defined along its inner margin, but fades outward into a general discoloration of the stone. He points out that in the Inveraray rock, as in that of the North-West Highlands, there is a general tendency of these ovate bodies to lie in one prevalent direction; and though he admits that the rocks have been considerably disturbed and crushed, he cannot trace among them any evidence of such stupendous movements as have been described from Sutherland. Accordingly he is disposed to look upon the parallelism of the stripes into which he thinks the original tubes have been flattened as evidence of the direction in which the worms burrowed through the still soft sand.

Perhaps the most original and valuable part of the Duke's paper was the account which he gave of his own experiments on the habits of the common lob-worms of our present shores. He had watched the operations of these creatures on the beach of dark silt at Inveraray; had cut out portions of the silt with the burrows and mounds intact, and had these removed to his own drawing-room to enable him to watch them more attentively. He had likewise injected plaster of Paris into the vertical or winding passages made by the worms in the silt, and had thereby obtained casts of the interior of these tunnels. He exhibited a very interesting and valuable collection of specimens illustrating these researches.

Mr. Geikie, the Director-General of the Geological

Survey, opened the discussion, and regretted that, though he had enjoyed the advantage of seeing the large collection of specimens made by the Duke of Argyll from the Inveraray quartzite, and also of examining the rock *in situ*, he was still unconvinced that the markings were really of organic origin. It was possible, he thought, to trace a series of stages from single crystals or irregular groups of crystals of pyrites through variously shaped aggregates into the "ovate bodies" of the Duke. In the more solid, massive, and uncrushed portions of the quartzite, these aggregates could be seen quite fresh, and probably not far from their original shape. But wherever the rock had undergone shearing (and this was the case throughout most of its mass), its component particles had been drawn out in the direction of movement, the original irregular, rounded or egg-shaped aggregates of sulphide of iron had been flattened and elongated, becoming eventually mere strips that run parallel to each other. The trend of these strips exactly coincided with that of the long axes of the foliation-minerals in the surrounding rocks, and were regarded by Mr. Geikie as pointing to the results of shearing in the rock-mass and not to the burrowings of worms. The ferruginous rings seemed to him to be due to an oxidation and leaching out of the pyritous matter of the little mineral aggregates, as so often happens among the Carboniferous and Jurassic sandstones that contain ferruginous concretions. While he could not admit that the markings in the quartzite of Inveraray had yet been shown to be of organic origin, he thought it quite possible that the precipitation of the iron-disulphide had originally taken place in presence of decomposing organic matter, as in many blue muds of the present day, and that portions of such pyritous mud had been drifted into the sandy deposit which is now quartzite.

Mr. B. N. Peach, of the Geological Survey, was also unable to recognize organic forms among the Inveraray markings. He thought that the parallelism of these markings where they were most elongated, and their coincidence with the general line of shearing movement in the rock, cast doubt upon their having any connection with worm-burrows.

Mr. Murray, of the *Challenger* Expedition, who thinks that sandstone deposits generally are sub-aërial formations, was disposed to refer the so-called annelid tubes of the Sutherland quartzite not to the borings of marine worms, but to the remains of terrestrial plants that grew upon sand-dunes.

In a paper which followed this discussion, Mr. Geikie gave an account of the evidence supplied by the rocks of the Highlands of remarkable deformation by mechanical movements. Illustrating his remarks by a large series of specimens, he showed how the Cambrian conglomerate of Assynt had its pebbles of quartz drawn out and its original sandy mud converted into a fine micaceous schist; how the conglomerates of the Central Highlands had their quartz-pebbles flattened like buttons and drawn out in the direction of movement, while their envelope of original sand and mud had been changed into a quartz-schist; how the granular quartzite of Sutherland had been crushed and rolled out into a thoroughly schistose mass; how the coarse Archæan pegmatites had been likewise crushed down until their material had, as it were, flowed onwards so as now to show a close parallel to the "fluxion-structure" of many porphyries, and even to assume a finely laminated or shaly structure, and lastly, how the highly crystalline basic dykes of the most ancient gneiss of the north-west had been sheared and rearranged until they passed into the most perfect forms of sericite-schist. He adverted to the obviously sedimentary origin of the great mass of the rocks constituting the Highlands east of the line of the Great Glen, and mentioned that the recent work of the Geological Survey in tracing the great belt of limestones from the coast of Banffshire through the Grampians into Argyllshire afforded now a good horizon, from which it might be hoped the general structure of the Highlands might be worked out. He exhibited specimens of quartzite from Perthshire and other districts containing various markings, some of which there could be little doubt were of organic origin. He also showed a singularly interesting series of specimens which he had recently received from Dr. Reusch, of the Geological Survey of Norway, displaying recognizable trilobites and corals embedded in a finely crumpled micaceous schist, exactly similar in character to much of the schist that constitutes wide regions in the Scottish Highlands. These specimens afforded much encouragement to search for fossils in the calcareous and ferruginous layers and concretions that occur so frequently among our finer mica-schists and phyllites.

THE LAW OF STORMS IN CHINA.

THE law of storms in Hong Kong was investigated by aid of the lithographed paths of the typhoons in 1884 and 1885, published in "Observations and Researches made in 1886" and in those of 1886 and 1887 now in course of publication. Only those within 300 miles of the Observatory were considered in this connection. The angles between the wind and the radius vector, *i.e.* the line joining the Observatory with the centre of the typhoon, were measured and mean values derived, and the same was done for Victoria Peak (1816 feet above the sea) and for the lower clouds.

No connection could in any case be traced between the distance from the centre and the direction of the wind, but the latter depends upon the bearing of the centre. As pointed out in "The Law of Storms in the Eastern Seas" (NATURE, vol. xxxv. p. 136), and elsewhere, the wind has a tendency to blow along the southern coast of China when a typhoon is raging in the China Sea, so that the wind in such cases veers only about half as much while the typhoon moves westward as in other cases, and this is the reason why the angle between the wind and the radius vector is larger than usual when the centre is situated to the south of Hong Kong.

When there is a typhoon anywhere between north and east within 300 miles of the colony—which, however, is not common—the wind at the Peak (about north-north-west) blows away from the centre—much more so than the clouds, which in fact describe almost a circle round the centre in that case; and this remarkable feature or something very like it has been found to obtain also at Ben Nevis with the centre of a depression in the north-east.

The angle between the wind and the radius vector is, at the Observatory, 81° north of the centre, 55° to the west, 56° to the south, and 58° to the east. At the Peak, it is 91° to the north, 87° to the west, 81° to the south, and 78° to the east. At the level of the lower clouds, it is 92° to the north, 85° to the west, 67° to the south, and 86° to the east.

The observations made at South Cape (Formosa) were treated similarly, with the following result: to the north of the centre the angle was 50°, to the west 56°, to the south 64°, and to the east 47°.

The angle observed on board ship in the China Sea in typhoons—say in about 16° N. lat.—is on an average 47°, as previously published; at South Cape (22° N. lat., the same as Hong Kong) 54°; at Hong Kong 62°; at Victoria Peak, above Hong Kong, 84°; and at the level of the lower clouds 82°. The angle previously obtained from observations made on board ship, and also at coast stations in about 32° N. lat., was 75° on an average, but so far north it seems to be more variable than in the China Sea, where it has been found remarkably constant, between (say) 12° N. and 20° N. But from the figures given it is seen that the angle increases with the latitude and with elevation above sea-level. The woodcut represents a typhoon in the neighbourhood of Hong Kong, or rather

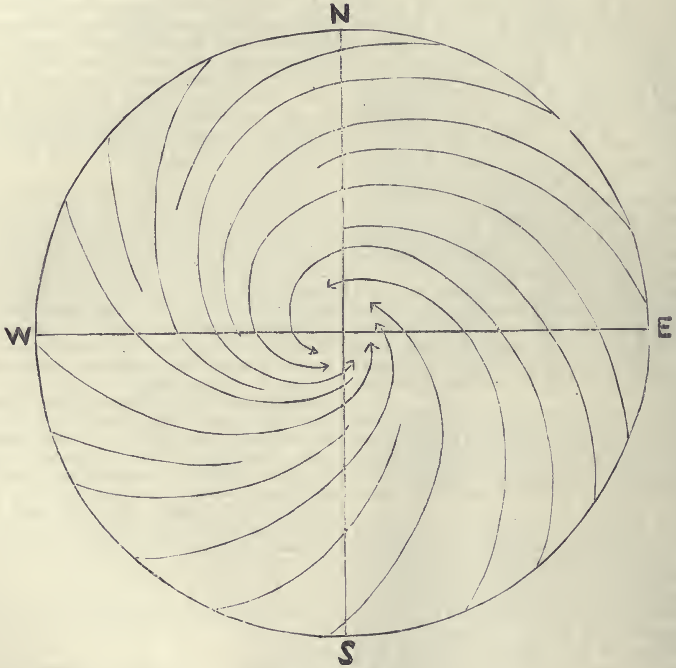
a mean of those observed during the four years. The diameter of the circle is 600 miles.

The average force of the wind according to Beaufort's scale (0–12), at various distances from the centre, expressed in nautical miles, is shown in the following table, but owing to the typhoons differing so much in size the figures representing the mean values are often widely different from the values obtained from observations made in a particular typhoon. That is not the case with the direction of the wind, which depends upon the bearing but not upon the distance from the centre or the size of a typhoon.

Distance.	Observatory.	Peak.	South Cape.	China Sea.
60	8	9	9	11
160	5	6	6	—
250	4	5	4	6

This table proves the wind to be strongest over the open sea, and also, though to a less extent, at some height above sea-level. The force of the wind increases at a greater rate on approaching the centre at sea, and that is to a certain extent likewise the case at South Cape, which is far from the mainland and soon reached by typhoons arriving fresh from the Pacific Ocean, where most typhoons originate, although some of them are formed to the westward of the Southern Philippines.

The force of the wind is much greater behind the centre than in the anterior semicircle both at sea and on shore, and the consequence is that the strongest blow is not experienced till the barometer begins to rise. For instance, at an average distance of about 160 miles, the mean force in Hong Kong is 7 to the north, 3 to the west, 6 to the south, and 5 to the east. At South Cape (Formosa) it is 6 to the north, 5 to the west, 7 to the south, and 6 to the east. To the north of a typhoon the wind is remarkably fresh along the southern coast of China, even when the centre is over 300 miles away. It makes an impression as if the trade-wind was blowing in the middle of summer, while a typhoon moves westward in the China Sea. In Southern Formosa, where typhoons moving north-westward predominate both in number and in intensity, the wind is strongest to the south or southeast of the centre.



A Typhoon in Hong Kong.

At Victoria Peak the force of the wind does not depend upon the bearing of the centre, or at any rate only slightly so. It follows that the wind-force registered there just before the approach of a typhoon considerably exceeds that registered at the Observatory. The difference in force is only about one on Beaufort's scale, when the centre is north or west of the colony, and while the centre is situated to the southward it usually blows harder at sea-level than on top of the Peak. W. DOBERCK.

THE STATE OF VESUVIUS.

THE "Note" in NATURE (p. 184) on the state of the Vesuvian volcano has been copied by many newspapers, and I have received a number of letters asking for further information. To satisfy this desire, I give the following particulars as to what occurred subsequent to December 15, 1888, and to the information above mentioned.

During the remainder of the month of December, the vent was extremely active, ranging from the second to the fourth degree of activity, so that the cone of eruption was often quite red, after a burst, from the large number of lava cakes falling on its sides. This constant ejection of fragments of red-hot pasty lava rapidly increased the

height and size of the eruptive cone, making its slope exceedingly steep. So rapid was its growth, that the most casual observers noticed it from Naples, and discussed it. In fact, from November 1 to January 6 at least 20 metres was added to the height of Vesuvius, whilst the size of the base of the cone of eruption was proportionally increased.

On January 1, 1889, the eruptive cone burst on the north side, allowing the lava to issue and flow down, turning east and west so as to fill up, in part, the crescentic depression between the annulus or crater ring of July and August 1886, and the cone of eruption which is situated eccentrically to the former. As I have shown elsewhere, outflows of lava from the cone of eruption are always very limited, the violence of the outburst being generally proportional to the distance of the lateral opening below the summit.

After this relief the activity fell to the first degree, but soon again rose to the third. On Sunday, the 6th, I was standing at the summit of the mountain on the 1872 crater plain, preparing my apparatus for a photograph of the cone of eruption, when suddenly (about 3 p.m.), at about half-way down the side of the eruptive cone, and facing me, a slight puff of dust occurred, followed by the oozing forth of some lava. This rapidly increased in quantity as it carried forward the fragments forming the sides of the aperture. I immediately changed my lens to an instantaneous one, and took two negatives. The explosive activity increased, so that I was standing in a constant hail of red-hot lava fragments. These it required constant vigilance to avoid, and my face and hands were scalded by the radiant heat from the rapidly advancing lava, and tormented by the whirlwinds that always occur under such conditions. My two porters abandoned me, so that I had just time to remove my apparatus two minutes before lava flowed over the spot where I stood. In consequence of these unfavourable conditions, I lost some of my coolness, and allowed my camera-cloth to partly hide the lens. I was therefore greatly disappointed to find only part of this splendid scene registered for the eyes of others who had not had the good fortune to see that interesting spectacle.

The point of rupture was a few degrees east of south, and nearly opposite the cleft of January 1. The opening at beginning could not have been more than 10 metres from the top of the vent, showing the great height of the lava in the volcanic chimney. The outflow was very rapid, for, half an hour after, the place where I took the photographs could not be approached by 40 or 50 metres, having been all inundated with lava. Part of the fluid rock rapidly reached the edge of the 1872 crater plain, and flowed some distance down the slope of the great cone in the direction of Torre Annunziata, and another portion flowed out by another gap a little farther east in the remaining edge of the 1872 crater ring. The supply, however, soon stopped, and late in the evening had already become consolidated. After this, the activity, as seen from Naples, slightly diminished, but the next evening it was again at the third degree. Cloud-cap somewhat interrupted the view up till last night (January 12), when it was again observed to be at the third degree, and the light emanating from the lava was very white, showing the high temperature.

So far, the great cone has resisted fracture, but the south-west fissure, to which I have already drawn attention, is more active, and from this side of the crater plain there is very great fumarolic activity. When, therefore, the hydrostatic pressure overcomes the resistance, it will probably be in this direction that a lateral outburst will take place.

H. J. JOHNSTON-LAVIS.

Naples, January 13.

VOLCANIC SEA WAVE.

THE following account from the Berlin *Annalen der Hydrographie*, 1888, p. 518, with reference to the wave observed in the regions about the north-east of New Guinea, already briefly noticed in NATURE (vol. xxxviii. p. 491), is of interest.

The data given are too vague to permit of definite conclusions as to the probabilities of the disturbances felt at Sydney and Arica having originated in a volcanic eruption in New Guinea, but it may be observed that, assuming that the volcanic centre was from 200 to 400 miles north of Hatzfeldt Harbour, in which direction sounds were heard at 6 a.m. on the 13th, followed in forty minutes by a wave, the disturbance recorded at Arica at 5 p.m. on the 14th would have travelled the intervening distance of 10,000 geographical miles at a speed of 416 miles an hour, a velocity which agrees very fairly with the probable mean depth of ocean traversed.

To Sydney, on the other hand, assuming the first disturbance to have occurred at 6 a.m. on the 15th, the speed would only have been about 60 miles an hour, which is much too low a velocity for the depth.

It will be observed that the waves both at New Guinea and Arica were of short period, and in this respect quite unlike the long-distance waves emanating from Krakatão in 1883.

W. J. L. WHARTON.

"With regard to the extraordinary tidal wave that was observed in the Bismarck Archipelago, and on the coast of New Guinea, on the 13th of March, Heft iii. of the 'Notices of Kaiser Wilhelm's Land and the Bismarck Archipelago' relates as follows:—

"After the Expedition which had been undertaken for the discovery of Herren von Below and Hunstein, who had attempted an exploration to the west coast of New Pomerania (New Britain), had returned without finding any trace of them, a second Expedition, consisting of seven officers and fourteen Miocese, under command of the surveyor, V. Brixen, was despatched on the 17th of March from Finsch Hafen to the west coast of the above-mentioned island. This discovered, on the 18th of March, the spot where Below's Expedition had landed, which was easily recognized by the objects lying there partly covered with sand—a tent, torn pieces of clothing, and bent bits of metal. A part of the Expedition then repaired to a ruined village near the place where the missing persons (according to the account of the two Miocese who had been saved) had encamped during the night of the 12th-13th of March on the shore. At this place the land falls very steeply, about 25 metres, to the sea, and there is only a narrow strip of flat coast between the declivity and the sea. The tidal wave had even occasioned a landslip, large stones and trees being torn away from the slope, so that here escape could have been scarcely possible, and, according to the two Miocese, the catastrophe happened before daybreak. With the exception of a few bamboos cut by a knife, no trace of an encampment was perceptible. An excavation, attempted on the 19th of March, led to no result. Sea-sand, stones, and things washed up by the sea, covered the former level of the shore for more than 4 feet. On the 20th of March parties were despatched into the interior in a north-easterly and southerly direction, who came upon the encampment of the natives who had escaped from the above-named village. As these confirmed, by gestures and signs, the accounts of the Miocese, hardly any doubt can remain that Below and Hunstein had fallen victims to the tidal wave. On the 21st of March a large cross, therefore, was erected at the place of the misfortune, and, to provide for necessity, two boxes with provisions and drink were buried under a

large and marked tree near the landing-place. The tidal wave on this portion of New Pomerania had rendered completely desolate a coast formerly covered with dense forest for a breadth of about 1 kilometre. Large spaces had been reduced to a swamp covered with trees heaped above one another, broken coral rocks, sea-sand, and a quantity of putrid fish. Measurements made at the declivities here give a height for the tidal wave of 12 metres (39 feet).

"As was to be expected, the tidal wave had also left its mark on other coasts of the German Protectorate, without having, however, caused any serious damage. In Hatzfeldt Hafen, on the coast of New Guinea, a noise like firing was heard on March 13, shortly after 6 a.m., from a north-north-easterly direction, and at 6.40 a.m. came an astonishingly high tidal wave from the north that rose 2 metres (6½ feet) above the highest flood-mark, and then receded with such violence that half the port was dry. The sea now rose and fell at intervals of three to four minutes, which lasted until 9 a.m.

"At 8 a.m. the height of the tidal wave stood at 7 to 8 metres (23 to 26 feet), so that the station was in imminent danger. In the course of the forenoon the movement gradually subsided, although the water still continued to rise and fall with steady intervals until 6 p.m., when it resumed its normal condition.

"In Kelana, the newly-established plantation near Cape King William, the phenomenon occurred from north-east at 6.30 a.m. The first wave forced itself 25 feet on the land the fourth, however, 35 feet; this was the greatest of the twenty waves observed, which came about every three minutes. The phenomenon was not observed here to be longer than an hour in occurring. No other circumstance of a striking nature was perceptible. The weather was calm and dull. On the morning of the 14th of March the whole coast to some distance was strewn with small pumice stones.

"From Matupi it was reported that from 8.15 until near 11 a.m. the sea receded at times from the island 12 to 15 feet below the lowest water mark, and then rose in several waves to the same height above high water mark. The phenomenon appeared chiefly on the south-east and north side of the island, the west side remaining untouched. The waves came partly from south, partly from west-north-west. The water appeared disturbed in its depths; it had a dark appearance, and carried discoloured foam. Neither earthquakes nor any subterranean rumblings were noticed. The weather was clear, with a gentle south-east breeze. On the south side of Gazelle Peninsula the phenomenon was also noticed by a ship ying at anchor.

"So far the report in the 'Notices of Kaiser Wilhelm's Land and Bismarck Archipelago.' Of the further movement of the tidal wave, nothing is as yet known, although it is not improbable that it spread further.

"In Sydney (Australia) and Arica (South America), extraordinary commotions of the sea were observed between the 14th and 17th of March, which may possibly have been in connection with this tidal wave. In Arica, as appeared in the *Mercurio* of Valparaiso of the 23rd of March, an immense wave was observed on the 14th of March towards 5 p.m., in the distance, which, increasing as it drew nearer, broke with great force near the pier. Three great waves followed quickly, one after another. Of the vessels busied in taking in cargo, several were shattered, and others capsized. The sea was for some time so agitated that the shipping of merchandize was attended with difficulty. On the island in front of the port the sea broke for a still longer period with great violence.

"According to the English journal NATURE (vol. xxxviii. p. 491), the tidal curves on the self-registering water-gauge in Sydney, showed on the 15th, 16th, and 17th of March, deviations from their customary form which may have been caused by the waves of an earthquake."

NOTES.

THE fifteenth general meeting of the Association for the Improvement of Geometrical Teaching was held on Saturday last at University College, London. After the reading of the Report of the Council, Mr. R. B. Hayward, who had been President for eleven years, resigned the presidency, and the post was conferred on Mr. G. M. Minchin, Professor of Applied Mathematics in the Royal Indian Engineering College at Cooper's Hill. In the place of Mr. Moulton, Q.C., Mr. Hayward was elected a Vice-President; while the other Vice-Presidents—the Rev. G. Richardson, Mr. R. Levett, and Mr. R. Tucker—retain their posts. In the course of his valedictory address, the retiring President remarked that, though they had not quite attained the expectations of some of their more ardent reformers, still they had met with a fair measure of success. Their influence was rather indirect than direct, and it must be expected that their advance would be, while steady, yet comparatively slow. The new President (Prof. Minchin) read a paper on "the vices of our scientific education."

IN the correspondence of Mrs. Austin, just published by her granddaughter, in the work entitled, "Three Generations of Englishwomen: Memoirs and Correspondence of Mrs. John Taylor, Mrs. Sarah Austin, and Lady Duff Gordon," there is an interesting and whimsical letter from Humboldt, dated Sans Souci, 1844. Mrs. Austin had written to him, suggesting a translation of his work, "Ansichten der Natur," into English. He jokes about the defects of his book from the translator's point of view, with its notes larger than the text, its "Teutonic sentimentality," and the impossibility of finding a title in English for it. He then proceeds:—"Alas! you have got someone in England whom you do not read, young Darwin, who went with the Expedition to the Straits of Magellan. He has succeeded far better than myself with the subject I took up. There are admirable descriptions of tropical nature in his journal, which you do not read because the author is a zoologist, which you imagine to be synonymous with 'bore.' Mr. Darwin has another merit—a very rare one in your country—he has praised me."

ON Tuesday, January 15, a new wing of the Leeds Mechanics' Institute, comprising the School of Science and Technology and Boys' Modern School, was opened by Sir James Kitson. The Leeds Mechanics' Institute was founded sixty-four years ago, and, like some other establishments of the same kind in various parts of the country, it has always recognized the need, not only from an intellectual but from an industrial point of view, of scientific education. Thanks, in part, to the wholesome influence of the Yorkshire College, Leeds, there has been lately in all the manufacturing centres of Yorkshire a remarkable growth of opinion as to the importance of this question; and the action taken by the Mechanics' Institute in adding to its buildings a set of rooms for scientific training must be regarded as a characteristic and eminently satisfactory sign of the times. The extension has involved a total cost of nearly £7000. The building is three stories high. The class rooms on the ground-floor will be used for the Boys' Modern School. On the first floor a series of rooms will be used jointly by the Boys' Modern School and the School of Science and Technology. On this floor there is a physics lecture theatre, with a sloping gallery capable of accommodating about fifty students. The metallurgical laboratory, the balance room, and the chemical laboratory occupy the second floor, which is reached by a wide stone staircase. In the former twenty-two students will be able to work at the same time.

EVERYONE who is in the habit of using Whitaker's Almanac is now familiar with the issue for 1889. It may not, however,

be too late to say that the work as a whole is more valuable than ever, and that especial credit is due to the editor for the excellent sections on subjects relating to astronomy. We may call his attention to the fact that for some mysterious reason the office of NATURE is not included in the list of newspaper offices in London.

THE prevention of smoke formed the subject of an interesting discussion at a recent meeting of the Institution of Engineers and Shipbuilders in Scotland. Mr. G. C. Thomson, who had read a paper on the subject, said, in summing up the debate, that he would like to add to his paper the effect of a day's fog in London. For the twenty-four hours ending Thursday morning, November 17, 1887, the gas sent out by the Gas light and Coke Company was 103,664,000 cubic feet, or 35,000,000 excess over the same day in 1886. The gas was sold at 3*s.* per 1000 feet, and was equal to £15,500, so that the value of the excess in money equalled £5250—a sum that would go a great way in putting many of the faulty furnaces in London into good working order, so that they would give no smoke. Mr. Thomson also called attention to the loss of health and life which a foggy day always entailed on a community.

AT the meeting of the Royal Geological Society of Ireland on January 9, Mr. Kinahan communicated a paper, a general supplement to his previous articles on the "Economic Geology of Ireland." In this the suggestion as to the pre-Cambrian age of some of the Irish rocks is of interest. The author pointed out that it is highly improbable that any Irish rocks are equivalents of the American Laurentians or Huronians; but in reference to the "Gap rocks" of the epoch between the Huronian and Primordial, called by Chamberlain the Agnotozoic epoch, he suggested that possibly rocks of this age might be found. He mentioned the Bray Head series, which he would provisionally call "Oldhamians," as rocks that seem to be evidently older than the Welsh Cambrians; and as the Welsh Cambrians by their fossils seem to be the equivalents of the American Primordials, any rocks older than the Welsh Cambrians ought to belong to strata of Agnotozoic age. The suggestion that the Oldhamians are older than the Welsh Cambrians was founded on the profound break between them and the Irish equivalents of the Llandriloes; while in Wales the Cambrians pass conformably upwards into the Welsh Llandriloes. The author then pointed out that if the Oldhamians are of pre-Cambrian age (Agnotozoic) it is probable the rocks of North-West Mayo (Mullet) are similarly Agnotozoic, while it is possible, if not probable, that Griffith's older rocks in Ulster (Donegal, Tyrone, and Antrim?) may also be Agnotozoic.

THE Quarterly Record of the Royal Botanic Society for April–June 1888 contains the report of a lecture, by Mr. G. J. Symons, on sunshine. The subject is discussed chiefly from an instrumental point of view, under the heads of thermometric solar radiation, sunshine-recorders, and sunlight-recorders. Mr. Symons points out that Newton, in the seventeenth century, compared the readings of two thermometers, one in the sun and the other in the shade. De Saussure, in 1774, was the first to make an apparatus for direct observations upon the heat of sunshine, and, in 1837, the subject was taken up by Sir John Herschel, M. Pouillet and others. Their researches led to the use of the black-bulb thermometer *in vacuo*, while bright and black-bulb thermometers were used by Arago in 1844. This class of instruments was further improved by the Rev. F. W. Stow, in 1869. The first direct sunshine-recorder was designed by the late Mr. J. F. Campbell, and erected by him in Whitehall, in December 1854; it consisted of a mahogany bowl, with a hollow sphere of glass, nearly filled with acidulated water, to form a lens. In December 1857, a solid glass sphere was substituted; the observations were discussed by Profs. Roscoe and Stewart (Proc. Roy. Soc., June 1875). Finally, towards the end of 1879, after various experiments at Greenwich and Kew Observatories, Prof. Stokes designed the card supporter which is now used by the Meteorological Office and other institutions. The observations have been discussed by Mr. Scott for the years 1880–85 (Quart. Journ. Roy. Met. Soc., July 1885). Mr. Blanford stated, some years ago, that this instrument would give better results than the thermometric method, which has now been practically discontinued in India. Of the photographic sunlight-recorders, the principal are those by Mr. J. P. Jordan and Prof. McLeod. Another pattern has been designed by Dr. Maurer, and illustrated in *La Nature* for May 19, 1888, in which it is stated that the paper can be left unchanged for twenty days. Mr. Symons concludes his interesting lecture by remarks upon the action of light upon vegetation.

REPORTS of earthquakes have lately been received from many different parts of the world. At Flekberö, in the Torrisdal, in South Norway, there was an earthquake on December 27, 1888. Shocks were felt at Herisau, Zug, Frauenfeld, and Zürich, and at Wyl (Aargau), on January 1, at 5 a.m. A severe shock occurred at Constance on January 7, at three minutes to 12 noon. It continued for two seconds, and seemed to move from west to east. It was also noticed in several parts of North Switzerland; and at Wattwyl the shock was so severe that the inhabitants rushed out of their houses in terror. At St. Gallen, the pictures, curtains, &c., swung about on the walls, and the woodwork creaked. According to a telegram sent through Reuter's agency from Smyrna on January 21, a disastrous earthquake occurred last Thursday at Sparta (?), in Asia Minor, in which 300 houses were destroyed. A shock was felt at Athens on January 22, as well as at Megara and Arachova. It was accompanied by heavy rains and a violent gale.

ON Friday morning last, a shock of earthquake was felt in the county of Midlothian. Of this earthquake we may have something to say on a future occasion.

REFERRING to the Calcutta earthquake of December 23 last, which is said to have been the most severe felt since 1885, the *Englishman* says that it took place at 10.50 p.m., and lasted for about a minute and a half. It was severe enough to try the stability of substantial houses. Sleepers were awakened by the loud rattling of doors and windows, and pemka frames and lamps swung about in a curious fashion. So far as could be judged, the direction of the wave was from east to west. The disturbance was wide-spread, but appears to have varied in intensity in different places.

THE papers on "Modern Views of Electricity," by Prof. Oliver Lodge, which have been appearing in NATURE, will soon be published as a volume of the "Nature Series."

A WORK on "The Principles of Inductive or Empirical Logic," by Dr. John Venn, is about to be issued by Messrs. Macmillan. It contains the substance of lectures delivered in Caius College for a number of years past. The general treatment of the subject is somewhat more in accord with that adopted by J. S. Mill than with that of the majority of recent English works on logic.

MESSRS. MACMILLAN AND CO. have in the press Part I. of "A Graduated Course of Natural Science for Elementary and Technical Schools and Colleges," by M. B. Loewy. The author's object is to place the teaching of natural science in schools upon an exclusively experimental basis, and to make it at the same time thoroughly methodical and systematic, the scholar being led from known and easily-understood facts to less-known and more difficult results. In this way, it is thought

instruction in science may be brought into close harmony with educational methods employed in other subjects of school teaching.

MESSRS. MACMILLAN AND CO. will also issue soon "Hydrostatics for Beginners," by F. W. Sanderson. The work is based on the author's experience in teaching physics to large classes of boys varying from 12 to 19, and in arranging and conducting each class in laboratory work.

A NEW compound, containing aluminium in a lower state of oxidation corresponding to ferrous iron, has been obtained by Prof. Hampe-Clausthal. It is a double fluoride of sodium and aluminium of the composition $2NaF . AlF_2$. In the earlier experiments which resulted in the production of this interesting substance, cryolite, the natural fluoride of sodium and aluminic aluminium, $6NaF . Al_2F_6$, was fused for several hours in a gas-carbon crucible along with a quantity of metallic aluminium. Air was rigidly excluded during the fusion, a current of hydrogen being led through the crucible by means of tubes inserted through the air-tight cover. The carbon crucible was protected from the direct flame of the furnace by means of an outer one o platinum. Under these circumstances the metal dissolved either wholly or in part, depending upon the amount present, in the melted cryolite; a little carbide of aluminium was at the same time formed and disseminated throughout the mass, especially aggregating near the surface, in minute particles, accompanied by small globules of the metal itself. After separation of these particles by various means as completely as possible, it was found that about half as much aluminium had entered into combination as that originally contained in the cryolite, indicating the probability of the course of the reaction being as follows: $6NaF . Al_2F_6 + Al = 3(2NaF . AlF_2)$. It was afterwards found, however, that by substituting a polished wrought-iron crucible for the carbon one, a product was obtained perfectly free from these particles, carbide of aluminium being no longer a possible product of the reaction, and the excess of metallic aluminium forming an alloy with the iron upon the walls of the crucible above the fused fluoride. Hydrogen was led through as before in order to exclude oxygen. 58 grammes of cryolite were fused for $5\frac{1}{2}$ hours with 29·5 grammes of the metal; at the end of the operation the homogeneous white substance formed at the bottom of the crucible on cooling was submitted to analysis, with results which entirely confirm the above supposition, the numbers corresponding to the formula $2NaF . AlF_2$. The new compound, which in outward appearance very much resembles cryolite, must therefore be considered as sodium aluminious fluoride. It may be remarked that all three elements were estimated, the sodium and aluminium in the ordinary manner, as chloride and hydrate, while the fluorine, which was found most difficult to determine satisfactorily and required prolonged treatment, was eventually weighed in the form of calcium fluoride. Now that an aluminious salt has at last been obtained, it is to be hoped that further attempts may follow, having for their object the formation of other compounds corresponding to the well-known salts of ferrous iron.

REFERRING to the discovery, last year, at Sandnaes, near Stavanger, in Norway, of enormous deposits of infusorial earth, at the time communicated by Lord Salisbury to the Royal Society, Prof. P. Waage, the well-known Norwegian chemist, is of opinion that this earth should be suitable for the preservation of food, after having been subjected to a process of intense heating, whereby all organic matter should be destroyed. Prof. Waage thinks that sterilized infusorial earth would be very much better as a means of preservation than boric acid, &c., now used in the preservation of fish.

LAST autumn, a family of the hazel-mouse, *Myoxus avellanarius*, was discovered in a wood at Slagelse, in Denmark. It is said that the animal had never before been found in that country. The mice had made their nest—ball-shaped in appearance—of grass and leaves between the branches of a tree, 6 feet above the ground. It had a circular entrance-hole at the side. Two of the animals are now hibernating in the possession of a farmer.

THE Museum of the Christiania University has just been enriched with a Runic stone, hitherto unknown, found in the Romsdal. The writing is in older Runic characters, and very clear, but parc of the stone is missing. It is believed to have been a memorial stone. Some years ago, a similar stone was found in the same locality, but the Runes are illegible.

THANKS to strict preservation, and to the fact that the inhabitants are realizing the value of the bird, the eider has greatly increased in number in Iceland during recent years. The people do all in their power to attract the bird to their property. Among these attractions are bells worked by the wind or by water, the hanging up of dress material of a glaring colour, and the keeping of brightly-coloured fowls. A Society has been formed for the granting of premiums for the killing of animals preying upon the eider, and, last year, 1155 such prizes were awarded.

THERE has been a very marked increase in the number of visitors to the South Kensington Museum during the last year, the numbers rising from 788,412 in 1887 to 897,225 in 1888. But this increase of 108,813 is quite put in the shade by that of 500,582 at the Bethnal Green Museum, which, in its total of 910,511 for the past year, has, as will be seen, distanced the parent institution. This great influx of visitors, more than double that of the previous year, was, no doubt, in great measure due to the exhibition there of Her Majesty's Jubilee presents after they had been shown to the West End at St. James's Palace. But some part of the increase must be attributed to the fine collection lent by the Hon. W. F. B. Massey Mainwaring. The increase in numbers at South Kensington was not confined to the main Museum, but extended to the separate collections—the Science Museum and the India Museum—which are in the galleries at the west side of Prince's Gate, and which are not open in the evening, as are, on three evenings in the week, the collections in the main building on the east of Prince's Gate, and the Bethnal Green Museum. The numbers visiting the Science collections increased from 177,465 in 1887 to 258,796 in 1888, notwithstanding the fact that the galleries have been severed by the new road cut across the Horticultural Gardens, while the visitors to the India Museum increased from 116,574 to 152,911. The numbers of visitors are taken in all cases by turnstiles.

WE have received several letters on "Hares Swimming." Mr. G. H. Kinahan writes that he believes the phenomenon to be not uncommon. "When I was stopping at Inver Lodge, Co. Galway," he says, "the keeper told me a hare had a nest with three young ones on a small island in the lake, and that it left them most of the day-time. I went with him to the island, which was about 30 yards in diameter, and about 100 yards from the shore, and after searching it most carefully, we could only find the three leverets. Sheep are animals that in general keep out of water, yet in Connemara I have seen them quite naturally swimming a river or even a lake." "E. H." writes:—"I was by the little River Arun below the old mill at Pulborough one day, when I saw a hare quietly cantering down the opposite field towards the river. A bank hid the actual crossing of the river from me; but when the hare emerged from the water into the field in which I was standing, I was amused to see the dog-like fashion in which it stood and shook off the moisture, scattering the spray far and wide, before resuming its leisurely

canter. The act had the air of being habitual." Mr. G. Plarr, writing from Tunbridge, tells us of a hare which he saw many years ago while he was walking along a mill-stream in Elsass. The hare was being chased by some boys in a meadow on the opposite side of the stream. It disappeared in the water, and emerged on the side on which Mr. Plarr was walking. Without stopping to shake the water away, it made off with great speed. The creature presented a strange appearance, its head seeming to be large beyond all proportion to its body. This was, of course, due to the fact that the head had been kept dry above water, while the rest of the body had been immersed.

MESSRS. DULAU AND CO. have sent us a catalogue of zoological and palæontological works, including works on Echinodermata, Vermes, and Crustacea.

IN the letter on "Alpine Haze," by Antoine d'Abbadie (p. 247, lines 13 and 17 from the top), *for* "earth-haze" *read* "earth-ashes," and *for* "Ventouk" *read* "Ventoux."

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Mrs. Henderson; a Rhesus Monkey (*Macacus rhesus* ♂) from India, a Brown Capuchin (*Cebus fatuellus*) from Brazil, deposited; two White Ibises (*Eudocimus*, sp. inc.) from Central America, purchased; a Rufous-necked Wallaby (*Halmaturus ruficollis* ♂) from New South Wales, received in exchange.

OUR ASTRONOMICAL COLUMN.

DISCOVERY OF A NEW COMET.—A faint comet was discovered on January 14, at 18h. 4·7m., by Mr. W. R. Brooks, of Geneva, New York. Its position at the time of discovery was R.A. 18h. 4m. 0s., Decl. 21° 20′ S. The comet was moving rapidly towards the west.

MINOR PLANETS.—Herr Palisa at Vienna discovered a minor planet on January 4, which may possibly be Siwa, No. 140. Should it be a new planet, it will be No. 282, and Herr Palisa's sixty-ninth discovery. Three minor planets, all discovered by Herr Palisa, have recently been named. No. 278 has been called Paulina; No. 279, Thule; and No. 280, Philia.

THE OBSERVATORY OF TOKIO.—An Astronomical Observatory has just been instituted at Tokio, Japan, by the combination of the astronomical portions of the old Naval Observatory and of the Home Office, together with the Astronomical Observatory of the Imperial University. The site of the old Naval Observatory has been selected for the new institution, the meteorological portion of the former having been transferred to the Central Meteorological Observatory of the Home Office. The principal instruments of the new Observatory are a Repsold meridian instrument of $5\frac{1}{4}$ inches aperture; a transit-circle, by Merz and Repsold, of 5 inches aperture; and two equatorials, the one by Troughton, of 8 inches, and the other by Merz, of $6\frac{1}{2}$ inches aperture. The staff of the institution has not yet been fully organized, but Prof. H. Terao has been appointed Director, and has commenced regular observation. The approximate position of the Observatory is—longitude E. of Greenwich, 139° 44′ 30″ 3; N. latitude 35° 39′ 17″·5.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 JANUARY 27—FEBRUARY 2.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on January 27

Sun rises, 7h. 47m.; souths, 12h. 13m. 5·4s.; sets, 16h. 39m.: right asc. on meridian, 20h. 40·9m.; decl. 18° 19′ S. Sidereal Time at Sunset, 1h. 8m.

Moon (New on January 31, 9h.) rises, 3h. 54m.; souths, 8h. 22m.; sets, 12h. 43m.: right asc. on meridian, 16h. 48·9m.; decl. 19° 10′ S.

GEOGRAPHICAL NOTES.

THE International Geographical Congress will be held at Paris from August 5 to August 10 next. The Geographical Societies of London, Berlin, Leipzig, Manchester, Edinburgh, New York, Melbourne, Lisbon, Antwerp, and Milan, and many French Societies will be represented at the meeting.

M. EUGENE MARKOW sends to the French Geographical Society an interesting account of his recent ascent of Mount Ararat. He and his companion, after passing the night among the rocks at a height of 13,000 feet, began their ascent on August 13, at 5 a.m. Soon they passed a conical rock which rises on the south-east face of Ararat, and here M. Markow places the limit of perpetual snow on the mountain. From the base of the rock extends in an opposite direction a broad plain of *névé*, which reaches the summit at a slope of 35°. Underneath this *névé* was heard the sound of a stream formed of the melted ice. At the height of 14,800 feet, M. Markow found among the rocks a *Coccinella septempunctata* of a very bright red. At 15,500 feet, some flowers were found on a small sandy eminence. At 2 p.m. the party reached the foot of the sacred summit of the mountain. This summit presents a vast extent of snow, separated into two by a precipice commencing on the north-east side, and getting broader and deeper as it reaches the south-east. Part of the right summit is almost entirely free from snow, and is covered with small stones. The left summit, on the north-west, presents a plateau covered with snow, but having a small elevation in the middle. It is much larger than the right summit.

A pyramid is being raised on the summit of the mountain, which it is hoped will dissipate the superstition among the natives below that no one can ever reach the top.

CAPTAIN TRIVIER, a French naval officer, has left France to undertake an expedition across Africa. One of his chief objects will be the exploration of the Lualaba and its tributaries, and more especially the Lukuga, the outlet of Lake Tanganyika, about the real nature of which there has been so much controversy. Captain Trivier will follow the Lukuga to the lake, and make a careful report on its actual condition. Captain Hore, who has been more than ten years on the lake, has just returned home. He states that during the whole period of his stay on the lake it has steadily decreased in size; its level has fallen quite 15 feet, but the Lukuga still flows out with a rapid current. This it will continue to do until its muddy bed is worn down to the rock, when it will cease to be an outlet of Tanganyika. Captain Hore seems to think the lake will go on decreasing in size. Captain Trivier will cross to Ujiji and endeavour to make his way to the east coast at Bagamoyo.

THE first number is to hand of the *National Geographic Magazine*, the organ of the recently founded "National Geographic Society" of the United States. The work of the Society, of which all the leading officers of the U.S. Survey are members, promises to be of much higher scientific value than that of the American Geographical Society of New York. The Society has 200 members. Among the articles in this number are "Geographic Methods in Geologic Investigations," by Mr. W. M. Davis; "Classification of Geographic Terms by Genesis," by Mr. W. J. McGee; "The Survey of the Coast," by Mr. H. G. Ogden; and the "Survey and Map of Massachusetts," by Mr. Henry Gannett.

CAPTAIN WAHAB reports as follows regarding the survey work accomplished by himself and one sub-surveyor while with the Hazara field force:—"Up to the end of the Ahazai country we have a complete survey extending a good way west of the Indus, and a certain amount of reconnaissance work in the Chagarzai country up to about Judbai. North-east of the Black Mountains we have surveyed from Nandihar (the limit of this survey in the 1868 expedition), north to the range beyond Allahi, and west to the hills overlooking the Indus. We have fixed the course of the river up to say 15 miles north of Thakot, and I have sketched, on the ¼-inch scale, as much as possible of the country between the Indus and the Swat Valleys, what I could see from the Chel Mountain and the Ghorapher Pass. I have made three stations, and fixed a number of points in the lower ranges between the snowy peaks fixed by the Great Trigonometrical Survey and our frontier, which I hope may be useful on future occasions. While I was triangulating on the top of Chel, Imam Sharif went down the hill to Pokal, for the day, and got in most of the Allahi Valley. There is a gap in the survey of the Indus Valley from the bend west of Thakot down to Judbai, which cannot be seen without going into the Chagarzai country, but even if we do not go, I have got the course of the river practically fixed within about half a mile one way or the other."

ELECTRICAL NOTES.

F. KOHLRAUSCH has just made a fresh determination of the ohm. He makes it equal to 106·32 centimetres of mercury 1 square millimetre in section.

PROF. ROWLAND has made preparations to repeat his classical Berlin experiment by which he demonstrated the fact that a static electrical charge in motion acted like a current. He is going to use higher speeds and higher electrification, and it is therefore hoped that he will get accurate quantitative determinations.

AT Paisley, an electric discharge, which seriously damaged a chimney and its defective lightning-conductor, also killed a quantity of fish that were in a pond close by in which the conductor was earthed. When will people take the precaution to examine their lightning protectors?

DUBS (*Centralblatt für Electrotechnic*, 1888, No. 28) has shown that a strong blowpipe or oxyhydrogen flame from one carbon to another sets up an E.M.F. which would fully account for the opposing E.M.F. of the arc.

A NEW mode of regulating dynamos for constant current and constant potential has been devised by the Waterhouse Company in the United States by means of a *third brush* slightly in advance of the positive brush, and an external variable shunt circuit which can be adjusted automatically or by hand. The desire to evade patents has at least one merit—it exercises the faculty of invention and stimulates design. The *Electrical Engineer* of New York (December 1888) has an excellent paper by Mr. Caldwell on this third brush.

IT is sometimes asserted that the unit of work—the *erg*—is too small to be of any use, but Prof. Langley has shown that the perception of the colour crimson is produced by an expenditure of energy upon the retina, which can be represented by 10^{-13} horse-power, or 0·001 of an erg; while the sensation of green is due to 0·00000001 of an erg.

HELMHOLTZ has shown that if an invisible jet of steam be electrified or heated it becomes visible with bright tints of different colours according to the potential or the temperature.

DR. GORE, F.R.S., has submitted to the Royal Society a new instrument of research, which he thus describes:—"Take two small glass cups containing known volumes of distilled water. Form two voltaic cells of them by means of strips of stout wires of unamalgamated zinc cut from the same piece, and two small sheets of platinum, also cut from the same piece. Connect them together in series to a sufficiently sensitive galvanometer, so that the currents from the two cells oppose each other, and produce no visible deflection of the needles. This arrangement constitutes a 'voltaic balance,' and is extremely sensitive to change of chemical composition of the liquid in one of the vessels. Make an aqueous solution of known strength of the substance, and add it in sufficiently small quantities at a time to the water in one of the cups until the needle of the galvanometer visibly commences to move, and note the proportion of the substance and of water then contained in that vessel. As the amount of energy required to move the needle is the same in all cases, the different numbers thus obtained with different substances represent the relative amounts of voltaic energy of those substances. And as each substance and mixture of substances gives a different number, it is possible by this method to detect substances, to ascertain the degrees of strength or concentration of liquids, to ascertain whether a substance contains a soluble impurity, &c. The method also is in many cases an extremely sensitive one."

PROF. J. J. THOMSON (R.S., January 17, 1889) has examined the screening influence of conducting plates upon alternating currents of great frequency, and has deduced thereby the resistance of electrolytes and of graphite. He shows that the screening effect depends on the conductivity and thickness of the plate and upon the frequency of the alternations. The secondary induced currents are confined to the skin of the plate next to the primary, the thickness of this skin varying inversely with the conductivity of the plate and the frequency of the currents. Thus a thin plate of badly conducting material will be efficient with currents of great frequency, such as those of the rate 10^8 per second; while a thick plate of the best conducting material will not be sufficient to screen off currents of low frequency, such as those with a rate below 10^2 per second. Thus to measure the resistance of electrolytes it is necessary to have vibrating electrical systems such as those examined by Hertz, whose frequency is of the former class; and if two different plates produce the same screening effect, their thickness must be proportional to their specific resistances. He supports Maxwell's theory that the rate of propagation of electrostatic potential is practically infinite, a point called in question by Hertz; and he agrees with Hertz that the rate of propagation of electro-dynamic action is finite and measurable. He shows that the rate of propagation of an electro-magnetic disturbance through a metallic conductor and through the surrounding dielectric is the same, and this differs from one of Hertz's conclusions. But he also shows that this is not so when the conductor is a dilute electrolyte or a rarefied gas. In such a case there would be interferences and standing vibrations. Hence the striæ in so-called vacuum-tubes. He also concludes that the relative resistance of electrolytes is the same when the current is reversed a hundred million times a second as for steady currents.

SOMEONE in the United States has proposed to call static electricity "amberism." It is a good analogue to "galvanism" and to "magnetism." It would be well to introduce some term to relieve the word "electricity" from the dreadful abuse to which it is now subjected. The Board of Trade in their draft Provisional Orders are using it in three distinct and different

senses: (1) for electrical energy, which is measured in *watts*; (2) for electric currents, which are measured in *amperes*; and (3) for electrical quantity, which is measured in *coulombs*.

JOÉ has discovered that the resistance of cobalt in a magnetic field is *increased* in the direction of lines of force, and *diminished* in directions at right angles to them.

STAR NAMES AMONGST THE ANCIENT CHINESE.

IN two recent numbers of the *Chinese Review* (vol. xvi. Nos. 5-6) the well-known scholar, Dr. Joseph Edkins, writes on the subject of star naming amongst the ancient Chinese. He says that there are two great periods of star naming in ancient China, the first being about B.C. 2300, and the second during the Chow dynasty from B.C. 1120 to B.C. 220. The real beginning of Chinese astronomy is, in Dr. Edkins's opinion, to be found in the period preceding B.C. 2300, about which date, by command of the Emperor Yan, the observation of the meridian stars was made. Amongst primitive Chinese observers our Scorpion was a dragon, Aquarius a serpent or tortoise, Taurus a tiger, and Leo a bird. These figures were, however, larger than our zodiacal signs; for instance, the chief portion of Virgo, Leo, and Cancer would form the Red Bird. At that remote period we find that Chinese astronomers divided the heavens into four large sections, and twenty-eight small groups or constellations. The former, the large ones, are all animals, and are arranged from east to west, while the constellations are arranged from west to east. There were seven eastern constellations forming the Green Dragon—which comprised the stars in Libra, Scorpio, and Sagittarius; seven southern constellations, the Red Bird, or *Feng-hwang*—comprising Cancer, Leo, and Virgo; seven western constellations, the White Tiger—made up of Aries, Taurus, and Gemini; and the seven northern constellations, the Dark Warriors—or the Serpent or Tortoise. Each group, whether large or small, had its Chinese name. The Red Bird or Pheasant is the constellation of summer or the south; the Dragon, of spring or the east; the Tiger, of autumn or the west; and the Serpent or Tortoise, of winter or the north. Since the Great Bear points to Spica Virginis, the Chinese astronomers made the group led by Spica the group of spring. Another reason for thus making Spica the gate of the year is, perhaps, to be found in the fact that the Babylonians, from whom the Chinese probably got their astronomy, for a long time regarded Scorpio as the first of the signs. This is, of course, a mere guess, for we cannot, after this lapse of time, tell how much of the astronomical knowledge of the Chinese is derived from external sources. On the probable Babylonish origin of some of the astronomical knowledge of the Chinese, Dr. Edkins says:—"The contests of the early Buddhists with the worshippers of fire show that the Persian religion was propagated in India during and after the sixth century before Christ, and the eagerness with which the Hindus adopted the Greek astronomy after Alexander's invasion of India, as well as our knowledge of the fondness of the Buddhists for astrology, make it probable that Babylonian ideas on the stars were familiarly known in ancient India, during the period when they became popular in China. The resemblance of the cosmogony of the laws of Manu to that of the Babylonians seems to support strongly the correctness of the statement that Babylonian astrology was accepted at the same time in ancient India and in ancient China." With regard to the names of the four zodiacal signs, they are, as we have seen, those of animals, and it is peculiar that they are all Chinese animals but the Dragon, and it is not known that any species of dragon ever existed in China. In the naming of the constellations a wider field is included. Thus, the following are found: parts of the body, as heart, stomach, lips; buildings, a house, a wall, a well, a tower; articles of daily use, a peck measure, a net, a carriage; animals, K'wei K'ien (a humped boar leading a cow to sacrifice); adjectives and numerical groups, &c. From these names it appears that the origin of the appellations was popular rather than Imperial. In B.C. 1144, Wen Wang began to write the treatise called "Yi King." The adoption by Wen Wang of red as the Court colour of the Chow dynasty, and the fact that his son introduced five colours into the sacrifices, show that the Babylonish doctrine of the five colours and the five planets was known in China at that time. There are, however, variations in the colours. Thus, Mars is red in both China and Babylon; Jupiter, orange in Babylon, blue or purple in China; Venus, yellow in Babylon, white in China; Mercury, blue in Babylon, black in China; Saturn, black in Babylon, yellow in China. The "Yi King" shows that the stars were divided into four groups from the earliest times, for the Dragon and the Tortoise lie at the root of all the divination of that work; and the Tiger and Red Bird are respectively assigned to the west and the south. Shortly after the date of "Yi King" we find the following points mentioned: the cycle of twelve years, dependent on a revolution of Jupiter; the twelve hours into which the horizon is divided by the pointing of the Bear; the cycle of ten days; the cycle of twenty-eight constellations; the four seasons; the sun, moon, and planets. Astrology was, of course, implicitly believed in; in fact, the end and aim of all ancient Chinese astronomy was astrology. The conjunction of the sun and moon controlled the good and bad luck of the Empire, and particular stars foretold the fortunes of the various portions of the Empire, for each province had its presiding star. During the Chow dynasty—that is, after B.C. 1120—many constellations are named. Thus the fifth Emperor ordered a group of stars in Cepheus to be called Tsau-fu, after his favourite charioteer. Wang-liang was also a charioteer about B.C. 470, and his name was given to a number of stars in Cassiopeia. The virtues of a duke of the Tsi kingdom who died in B.C. 488 were so great that a star was called after him. Unlike the old names, all of which seemed to denote a popular origin, those named during the Chow dynasty show their Imperial origin. Thus several stars in Leo were styled Wu-ti-tso—that is, "throne of the five emperors." During the second century before the Christian era, Chinese astronomers pointed out the five emperors. The chief ruler of Heaven is the ancient pole, the star Tai-yi, 22° from our present pole. The seven stars of the Great Bear are the Government—rulers of the sun, moon, and five planets. The palace of the heavenly emperor is bounded by the oval formed of the fifteen stars of Draco, amongst which is Tai-yi. At the back of the bear is the group Wen Ch'ang Kung, "the palace of literature brilliantly spread abroad," the favourite object of the adoration of the *literati*. The abode of the eastern emperor is in Scorpio. The group containing Antares is Ming-t'ang, the council-hall of the emperor, where he give laws to his subjects. The adjoining stars are the sons of the emperor. The palace of the emperor is Arcturus, and the two large stars in Centaur to the south of Sagittarius form the south gate of his dominions. In Cancer and Leo lies the residence of the southern emperor. One group is the palace of the sun, moon, and planets, and surrounding this group is a guard of twelve feudal barons who keep the throne of the five emperors. Between Procyon and Regulus, and between the ecliptic and equator, there is a group in Hydra called the willow-branch, which rules over planets, and forms the beak of the Red Bird. The constellations of the Seven Stars adjoin this, and form the neck of the Red Bird: its crop is the kitchen of the palace; Hydra forms the bird's wings; the constellation Yi is the imperial hotel where visitors at the palace are accommodated; the constellation Corvus finishes the shape of the Red Bird, and is the last in the zodiac. The seven western constellations—that is, those made up of Aries, Taurus, and Gemini—are "the lake of fulness," "the five reservoirs of heaven," "the home of the five emperors." Hyades is "the announcer of invasion on the border." Later on—that is, probably about the second century—the stars are grouped into three principal sections, the first section containing the circum-polar stars, the second stars in Leo and Virgo, the third twenty-two stars in Serpens, Hercules, and Ophiuchus, the latter being said to be feudal rulers paying homage to the Emperor. The whole history, in fact, of Chinese astronomy is full of this comparison of the state of the kingdoms on the earth with the heavenly bodies. Thus, under the Tsin dynasty, the pole star is the abode of the supreme ruler. "The circum-polar stars form his court. Their name as a whole is the 'purple subtle inclosure.' The stars selected to represent the emperors of the five colonies" (*i.e.* blue, red, yellow, white, and black) "were Denebola and four others in Leo. They are surrounded by twelve groups, which have received names of office and rank representing together the court of an earthly emperor. This inclosure is the court, especially, it is said, of the yellow emperor, whose essence is called Han-shu-nieu. The four remaining colours are near him. The blue emperor is Ling-wei-yang. The red or south emperor is Chi-piau-nu. The white emperor of the west is Pe-chan kü, 'the white beckoning mason's rule.' The north or black emperor is

Hie-kwang-ki, 'mark of combining light.' Besides this palace in Leo and Virgo, there is another, Tien-shi-yuen, 'inclosure of the heavenly market.' It is not far to the north-east of Scorpio. It is the serpent in our astronomy. Within the brilliant circle of the serpent is a star called 'court of the western heaven.' There is also a bright star, α Herculis, which is called 'emperor's throne.' The twenty-two stars in the Serpent are named after the States into which China was formerly divided."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Among the numerous lectures on physics and chemistry this term, we note those of Prof. Liveing, on spectroscopic chemistry; Prof. Dewar, on physical chemistry; Mr. Pattison Muir, on chemical affinity; Mr. Robinson, on agricultural chemistry; Mr. Heycock, on chemical philosophy; Prof. Thomson, on electricity and magnetism, and on the kinetic theory of gases; Mr. Shaw, on thermodynamics and radiation; and Mr. Wilberforce, on dynamo electric machines (continuous current generators and motors). Prof. Stuart lectures on theory of structures.

Prof. Foster continues his elementary course of physiology; Dr. Lea his chemical physiology; and Mr. Langley his advanced histology and physiology.

In zoology, Prof. Newton lectures on the geographical distribution of Vertebrates. Mr. Sedgwick and Mr. Darwin conduct the large class of elementary biology. Mr. Gadow's course is on the morphology of the Amniota (recent and extinct). Mr. Sedgwick, Mr. Harmer, and Mr. Weldon continue their classes on the Invertebrata.

Mr. Darwin lectures on the physiology of plants (advanced), Mr. Gardiner has a general elementary course, Mr. Vaizey lectures on the morphology and classification of Cryptogams, and Dr. Hicks on elementary botany.

The lectures on geology are divided thus: Prof. Hughes, geology of a district to be visited at Easter; Mr. Marr, principles, and geology and scenery; Mr. Harker, petrology; Mr. Roberts, palæontology; Mr. Seward, palæobotany.

The principal mathematical lectures are the following: Prof. Stokes, semi-convergent series involving powers of a complex variable; Prof. Cayley, analytical geometry; Prof. Adams, lunar theory; Mr. Pendlebury, projective geometry; Mr. Glazebrook, hydrodynamics (waves and sound); Mr. Hobson, spherical and cylindrical harmonics; Mr. Larmor, geometrical optics and electro-magnetism; Mr. Forsyth, modern algebra (binary forms); Dr. Ferrers, elliptic functions; Dr. Besant, analysis; Mr. H. M. Taylor, higher plane curves; Mr. Webb, dynamics (elasticity and viscosity); Mr. Stearn, hydrodynamics (multiply-connected velocity-potentials and vortices); Mr. Herman, hydrodynamics (viscous and gravitating fluids).

An examination will be held at Gonville and Caius College on March 15 for one Shuttleworth Scholarship, value £60 per annum for three years. Candidates must be medical students of the University of not less than eight terms standing. In the case of candidates not already scholars of the College, the examiners may recommend at the same time for a foundation scholarship. Further particulars may be obtained from the tutors.

SCIENTIFIC SERIALS.

American Journal of Science, January.—The history of a doctrine, by S. P. Langley. This is the address delivered last year to the American Association for the Advancement of Science, here published complete with the notes that have not hitherto appeared. Its object is to show the steady progress of scientific truth, as illustrated by the history of the undulatory and corpuscular theories of light from the time of Descartes, Boyle, and other precursors of Newton down to the present day, when the identity of radiant light and heat as forms of motion, or as different effects of radiant energy, has been finally established.—Description of the new mineral beryllonite, by Edward S. Dana and Horace L. Wells. This is a new phosphate of sodium and beryllium discovered in 1886 by Mr. Sumner Andrews near Stoneham, Maine, the same district that has already yielded fine specimens of phenacite, herderite, and other rare minerals. It occurs mostly as a crystal in a fragmentary state, of small size and seldom well formed, but remarkable for the number of planes they present, eight or more distinct planes being frequently presented in each zone on a single crystal. Twins are common, leading to many curious variations of form. The crystals are colourless, or slightly yellowish, and transparent, with specific gravity 2·845, and hardness 5·5.—The iron ores of the Penokee-Gogebic series of Michigan and Wisconsin, by C. R. Van Hise. The author's recent explorations of this region confirm Prof. Irving's conclusion that the original rock of the iron-bearing formation is a cherty iron carbonate from which the various phases of rock and the ore found in it have been produced by a complex series of alterations. The iron ore is a soft, red, somewhat hydrated hæmatite, more or less manganiferous, and mostly very friable.—A quartz-keratophyre from Pigeon Point and Irving's augite-syenites, by W. S. Bayley. The remarkable bright red rock of Pigeon Point, Minnesota, is here studied in its various phases, with the general result that the sections described by Irving as augite-syenites are partly identical with the typical red rock itself, and partly the same in all essentials as the formations which have been called its intermediate varieties. The space between the fresh olivine-gabbro and the typical quartz-keratophyre is occupied by a series of rocks exhibiting a gradual transition between the heavy dark basic rock and the light red keratophyre.—On the occurrence of hanksite in California, by Henry G. Hanks. This anhydrous sulphate of soda has hitherto been found in limited quantities amongst the various borax fields of California. But the author's researches tend to show that it exists in great abundance, and that it plays an important part in the metamorphoses that produce gay-lussite, thinolite, and perhaps borax.—Further papers on Mount Loa are contributed by James D. Dana and the Rev. E. P. Baker, bringing its history down to July 1888.—H. L. Wells and S. L. Penfield contribute notes on the new mineral sperrylite.

American Journal of Mathematics, vol. xi. No. 2 (Baltimore, January 1889).—The number opens with an instalment of a memoir entitled "Remarque au sujet du théorème d'Euclide sur l'infinité du nombre des nombres premiers," by J. Perott (pp. 99–138). A footnote supplies bibliographical information as to previous memoirs on the same subject.—Next, Prof. Cayley writes on "The Theory of Groups" (pp. 139–57), a subject he has pretty largely written upon before, and to which his attention has been recalled by the section, in Mr. Kempe's Philosophical Transactions memoir "On the Theory of Mathematical Form," entitled "Groups containing from One to Twelve Units." The paper is largely illustrated by what the author styles "colour groups."—Mr. A. E. H. Love discusses "Vortex Motion in certain Triangles" (pp. 158–71), by a method explained by Dr. Routh in a paper in vol. xii. of the London Mathematical Society's Proceedings.—Another hydrodynamical paper follows, by Mr. Basset, "On the Steady Motion of an Annular Mass of Rotating Liquid" (pp. 172–81), wherein he follows up previous work in the line of Poincaré's and Prof. G. H. Darwin's recent investigations of the figures of equilibrium of rotating masses of liquid. The case considered is for an approximately circular cross-section and for rotation under the influence of its own attraction about an axis through its centre of inertia, which is perpendicular to the plane of its central line.—A paper, by Sophus Lie, "Die begriffe Gruppe und invariante" (pp. 182–86), is reprinted from the *Berichte der k. Sächs Gesellschaft der Wissenschaften*, August 1887.—A short note, by E. Picard, "Sur les formes quadratiques binaires à indéterminées conjuguées et les fonctions fuchsiennes" (pp. 187–94), closes the number. The method employed is that used by Poincaré in his memoir on fuchsian functions (*Journal de Jordan*, 1887).

SOCIETIES AND ACADEMIES.

LONDON.

Royal Meteorological Society, January 16.—Dr. W. Marcet, F.R.S., President, in the chair.—The Report of the Council showed that a large amount of work had been done during the past year, and that considerable progress had been made in the investigation of one of the most interesting and hitherto neglected branches of meteorology, viz. thunderstorms. Forty-nine new Fellows were elected last year, the total number on the books now being 525.—After the Report had been

adopted, the President delivered an address on "Fogs," which he illustrated by a number of interesting lantern slides. Fogs and clouds are one and the same thing. A cloud is a fog when entered into, and a fog seen from a distance, suspended in the air, becomes a cloud. After describing the various kinds of fog—*e.g.* river, sea, Newfoundland, radiation, town, &c., fogs—Dr. Marcet referred to London fogs. Dr. Tyndall has accounted for them by assuming each particle of condensed vapour to be covered by coal-smoke. These fogs usually accompany a high barometer, and are frequently dry in their character. It is a well-known fact that cold air on the tops of hills, being heavier than the air below, slides down the slopes, so that the lower parts of the hill-sides are actually colder than the plains at some distance from the hills. Now, London, in the Thames Valley, is surrounded by hills—to the north, Highgate, Hampstead, and Harrow; in a westerly direction, Putney and Wimbledon; and in a more southerly direction, Clapham and Sydenham. The air is colder on these hills than in London with its millions of inhabitants, its coal-fires and factories, hence it is heavier, and will have a great tendency to slide down the hills towards the town and the river. Should the air in town be on the point of saturation, and the cold air from above saturated with vapour, it is obvious that the increased cold from above will produce a precipitation of moisture, and it will come to pass that a fog is produced. If the hill-tops be not only colder than the air below, but enveloped in a fog, it stands to reason that the fog below will be all the denser, and especially in the neighbourhood of water, such as the River Thames and the ornamental waters in the parks.—The following gentlemen were elected the officers and Council for the ensuing year:—President: Dr. Wm. Marcet, F.R.S. Vice-Presidents: Francis Campbell Bayard, Henry Francis Blanford, F.R.S., William Ellis, Richard Inwards. Treasurer: Henry Perigal. Trustees: Hon. Francis Albert Rollo Russell, Stephen William Silver. Secretaries: George James Symons, F.R.S., Dr. John William Tripe. Foreign Secretary: Robert Henry Scott, F.R.S. Council: Edmund Douglas Archibald, William Morris Beaufort, Arthur Brewin, George Chatterton, William Henry Dines, Frederic Bernard Edmonds, Charles Harding. Baldwin Latham, Capt. John Pearse Maclear, R.N., Edward Mawley, Henry Southall, Dr. Charles Theodore Williams.

Zoological Society, January 15.—Prof. Flower, F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of December 18 8, and called attention to the young Chimpanzee purchased of Mr. Cross, of Liverpool, on December 6 (see NATURE of January 10, p. 254).—A letter was read from Heer F. E. Blaauw, of Amsterdam, containing an account of the development of the horns of the White-tailed Gnu as observed in specimens bred in his menagerie.—Prof. Newton exhibited a specimen of *Pennula millsi*, Dole, brought from the Sandwich Islands by Mr. S. B. Wilson, remarking that it seemed to be identical specifically with *Rallus obscurus*, Gmelin, a species which has not been lately recognized.—Prof. Bell made some remarks on the question of the food of *Bipalium*.—Canon Tristram made some remarks on a specimen of *Emberiza cioides*, a Bunting of Siberia, of which a specimen was believed to have been obtained in this country at Flamborough in October 1887.—Prof. F. Jeffrey Bell read a note on the Echinoderm fauna of the Bay of Bengal.—Mr. F. E. Beddard and Mr. Frederick Treves gave an account of the anatomy of the Sumatran Rhinoceros as observed in two specimens of this animal that had lately died in the Society's Gardens. The muscular anatomy of the limbs of this Rhinoceros was especially treated of.—Prof. Newton read a paper on the breeding of the Seriema (*Cariama cristata*) in the Society's Gardens.

Entomological Society, January 16.—Fifty-sixth Anniversary Meeting.—Dr. D. Sharp, President, in the chair.—An abstract of the Treasurer's accounts, showing a balance in the Society's favour, was read by Mr. Osbert Salvin, F.R.S., one of the auditors; and Mr. H. Goss read the Report of the Council. It was announced that the following gentlemen had been elected as officers and Council for 1889:—President: The Right Hon. Lord Walsingham, F.R.S. Treasurer: Mr. Edward Saunders. Secretaries: Mr. Herbert Goss and the Rev. Canon Fowler. Librarian: Mr. Ferdinand Grut. And as other members of Council, Mr. Henry W. Bates, F.R.S., Capt. H. J. Elwes, Mr. William H. B. Fletcher, Mr. F. DuCane Godman, F.R.S., Prof. Raphael Meldola, F.R.S., Dr. P. B. Mason, Mr. Osbert Salvin, F.R.S., and Dr. D. Sharp.—Dr. Sharp, the outgoing President, then delivered an address, for which a vote of thanks to him was moved by Capt. Elwes, seconded by Mr. Salvin, and carried. A vote of thanks to the Treasurer, Secretaries, and Librarian was moved by Mr. J. W. Dunning, seconded by Lord Walsingham, and carried. Mr. Saunders, Mr. Goss, and Mr. Grut severally replied.

PARIS.

Academy of Sciences, January 7.—M. Janssen in the chair.—On the Lindstedt series, by M. H. Poincaré. Although these series are not convergent in the strict sense of the word, they are often very useful in astronomical calculations owing to the rapidity with which the terms decrease. Here M. Lindstedt's method is presented from a fresh standpoint, and brought into connection with the principles expounded in Jacobi's "Vorlesungen über Dynamik."—On the reactions between chromic acid and oxygenated water, by M. Berthelot. This peculiar reaction has acquired a fresh interest since M. Ad. Carnot's recent discovery of an ingenious method for effecting the quantitative analysis of chromic acid by means of oxygenated water, and reciprocally, with simultaneous reduction of both compounds. The analogy of the reaction with that of permanganic acid has induced M. Berthelot to repeat the experiments, with the result that this, like other reactions of oxygenated water, may now be interpreted by the laws of thermo-chemistry.—On an hydraulic machine constructed in England, by M. Anatole de Caligny. The reference is to Mr. Pearsall's apparatus, in which M. de Caligny's open tube is replaced by a chamber allowing the air to escape freely.—Observations made on the summit of Mont Ventoux on the calorific intensity of solar radiation, by MM. A. Crova and Houdaille. The object of these observations has been to ascertain whether, at an altitude of 1900 metres, solar radiation undergoes daily variations analogous to those recorded at Montpellier, and whether from the curves registered at the higher elevation a value may be deduced for the solar constant more exact than those obtained from the calculation of the curves traced at sea-level. It results from these researches that at the altitude of 1900 metres the solar constant may acquire a value very close to the 3 calories obtained by Mr. Langley from his observations on Mount Whitney. The polarization of the blue light of the sky was also studied by means of M. Cornu's photopolarimeter, and its spectrum analysis made with M. Crova's spectrophotometer modified for the purpose. The polarization appears in general to increase with the solar constant, thus furnishing useful data for determining the degree of calorific transparency in the atmosphere.—On the true and mixed butylic ethers, by M. E. Reboul. Theory anticipates ten of these compounds; but two only are known, the normal diprimary butylic ether of Lieben and Rossi, and Kessel's disecondary. Williamson's general method having mostly failed, or yielded only doubtful results, M. Reboul has attempted by the process here described to complete the whole series. He has so far obtained five, not yet described, which with the two already known leave three to be still procured under other conditions.—On M. Hirn's new work, entitled "Constitution de l'Espace céleste," by M. Faye. This important work deals with the question of an ether or subtle medium filling all space, as postulated by physicists to explain the phenomena of light, heat, and electricity, but the presence of which astronomers have failed to detect as a resisting medium in the movements of the heavenly bodies. With a view to putting this seeming contradiction in a clear light, M. Hirn has worked out some delicate calculations which have led to several remarkable and at times wholly unexpected conclusions. Thus in estimating the density of a new medium capable by its resistance of causing a secular acceleration of half a second in the mean velocity of the moon, he finds that such a density would correspond with a kilogramme of matter uniformly diffused throughout a space of about 390,000 square miles. This is a density one million times rarer than that of the air reduced to one millionth of its normal density in Mr. Crookes's ingenious apparatus.—On the perturbations of the planet Hestia (46), according to the theory of M. Gyldén, by M. Brendel. The application of M. Gyldén's theory of perturbations to this planet shows that it is subject to some very considerable disturbances, its mean motion being about three times that of Jupiter.—On a process by which diurnal nutation may be demonstrated, and its constants determined, by M. Folie. This extremely simple process consists in observing at intervals of six hours two stars distant not more than 3′ from the Pole.—On the quantitative analysis of organic nitrogen by the Kjeldahl method, by M. L. L'Hote. This new method is here

subjected to a thorough test, and is found to yield results greatly inferior in accuracy to those obtained from the old process by means of sodaic lime.—On the early and late varieties of beetroot, by MM. C. Viollette and F. Desprez. The early maturing plant, although yielding the largest proportion of sugar, is in other respects subject to many drawbacks preventing its general adoption by growers. A series of experiments here described show that a late variety may be obtained, which, while free from these disadvantages, yields an abundant supply of sugar.—M. Hermite has been unanimously elected Vice-President, and MM. Becquerel and Fremy members of the Central Administrative Committee, for the current year. In the present number is also published the list of the members of the Academy on January 1, 1889. The following are the English and American corresponding members:—*Geometry:* James Joseph Sylvester, George Salmon. *Astronomy:* John Russell Hind, J. C. Adams, Arthur Cayley, Joseph Norman Lockyer, William Huggins, Simon Newcomb, Asaph Hall, Warren De La Rue, Benjamin Althorp Gould, Samuel Langley. *Geography and Navigation:* Admiral G. H. Richards. *General Physics:* James Prescott Joule, George Gabriel Stokes. *Chemistry:* Edward Frankland, Alexander William Williamson. *Mineralogy:* James Hall, Joseph Prestwich. *Botany:* Joseph Dalton Hooker, Maxwell Tylden Masters. *Rural Economy:* Sir John Bennet Lawes, Joseph Henry Gilbert. *Anatomy and Zoology:* James Dwight Dana, Thomas Henry Huxley. *Medicine and Surgery:* Sir James Paget. Foreign Associates: Sir Richard Owen, Sir George Biddell Airy, Sir William Thomson.

January 14.—M. Des Cloizeaux in the chair.—On the solar statistics of the year 1888, by M. R. Wolf. From the various solar and magnetic observations made at the Observatories of Zurich and Milan, M. Wolf has by his well-known method deduced and tabulated for last year the mean monthly values for the relative number r, for the variations in declination v, and for the increase Δr and Δv that these quantities have received since the corresponding epochs of the year 1887. It results from these tables that both the relative number and the magnetic variation have continued to diminish, and that it is probable the minimum has now been nearly reached. It also appears that the slight anomalies recorded during the previous year have disappeared, and that the parallelism between these two series has been almost completely re-established.—Mode of diffusion of the voltaic currents in the human organism, by M. L. Danion. From the series of experiments here described it appears that, excepting the skin and bones, the various tissues and substances constituting the organism have practically the same electric conductibility. The skin is in general highly resisting, while the conductibility of the bones, which alone affect the diffusion of the current, is perceptibly less than two-fifths of that of the other hypodermic tissues. Under like conditions the diffused intrapolar and extra-polar intensities have the same value. Contrary to the universal opinion, the choice and combination of electrodes of various dimensions does not perceptibly modify the effects of hypodermic electrization. The experiments made on animals and on man confirm those carried out on homogeneous liquid masses, while at the same time showing the extreme diffusion of the voltaic currents, hence the deductions drawn from the latter order of experiments are applicable to the electrization of the animal organism.—Observations of Faye's comet, made at the Observatory of Algiers with the 0·50 m. telescope, by MM. Trépied, Rambaud, and Sy. These observations cover the period from December 28 to January 5.—On the influence of the shock on the permanent magnetism of nickel, by M. G. Berson. These experiments form a supplement to those lately made by the author with a bar of steel. The various phenomena are in both cases strictly analogous, tending to show that with a field of feeble intensity a bar of either metal may be permanently magnetized, provided the shocks be given while the bar is within the field. The vibrations of the apparatus furnished with permanent magnets should also be carefully avoided, as they tend rapidly to diminish the force of the magnetic momentum.—On the oxidation and scouring of tin, by M. Léo Vignon. In a previous communication (*Comptes rendus*, November 5, 1888) the author showed that crystallized tin, deposited by the action of zinc and of the chemically neutral solutions of the stannous or stannic chlorides, is capable of high oxidation, and also when heated in contact with the air presents the curious property of combining with oxygen without melting, but burning like tinder (*amadou*). His further experiments with this partially oxidized tin have disclosed several facts, which explain the phenomena already described, and at the same time supply the elements of the theory on which depend the common industrial operations known as tinning and tin-soldering. In general it may be concluded that tin is capable of considerable oxidation in a dry or moist atmosphere, a conclusion which agrees with the comparative data already obtained on the heats of formation of the metallic oxides.—On ergosterine, a new immediate principle of the ergot (spur) of rye, by M. C. Tanret. The ergot of rye contains a crystallized substance, which closely resembles, and may readily be confounded with, cholesterine. But the careful study made by M. Tanret of this fungus shows that it differs in its composition both from animal cholesterine and its isomerous vegetable substances. This new principle is accordingly here described and analyzed under the name of ergosterine. Its composition may be represented by the formula—

$$C_{52}H_{40}O_2, H_2O_2.$$

It crystallizes in alcohol in the form of little pearly pellets, and in ether in that of sharp needles, and is quite insoluble in water. Like cholesterine, it is a monatomic alcohol, as appears from the analysis of its formic, acetic, and butyric ethers.—Papers are contributed by M. Hugo Gyldén, on the elementary terms in the co-ordinates of a planet; by M. Maquenne, on the heptine of a perseite; by MM. Ed. Heckel and Fr. Schlagdenhauffen, on the chemical constitution and industrial value of the gutta yielded by *Bassia latifolia*; and by M. Hueppe, on the virulence of cholera parasites.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Annuaire de l'Académie de Belgique, 1889 (Bruxelles).—Longmans' School Arithmetic with Answers: F. E. Marshall and J. W. Welsford (Longmans).—Biologia Centrali-Americana (Botany): W. B. Hemsley and Sir J. D. Hooker.—Hulfstabellen zur Mikroscopischen Mineralbestimmung in Gesteinen: H. Rosenbusch (Stuttgart, Koch).—Les Minéraux des Roches: A. M. Lévy and A. Lacroix (Paris, Baudry).—A Course of Easy Arithmetical Examples for Beginners: J. G. Bradshaw (Macmillan).—Solutions of the Examples in a Treatise on Algebra: C. Smith (Macmillan).—Calendar and General Directory of the Department of Science and Art for the Year 1889 (Eyre and Spottiswoode).—A Monograph of the British Uredineæ and Ustilagineæ: C. B. Plowright (Kegan Paul).—Graphics, or the Art of Calculation by Drawing Lines, Part 1: R. H. Smith (Longmans).

CONTENTS.

THURSDAY, JANUARY 31, 1889.

MIND IN MAN AND BRUTE.

Mental Evolution in Man: Origin of Human Faculty. By G. J. Romanes, M.A., LL.D., F.R.S. (London: Kegan Paul, Trench, and Co., 1888.)

THE subject with which Mr. Romanes deals in this volume is one which presents great, if not insuperable, difficulties. Whether or not there be a difference in kind—that is, in origin—between the mind of man and the mind of the brute, it is only in terms of the former that the latter can be interpreted. We can only reach minds other than our own by an ejective process of inference. Fully admitting that the evidence is amply sufficient to justify us in inferring the existence of mental processes in our dumb companions, the fact remains that there are enormous difficulties in getting at the nature of these mental processes. Our mental life is carried on in a rare atmosphere of self-conscious conceptual thought. And before we can put ourselves ejectively into the place of the brute, we have to divest ourselves of our conceptual habiliments; nay, more, we have—if current views be correct—to strip off the inner garment of our self-consciousness. Hence, some thinkers are driven to the extremity of agnosticism in this matter, and hold with Prof. Max Müller that, "according to the strict rules of positive philosophy, we have no right to assert or deny anything with reference to the so-called mind of animals." This, no doubt, is going too far. But, seeing that mind in the animal world and in very young children has to be interpreted not only by, but also in terms of, human consciousness, it behoves the investigator to at least express his opinions with becoming modesty. I cannot say that Mr. Romanes's modesty is obtrusive. There is, indeed, a tone of "cocksureness" ill befitting the subject in hand, and painfully marring the dignity of a work the ability and earnestness of which are conspicuous.

The problem which Mr. Romanes has set himself to solve in this volume is the genesis of self-consciousness and conceptual thought. He therefore begins by analyzing and classifying *ideas.* "Psychologists," he says, "are agreed that what they call particular ideas, or ideas of particular objects, are of the nature of mental images, or memories of such objects—as when the sound of a friend's voice brings before my mind the idea of that particular man. Psychologists are further agreed that what they term general ideas arise out of an assemblage of particular ideas, as when, from my repeated observation of numerous individual men, I form the idea of man, or of an abstract being who comprises the resemblances between all these individual men, without regard to their individual differences. Hence, particular ideas answer to percepts, while general ideas answer to concepts." This twofold classification, thus broadly and somewhat unsatisfactorily stated, Mr. Romanes deems inadequate. Defining *idea* as a generic term to signify indifferently any product of imagination, from the memory of a sensuous impression up to the result of the most abstract generalization, he classifies as under.

A "simple idea," "particular idea," or "concrete idea," is the mere memory of a particular sensuous perception.

A "compound idea," "complex idea," or "mixed idea," is the combination of simple ideas into that kind of composite which is possible without the aid of language.

A "general idea," "abstract idea," "concept," or "notion," is that kind of composite idea which is rendered possible by the aid of language, or by the process of naming abstractions as abstractions.

With regard to these, he says that the first division has to do only with what are termed percepts, while the last has to do with what are termed concepts. And there being no word to meet the middle division, he coins the term *recept* (= generic idea), which appears to him exactly to meet the requirements of the case, because in *receiving* such ideas the mind is passive, whereas in conceiving abstract ideas the mind is active.

I do not regard this classification as very satisfactory, and I doubt whether it will find much favour among modern psychologists. Regarding, as I do, every percept as a synthesis effected by the mind at the bidding of a sense-impression, I am not prepared to regard the mind as passive in what Mr. Romanes calls "reception." And I think that a subdivision of percepts into particular and generic would have been sufficient to meet all the requirements of Mr. Romanes's argument. As it is, he narrows down perception to a very limited province; for he admits that the ideation of infants is from the first generic. Throughout the whole of this chapter on *ideas*, Mr. Romanes seems to ride the "sensitive plate" analogy too hard. His percepts are photographs of particular objects; his recepts are composite photographs, like Mr. Galton's picture of the average blackguard. But this is to lose sight of the activity of mind, which, automatic though it be, is none the less real. In the great body of percepts and recepts there is far more give than take in the mental operation involved.

Turning to one of the examples of what, I presume, Mr. Romanes regards as a recept, he says: "All the higher animals have general ideas of 'good-for-eating' and 'not-good-for-eating,' *quite apart from any particular objects of which either of these qualities happens to be characteristic.*" I very much question whether any animals have the power of isolating qualities, implied in the words I have italicized. Nor should I call the idea of such an isolated quality either a percept or a recept. A dog may, by an automatic action of the mind, build into his percepts or recepts the element of niceness or nastiness as part of the object constructed by mental synthesis. But this is a very different thing from having a general (or generic) idea of niceness or nastiness apart from the object. Such an idea is the result of analysis, and the hanging of the isolated results of analysis on separate name-pegs.

Much of Mr. Romanes's work is necessarily devoted to language, and here, although he does not profess to speak as an expert, will be found much that will repay careful perusal. He introduces the term "denominative" for a sign consciously bestowed as such with a full conceptual appreciation of its office and purpose as a name. He considers that a parrot may use *bow-wow* as a denotative sign for a particular dog, and then extend it to other dogs, thus using it as a connotative sign. No parrot, however, could employ a word in its truly denominative sense. This is a conceptual, as opposed to a merely re-

ceptual, act. Natural or conventional signs may thus be built, by the animal, into the structure of its percepts or recepts. They cannot be consciously given for the purposes of conceptual thought. Mr. Romanes, at this stage of his inquiry, extends his classification, marking off four stages of ideation.

(1) *Lower recepts*, comprising the mental life of all the lower animals, and so including such powers of receptual connotation as a child when first emerging from infancy shares with a parrot.

(2) *Higher recepts*, or *pre-concepts*, comprising all the extensive tract of ideation that belongs to a child between the time when its powers of receptual connotation first surpass those of a parrot up to the age at which connotation as merely connotative begins to become denominative.

(3) *Lower concepts*, comprising the province of conceptual ideation when this first emerges from the higher receptual, up to the point where denominative connotation has to do, not merely with the naming of recepts, but also with that of associated concepts.

(4) *Higher concepts*, comprising all the further excellencies of human thought.

With this apparatus of terms, Mr. Romanes is prepared to enter upon the question of self-consciousness, which, he says, consists in paying that same kind of attention to internal or psychical processes as is habitually paid to external or physical processes, or in bringing to bear upon subjective phenomena the same powers of perception (*sic*) as are brought to bear upon the objective. I question whether Mr. Romanes's opponents will be quite satisfied with this definition. Starting with it, however, Mr. Romanes contends that, "given the protoplasm of the sign-making faculty so far organized as to have reached the denotative stage; and given also the protoplasm of judgment so far organized as to have reached the stage of stating a truth without the mind being yet sufficiently developed to be conscious of itself as an object of thought, and therefore not able to state to itself a truth as true; by a confluence of these two protoplasmic elements an act of fertilization is performed, such that the subsequent processes of mental organization proceed apace, and soon reach the stage of differentiation between subject and object." In working out this contention he makes use of the fact that a large number of the recepts of the brute have reference, not to objects of sense, or even to muscular sensations, but to the mental states of other animals. We wish he had given us more information on this head—not as to the fact, which can hardly be questioned, but as to the mode of origin of this ejective element, and as to how far such an element modifies the perceptual or receptual nature of the mental product or synthesis into which it enters. The ejective element is so purely inferential, and would seem to be reached by so indirect a process through the mental states of the animal itself, that further information on Mr. Romanes's view of the matter would have been welcome. Proceeding, however, from this basis, he takes it to be a matter of general observation that animals habitually and accurately interpret the mental states of other animals, while they well know that other animals are similarly able to interpret theirs—as is best proved by their practising the arts of cunning, concealment, hypocrisy, &c. Thus the truth is "gradually borne in upon the mind of an animal that it is a separate individuality; and this, though it is conceded that the animal is never able, even in the most shadowy manner, to think about itself as such. In this way there arises a sort of 'outward self-consciousness,' which differs from true or inward self-consciousness only in the absence of any attention being directed upon the inward mental states as such." Turning then from the animal to the child, Mr. Romanes contends that at an early age he only possesses outward or receptual self-consciousness. As yet he has paid no *attention* to his own mental states further than to feel that he feels them: he speaks to and of himself in the third person or by his proper name. "The change of a child's phraseology from speaking of self as an object to speaking of self as a subject does not take place—or but rarely so—till the third year. When it has taken place, we have definite evidence of true self-consciousness, though still in a rudimentary stage." These in brief—and it is difficult to condense the argument into a small compass—are the steps by which Mr. Romanes ascends to rudimentary self-consciousness as it first dawns upon the child-mind. I find myself unable either to accept or to criticize Mr. Romanes's account of the genesis of self-consciousness. I have read and re-read it, but find myself incapable of thinking myself into the gradually ascending stages. I fail adequately to imagine the mental condition of the dog or the very young child in which outward or receptual, and eventually inward or conceptual, self-consciousness is being evolved. I believe with Mr. Romanes that the evolution has taken place; but I fail to realize the *how*. This is, of course, not his fault: he gives me the steps of the process; he cannot give me the capacity to conceive them. In any case, Mr. Romanes claims to have shown—and how far the claim is justifiable the reader must determine for himself—"that, in whatever way we regard the distinctively human faculty of conceptual predication, it is proved to be but a higher development of that faculty of receptual communication, the ascending degrees of which admit of being traced through the brute creation up to the level which they attain in a child during the first part of its second year,—after which they continue to advance uninterruptedly through the still higher receptual life of the child, until, by further though not less imperceptible growth, they pass into the incipiently conceptual life of the human mind."

I have left myself no space to deal with the purely philological part of the work. I may note, however, that, in speaking of the roots into which language may be analyzed, Mr. Romanes contends that they can only be regarded as original or primary in the sense that they are the ultimate results of analysis, *i.e.* that they are not original in the sense of representing the ideation of really primitive man; and, again, that they for the most part stand for named recepts or lower concepts, and in a comparatively small degree for higher concepts or the results of conceptual analysis. In both these contentions I conceive he is right. Speaking as a layman of the work of one who freely admits that he is not an expert, the philological analysis seems to me extremely well done.

In conclusion, I would congratulate Mr. Romanes on this his latest volume, which undoubtedly contains much excellent and painstaking work. If I am not altogether satisfied with his psychology; if I am unable to agree

with him that "the phases of development which have gradually led up to conceptual thought admit of being as clearly traced as those which have led to any other product, whether of life or of mind"; if I even go further, and confess my belief that mental evolution never will be and never can be independently established, though it may be accepted as a corollary from organic evolution by those who are content to remain naturalists;—this does not lead me to welcome any the less cordially the valuable researches of Mr. Romanes in a very interesting but exceedingly difficult field of investigation.

C. LLOYD MORGAN.

THE MICROSCOPICAL STUDY OF MINERALS IN ROCKS.

Microscopical Physiography of the Rock-making Minerals: an Aid to the Microscopical Study of Rocks. By H. Rosenbusch. Translated and Abridged for use in Schools and Colleges by Joseph P. Iddings. Illustrated by 121 Woodcuts and 26 Plates of Photomicrographs. (New York: John Wiley and Sons. London: Macmillan and Co., 1888.)

Hülfstabellen zur mikroskopischen Mineralbestimmung in Gesteinen. Zusammengestellt von H. Rosenbusch. (Stuttgart: E. Koch, 1888.)

Les Minéraux des Roches. Par A. Michel-Lévy et Alf. Lacroix. (Paris: Libraire Polytechnique, Baudry et Cie. 1888.)

IT has been well said that this is an age of books. With equal propriety it might be characterized as an age of text-books. Indeed, so rapidly do these aids to learning increase and multiply, that it seems almost incredible that any rational proportion can still exist between demand and supply. In works on petrography, the year just passed away has been exceptionally fruitful. From the ponderous tome, replete with detail and illustrated by magnificent plates, down to the superficial shilling primer, we have before us a remarkable series of volumes in which rocks and their constituent minerals are treated from all the most recent points of view. It was in the early months of 1888 that Prof. Rosenbusch's invaluable "Mikroskopische Physiographie," was completed by the publication of the second part of Volume II., and the same year has also witnessed the appearance of Mr. J. P. Iddings's translation of the first volume, on the "Mikroskopische Physiographie der petrographisch wichtigen Mineralien." The usefulness of this book as a work of reference cannot be over-rated, as will be acknowledged by all those who have had occasion to use it. Unfortunately, it has hitherto been sealed to those who possessed no knowledge of German, and Mr. Iddings has earned the thanks of English-speaking petrographers in undertaking its translation, a task involving no inconsiderable amount of patient labour.

In the English edition the book has been slightly abridged, but in doing this the translator has "endeavoured to retain all that appeared essential to a fair general comprehension of the subject, omitting what seemed to be refinements beyond the need of the average student, and for which the advanced student is referred to the original work. Thus most of the historical portions have been omitted, as well as the elaborate treatment of the optic anomalies of certain minerals, and many notes on European localities; while a number of notes on American occurrences have been inserted." We cannot help thinking, however, that it would have been an advantage to retain the alphabetical index to petrographical literature, which, on account of its completeness, forms one of the most valuable features of Prof. Rosenbusch's work. Reference to original sources should be encouraged to the utmost in a students' book.

Mr. Iddings has added some useful information on allanite, or orthite, as some prefer to name it. According to his researches, carried out in conjunction with Mr. Whitman Cross, the occurrence of this mineral as an accessory constituent of rocks is much more wide-spread than is usually supposed. These authors have shown it to be widely distributed through a great variety of rocks in the United States, it having been found in gneiss, granite, granite-porphyry, quartz-porphyry, diorite-porphyrite, andesite, dacite, and rhyolite. It is possible that it has sometimes escaped recognition, owing to its resemblance in colour and pleochroism, to some varieties of hornblende and biotite. It may, however, be distinguished from the former by its higher double refraction, and from the latter by its larger optic axial angle.

The translator must be congratulated on the very successful way in which he has rendered the original into clear and concise English, while keeping strictly within the author's meaning; indeed, were any fault to be found with Mr. Iddings's style, it would perhaps be that he has a tendency to translate too literally. But this is erring on the safe side. Occasionally, however, he goes to the other extreme, the translation becoming so free as to be inaccurate, as, for instance, when "*crystallinische Schiefer*" is rendered "Archæan formation," so that phenomena of dynamic metamorphism (such as the marginal crushing of crystals, or "cataclastic structure"), that are common to the crystalline schists of whatever age, are thereby limited, inferentially of course, to rocks of Archæan age (pp. 251, 277, 279, 284, 307, 309, 310). The word *Sphärokrystal* has been rendered *spherulite*, on the ground that the latter has become well established in English literature. This is true; but the word spherulite is equally well known in Germany. On p. 392 of the "Physiographie der massigen Gesteine," Prof. Rosenbusch carefully distinguishes between the meanings he attaches to *spherocrystal* and *spherulite* respectively; the former being applied by him to spherular bodies consisting of radially-aggregated fibres of a single mineral (*e.g.* chlorite), the latter to those imperfectly individualized fibrous bodies so common in vitreous rocks.

In one or two instances only has Mr. Iddings been led astray by the peculiarities of the German idiom. The most serious of these slips occurs on p. 286, where we read that, "in the so-called pseudomorphs of cassiterite after orthoclase from Huel Coates, tourmaline and quartz, besides cassiterite, *form a principal part of the muscovite.*" The meaning of the original, which is, it is true, somewhat ambiguously expressed, is, that besides cassiterite, tourmaline, and quartz, muscovite forms one of the principal constituents of the pseudomorphs after orthoclase from Huel Coates.[1]

[1] "Auch bei der sog. Pseudomorphose von Cassiterit nach Orthoklas von Huel Coates im Kirchspiel St. Agnes, Cornwall, bildet neben Cassiterit, Turmalin und Quarz der Muscovit einen Hauptgemengtheil."

Typographical errors are rather numerous; but these, with few exceptions, are corrected in the page of errata inserted after the title-page.

Prof. Rosenbusch's "Tables for the Microscopic Determination of Minerals in Rocks" is one of the most useful compilations which have appeared for some time. It has doubtless been suggested by, and to some extent modelled on, Dr. E. Hussak's "Anleitung zur Bestimmung des gesteinsbildenden Mineralien," which, in spite of numerous inaccuracies, was found to be in such demand among students that soon after its publication it was translated into English, errors and all. Tables of this kind are sure to be favourably received by the practical worker, on account of the saving in time and labour resulting from their use, a single glance being sufficient to obtain all the requisite information about a given mineral. The book consists of nine two-page tables, in which we find recorded data concerning the cleavage, form, crystallographic development, colour, pleochroism, indices of refraction, optic orientation, dispersion, crystal-system, specific gravity, behaviour with reagents, and chemical composition of all the minerals occurring in rocks, whether as essential or accessory constituents. Many will be surprised to hear that these amount to as many as 190. There can be no hesitation in predicting a wide circulation for this very serviceable little book. An English edition is being prepared, we understand, by Messrs. Swan Sonnenschein and Co.

"Les Minéraux des Roches," by Messrs. A. Michel-Lévy and A. Lacroix, is a more elaborate work, dealing with the same subject. This book, as we are informed in the preface, is complementary to the "Minéralogie Micrographique," published in 1878 by the first-named author in collaboration with M. Fouqué. It is divided into two parts: (1) the application of optical and chemical methods to the microscopical study of minerals, by A. Michel-Lévy alone; (2) a descriptive summary of the principal minerals occurring in rocks, by both authors.

The first part contains a mathematical exposition of the optical properties of minerals, which, though tending occasionally to abstruseness, is characterized by a true French elegance of treatment, the excellent use made of curves in representing graphically the variation of extinction-angles being especially worthy of commendation. On p. 54 we have a description of an instrument for the measurement of double refraction, which has been constructed for the author by M. Nachet, the celebrated Parisian microscope-maker. The *comparateur*, as it is named by its inventor, consists of a special eye-piece, to which is attached an arrangement of prisms and lenses, by which the tint and luminous intensity of a given mineral can be compared with those of a movable quartz wedge. A series of measurements of the double refraction of the principal rock-forming minerals, made by the authors with this instrument, follow on p. 66, together with the colours presented by plates of 0·01, 0·02, and 0·03 mm. respectively. At the end of the book there is also a magnificent plate, representing Newton's scale of colours up to the fifth order. By an ingenious contrivance, the colours given by the different minerals are shown for thicknesses ranging between 0 and 0·06 mm.

In the second part of the book the minerals are arranged in accordance with a scheme which is partly alphabetical, partly systematic—*i.e.* the members of a natural group (*e.g.* the felspars, micas, amphiboles, and pyroxenes) have not been separated. This method is, perhaps, not quite satisfactory, as the advantage of an alphabetical arrangement is in great part lost, while at the same time the systematic classification is necessarily incomplete. But reference to the minerals is much facilitated by an excellent index.

This part of the book contains a number of new determinations made by the authors, who have "endeavoured," and let us add with success, "to make it as complete as is consistent with the present state of the science." It concludes with a synoptical table, in which the optical data are again briefly recapitulated.

F. H. H.

SEWAGE TREATMENT, PURIFICATION, AND UTILIZATION.

Sewage Treatment, Purification, and Utilization. By J. W. Slater, F.E.S. (London: Whittaker and Co., 1888.)

THIS is the work of an advocate of chemical precipitation processes for the treatment of sewage. It cannot claim to be an impartial review of the "sewage question," for the bias of the author is exhibited in nearly every page. The author is evidently of opinion that his case is likely to derive support from what is known as *argumentum ad hominem*, or abuse of the other side (those who hold different views from his own). The Rivers Pollution Commissioners come in for a considerable share of these attentions, as the following passages will show:—"Such a man was by nature qualified for a Royal Commissioner, who can never admit that either himself or any of his predecessors can have been mistaken" (p. 165). The spoiling of an effluent from a chemical precipitation process by fermentation of the deposited sediment is spoken of as a result "to gladden the heart, and for once justify the representations of ex-Royal Rivers Pollution Commissioners" (p. 172). "Mr. Bailey-Denton—who seems to be to Prof. Frankland what Ali was to Mahomed and Mr. Grant Allen to Charles Darwin" (p. 79). The Royal Commissioners on Metropolitan Sewage Discharge are alluded to in the following terms (p. 86): "That Commission refused or neglected—and in such a case these two terms are nearly equivalent—to examine fully and fairly into the merits of precipitation. . . . It would not, or at least did not, visit Aylesbury. It was satisfied to condemn precipitation on the faith of the archaic reports of the Royal Rivers Pollution Commissioners, reports which, if true at the date when written—and this is a fairly strong concession—are demonstrably false if applied, *e.g.*, to the process now in operation at Aylesbury."

It will perhaps raise a smile amongst *connoisseurs* in sewage matters to learn that managers of sewage works require protection from the (dishonourable) tricks of critical visitors. The author, at any rate, believes their innocence is likely to be imposed upon. He writes (p. 168):—"A few hints may here be given about sampling effluents for analysis or for preservation. I write here mainly for the guidance of officials left in charge of

sewage works, that they may know what tricks may be attempted. It is commonly said 'that any stick is good enough to beat a dog with,' and on a similar principle, any unfair, dishonourable stratagem is held legitimate to bring discredit on a process for the chemical treatment of sewage." "Another necessary precaution relates to sampling. If any visitor asks for a sample, it should be given him solely on the condition that he takes and seals up at the same time a check sample, to be left at the works for analysis by some independent chemist. Without this precaution he may, for instance, add to his sample a little urine or blood, or a culture solution, and still represent it as a normal sample" (p. 170). These passages serve to show the opinion in which the author holds his brother experts.

It is very plain that the author rejects *in toto* all experience but what is favourable to his own views. The following passage is a specimen of the assertions constantly made throughout the book:—"Just in proportion as a sewage is purified by precipitation, its manurial value for irrigation will decrease down to that of plain water" (p. 70). This statement, which implies that complete purification is attainable by precipitation processes, is at total variance with the truth, and has been disproved over and over again; but it is a sufficient index of the kind of treatment the subject throughout receives.

On the subject of sewage manures the author quotes, as representative of their average composition and value, the results of Dr. Tidy's analysis of the sewage manure from the "A.B.C." process at Aylesbury. Can the author not be aware that the Aylesbury manure has become one of the wonders of the scientific world? How is it that the "A.B.C." process can convert a nearly worthless substance—sewage sludge—into a rich and paying manure? Can the author tell us?

OUR BOOK SHELF.

The International Annual of Anthony's Photographic Bulletin. Edited by W. Jerome Harrison, F.G.S., and A. H. Elliot, Ph.D. (London: E. and H. T. Anthony and Co., 1888.)

IN the pages of this volume we have a valuable collection of articles written by men many of whom are eminent in the art and science of photography.

At the present day, considering the great number working, either as amateurs or professionals, at this subject, and that that number is still on the increase, and also the numerous books that have been published, one would think it hard for another work to differ a great deal from those preceding it. The editors, in their preface, tell their readers to "partake of and enjoy the feast that they have set before them; and, if the viands tickle their palates, praise rather the maker of that particular dish than those who have spread the table."

The present work consists of a popular account of nearly every branch of the subject, including stellar photography.

The volume is beautifully illustrated by specimens of various methods of printing, engraving, &c. The appendix contains a list of Photographic Societies of the British Isles, colonies, and of America, with numerous tables.

The editors have produced a volume which will not only be appreciated by members of the photographic world, but will be interesting to any ordinary reader.

Instruction in Photography. By Captain W. de W. Abney, C.B., R.E., F.R.S. Eighth Edition. (London: Piper and Carter, 1888.)

ALL that is needed for photographers, whether amateur or professional, will be found in this well-known book, which has been thoroughly revised and brought up to date. By the addition of new matter the volume has been slightly increased, and an alteration of some importance consists in the introduction of both the French and English measures for the various formulæ used throughout.

The work is profusely illustrated, and the least we can say is that no studio ought to be without it.

Lessons in Elementary Physics. By Balfour Stewart, M.A., LL.D., F.R.S. New and Enlarged Edition. (London: Macmillan and Co., 1888.)

THE present edition of this well-known book was prepared only in part by the late author. The task has been completed by Mr. W. W. Haldane Gee, B.Sc., Lecturer of the Victoria University. No material alterations have been made, except in the chapters relating to electricity and magnetism, which have been rearranged, and expanded by the addition of new matter and figures.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Supposed Fossils from the Southern Highlands.

IN the article in your last number upon my paper lately read before the Royal Society of Edinburgh, respecting the discovery of some supposed annelid tubes in the quartzites of Loch Fyne, some observations are made on the interest attaching to the question as bearing on the geological horizon of the metamorphic series which constitute the great bulk of the South-Western and Central Highlands. With reference to this question, however, I am anxious to disclaim attaching any great importance to the discovery of annelids, because I do not admit that any real doubt exists as to the Silurian horizon to which our rocks were referred by Murchison. In this country, particularly, the evidence seems to me complete whether fossils be, or be not, found in them; because in this country we have complete stratigraphical evidence from the occurrence of a small local coal-basin in the district of Kintyre. The backbone of that long peninsula consists of the same metamorphic rocks as the rest of the country. Along its shores it is fringed by cakes of Old Red Sandstones which have resisted denudation, or have survived destructive dislocations. At the southern end of the peninsula these sandstones have survived in considerable masses—including beds of conglomerate, of freestone, and of limestones. All these beds rest unconformably on the metamorphic schists and limestones, whilst they are, again, also to be seen dipping and passing under the coal-measures and Carboniferous limestones in their usual and natural order. There can be no doubt of the order of succession in this case, and it establishes the position of our metamorphosed slates and quartzites as rocks which belong to the horizon below the Old Red.

Of course, the discovery of fossils would put an end to the new surmise that they are not sedimentary deposits at all, but intrusive rocks, simulating true bedding in consequence of "foliation," or some other process of mineralization. But this surmise is so wild that I feel no doubt about its early disappearance.

In this, I believe Dr. Geikie entirely agrees; and he has consequently expressed a confident expectation that fossils will be found in our schists and quartzites some day.

I may add that since my return from Edinburgh a correspon-

dent has sent to me an unmistakable specimen of annelid piping from a rock at Killin. Now that we are all on the scent, I have no doubt that my Loch Fyne worms will be found at the head of a long procession. ARGYLL.

Inveraray, January 28.

Mr. Howorth on the Variation of Colour in Birds.

PERMIT me to point out that the fact cited by Mr. Howorth (*antea*, p. 294), of the similarity between the birds of Western Europe and those of Japan, which, according to him, illustrates "from an unexpected quarter" the views expressed in his work "The Mammoth and the Flood," is by no means so novel as the general reader might, from his communication, suppose. On the contrary, it has been before the world for more than half a century, and is, or ought to be, familiar to every well-informed ornithologist, since it was in 1835 that Temminck gave ("Manuel d'Ornithologie," Part 3, Introd. pp. l.–liii.) a list of 114 species of birds, which he said were common to the Japanese Empire and to Europe. It has subsequently been shown that this number was exaggerated; but, as observed in 1857 by Mr. Sclater, in his classical paper on the geographical distribution of birds, "there can be no question as to the general strong resemblance of the Japanese avifauna to that of Europe" (Journ. Linn. Soc., Zoology, ii. p. 134).

That the birds of Siberia differ in appearance from those of Japan and of Western Europe has also been abundantly shown by the long succession of illustrious explorers and naturalists from whom we derive all but an infinitesimally small portion of our knowledge of Siberian and Central Asiatic zoology; but Mr. Howorth does not seem to be aware that another hypothesis has usually been brought forward to account for that difference, as well as for the similarity of the Japanese avifauna and our own. In regard to the latter, this hypothesis has been propounded to my certain knowledge for more than five-and-twenty years (*Ibis*, 1863, p. 189); and, whether true or false, has not, so far as I am aware, been refuted. It is that the resemblance is an effect due to "the prevalence in both localities of an insular, as opposed to a continental climate," for it has been observed over and over again in various parts of the world (and not only in birds) that island forms possess a darker coloration than their continental representatives (*cf.* Gould, Proceedings of the Zoological Society, 1855, p. 78), while the fact that neither British nor Japanese birds exhibit the brilliant hues of their continental kinsfolk is notorious.

Another remark upon Mr. Howorth's communication I would offer. His theory, of which he has "little doubt," that "the willow grouse of the Continent is an altered form, and that our red grouse is the parent," is not new, but was definitely stated some eight or nine years ago in the "Encyclopædia Britannica," from the article "Grouse" in which I venture to quote a passage showing that there is a side of the question which he does not seem to have considered.

"A very interesting subject for discussion would be whether *Lagopus scoticus* or *L. albus* has varied most from the common stock of both. We can here but briefly indicate the more salient points that might arise. Looking to the fact that the former is the only species of the genus which does not assume white clothing in winter, an evolutionist might at first deem the variation greatest in its case; but then it must be borne in mind that the species of *Lagopus* which turn white differ in that respect from all other groups of the family *Tetraonidæ*. Furthermore, it must be remembered that every species of *Lagopus* (even *L. leucurus*, the whitest of all) has its first set of *remiges* coloured brown. These are dropped when the bird is about half-grown, and in all the species but *L. scoticus* white *remiges* are then produced. If, therefore, as is generally held, the successive phases assumed by any animal in the course of its progress to maturity indicate the phases through which the species has passed, there may have been a time when all the species of *Lagopus* wore a brown livery even when adult, and the white dress donned in winter has been imposed upon the wearers by causes that can be easily suggested, for it has been freely admitted by naturalists of all schools that the white plumage of the birds of this group protects them from danger during the snows of a protracted winter. On the other hand, it is not at all inconceivable that the Red Grouse, instead of perpetuating directly the more ancient properties of an original *Lagopus* that underwent no great seasonal change of plumage, may derive its ancestry from the widely-ranging Willow-Grouse, which, in an epoch comparatively recent (in the geological sense), may have stocked Britain, and left descendants that, under conditions in which the assumption of a white garb would be almost fatal to the preservation of the species, have reverted (though doubtless with some modifications) to a comparative immutability essentially the same as that of the primal *Lagopus*."

In conclusion, let me recommend those interested in the local variation of colouring in the plumage of birds to study Gloger's "Das Abändern der Vögel durch Einfluss des Klima's" (Breslau, 1833), a treatise which, though naturally out of date in many respects, contains much that ornithologists would be the better for not overlooking. ALFRED NEWTON.

Magdalene College, Cambridge, January 26.

Constitution of the Chlorides of Aluminium and the Allied Metals.

IN NATURE of December 27 (pp. 198–200), Dr. Young has directed the attention of your readers to the formulæ of the so-called hexachlorides, R_2Cl_6, and bodies of similar constitution. As this question possesses a great theoretical interest, I may be allowed to say a few words about it.

The constitution of the chlorides R_2Cl_6 was regarded by Friedel as analogous to that of carbon hexachloride, $Cl_3{\equiv}C{-}C{\equiv}Cl_3$, and the metals themselves were said to be tetravalent. Mendelejeff, in his classical paper on the periodic law—a gem of chemical literature—was the first to point out that it is not necessary to regard aluminium in Al_2Cl_6 as tetravalent, but that a compound of this formula represents only a molecular combination—a polymeric state—of $AlCl_3$. This view was very little regarded by chemists. It was, ten years later (Proc. Vienna Acad., 1882), extended by the author of the present lines, to other bodies of similar constitution, and it was shown that several chlorides give a vapour consisting partly or entirely of polymeric modifications of the simple chloride. So we have the molecules $Sn_2Cl_4{-}SnCl_2$, $Fe_2Cl_4{-}FeCl_2$ ($N_2O_4{-}NO_2$), and it was supposed that other substances of similar constitution would split up into simpler molecules, if they could bear higher temperatures, especially Al_2Cl_6, aluminium belonging to a natural group of *triad* elements, whose other members, viz. B and In, give chlorides of the simple and molecular formulæ, BCl_3 and $InCl_3$. As further instances of the above case may be quoted to-day, $H_2F_2{-}HF$, $Be_2Cl_4{-}BeCl_2$, $Ga_2Cl_6{-}GaCl_3$.

It may, however, be useful to those readers of NATURE who cannot follow completely the current chemical literature, to know that the values of vapour-densities obtained by Dumas's method are not strictly comparable with those obtained by V. Meyer's method; for, as has been shown lately by Victor Meyer and his pupils, especially Biltz, the vapour density of dissociable substances is found smaller by V. Meyer's apparatus than by that of Dumas at one and the same temperature. So Dumas's method shows, for the above chlorides, the existence of double molecules at a temperature at which that of V. Meyer indicates single molecules. It was already pointed out by Dr. Young that the single molecules, $GaCl_2$, $InCl_2$, $InCl_3$, and $CrCl_3$, were found by V. Meyer's method only, and there is no doubt that some of them may be found double by Dumas's method.

The result of the vapour-density determinations of aluminium chloride and the chlorides of the allied metals, carefully collected by Dr. Young in NATURE, is of great theoretical importance, for, as the chlorides RCl_3 exist as single molecules in the gaseous state, the respective metals are undoubtedly *trivalent* in these compounds.

But the question arises, what is the valency of these metals when their chlorides have the double molecule R_2Cl_6?

It is impossible to regard these compounds as analogous to carbon-hexachloride and the said metals as tetravalent, for that compound, when heated to a higher temperature, does *not* split up into two molecules, CCl_3, as the chlorides R_2Cl_6 do. Moreover, it must be admitted that the theory of valency which was developed by the study of organic compounds (*carbon* derivatives) does not strictly hold good in the case of the remaining elements. It is impossible to state the number of "bonds" by which the chlorides RCl_3 are kept together in double molecules, R_2Cl_6. This number is certainly not *one* ($Cl_3R{-}RCl_3$); just as two molecules of $SnCl_2$ in Sn_2Cl_4 cannot be regarded as being united by one bond, $Cl_2Sn'''{-}Sn'''Cl_2$, for no one will assume that tin is trivalent in this compound. If we admit any bonds at all between the two Sn atoms, we must admit two; $Cl_2Sn{=}$

$SnCl_2$. Again, silica (as has been shown by Mendelejeff long before Henry) certainly has a more complicated molecular formula than SiO_2, say $nSiO_2$, otherwise it would be a gas, analogous to CO_2, for $SiCl_4$ boils at 57° and CCl_4 at 76°. But would it be reasonable to say that the SiO_2 molecules are held together by the fifth valency of Si?

The only satisfactory answer to the above question is that in molecules R_2Cl_6 the two RCl_3 groups are held together by their own—let us say residual—affinity.

I think that the study of the question touched in the above lines will greatly add to the development of our theoretical ideas in chemistry, and deserves the careful attention of chemists.

B. BRAUNER.

Bohemian University, Prague, January 8.

IN my letter, referred to by Dr. Brauner, I considered only the molecular formulæ of the chlorides, as indicated by the experimental results.

Dr. Brauner has now, in his interesting letter, enlarged the field of discussion by introducing the question of the constitutional formulæ of these compounds, involving the vexed question of the valency of the elements. Dr. Brauner points out the importance of the proof of the trivalency of these metals in their chlorides when in the gaseous state at high temperatures, and he then discusses the valency of the metals when their chlorides have the formula R_2Cl_6.

Although I am inclined to believe that the views expressed by Dr. Brauner may eventually prove to be correct, yet I cannot help thinking that we are not yet in a position to speak with certainty on one or two points. Dr. Brauner states that the number of "bonds" by which the atoms of the metal in the compounds R_2Cl_6 are united is certainly not *one*, and again, that Sn_2Cl_4 cannot be expressed by the formula $Cl_2Sn'''—Sn'''Cl_2$. But is this quite certain? Indium, the metal next to tin in the seventh horizontal series, is mono-, di-, and tri-valent in the compounds InCl, $InCl_2$, $InCl_3$; is it, then, quite unwarrantable to assume that tin is di-, tri-, and tetra-valent in the compounds $SnCl_2$, Sn_2Cl_4, $SnCl_4$?

As regards silica, $nSiO_2$, the properties of the compound seem to indicate that n is a large number, and here, unless we arrange the Si atoms in a ring, like the carbon atoms in benzene, we must probably look on the compound as "molecular."

It is difficult to find experimental evidence which bears directly on the question; perhaps such results as those obtained by Dr. Ramsay and myself on the dynamical and statical methods of measuring vapour-pressures may throw some light on the matter. We find that the two methods give identical results with ammonium chloride, nitrogen peroxide, and acetic acid, just as they do with all stable solids and liquids, but very different results with all the other dissociating substances examined. This appears to indicate some difference in the molecular arrangement of the two groups of compounds, but it is quite uncertain whether the difference is one between "molecular" and "atomic" compounds, or between compounds formed in a very simple manner, such as $2O_2N = O_2N—NO_2$, and those in which there is a breaking down of a stable molecule, as in the case of chloral hydrate, $Cl_3C—C\begin{smallmatrix}\diagup H\\ \diagdown O\end{smallmatrix} + H.OH = Cl_3C—CH\begin{smallmatrix}\diagup OH\\ \diagdown OH\end{smallmatrix}$.

I am at present engaged in a study of the vapour pressures of halogen compounds by both methods, and it is just possible that some further light may be thrown on this question by the results of the investigation.

SYDNEY YOUNG.

University College, Bristol, January 15.

Remarkable Rime and Mist.

YOU have a letter in NATURE of January 17 (p. 270), signed "Annie Ley," which induces me to add the following:—We had here on January 6 an extraordinary rime formed at a temperature varying between 21°·5 and 25°·7 (1° warmer on the grass than at 4 feet), the air being almost calm. This rime increased in thickness and in length with the height above the ground. The length measured of the deposit on a birch-tree at 5 feet was ⅝ of an inch; at 10 feet, 1 inch; at 15 feet, 1¼ inch; and at 25 feet, 1½ inch. The hoar was nearly horizontal, pointing downwards at an angle of 15°. That deposited on the grass, however, was perpendicular, rising with a thin stem and having a large funnel-shaped head. Suddenly, at 10 a.m. of the 7th (next morning), the whole of the rime (still frozen) fell to the ground, and under the birch-tree of 30 feet in height and 18 feet across (sparse of branches, and none for 10 feet), the fallen rime covered the ground to the depth of rather more than 2 inches, and this, when melted, yielded 0·550 of an inch of water (or 3⅝ inches of rime to 1 of water). The rime on the grass when carefully collected and melted yielded 0·033 of an inch. There was a dense mist whilst the rime was being deposited.

From this elevation (530 feet) we frequently look over dense mists that cover the water of the Bristol Channel and see the hills of Somerset, Devon, Monmouth, and Glamorgan. On the 19th instant, with a hoar frost, over the Bristol Channel was a dense dark mist apparently extending 100 feet into the air. This mist, at 8.30 a.m., rapidly changed on its upper surface to cirri clouds, and then to transparent vapour, and in an hour the whole mist by this process had disappeared. Elsewhere the sky was cloudless. These mists of the Bristol Channel change on their upper surface sometimes to cirro-strati, sometimes to cumuli, and twice they have been known to change to thunder-clouds during the last two years. The change to cirri has only been seen once.

E. J. LOWE.

Shirenewton Hall, near Chepstow, January 22.

Cercyonis alope and *nephele*.

IN his review (NATURE, December 27, 1888, p. 193) of my work on butterflies now in course of publication (in which I receive a far more generous treatment than I am accustomed to), Captin Elwes thinks me illogical in holding to the probable specific distinction of *Cercyonis alope* and *nephele*, and at the same time the specific unity of the Eastern American forms of *Cyaniris pseudargiolus*, *lucia*, *violacea*, and *neglecta*; and suggests as to the former that climatic differences in the regions they respectively occupy may have brought about the distinctions noted.

On general grounds, it seems in the highest degree probable that climatic differences have had much to do with the origin of the different forms in both cases, be they species formed or forming. But surely Captain Elwes is confusing the judgment when he fails to make a distinction between the successive seasonal forms of a digoneutic butterfly, as in the case of *Cyaniris* and de Nicéville's Indian species to which he alludes, and the synchronous variation of a monogoneutic species, like those (or that) of *Cercyonis*.

MODERN VIEWS OF ELECTRICITY.[1]

PART IV.—RADIATION.

XIII.

Possible Accounts of the Faraday and Hall Effects.

THE account I have given of the magnetic rotation of the plane of polarization has made it depend on the phenomenon of hysterĕsis, in a way which may be thus summarized. The value of μ for increasing magnetization is different from that for decreasing magnetization; an electric displacement such as occurs in every half-swing of a light-vibration is resolvable into two opposite circular components, one of which increases, while the other decreases, any magnetization already existing in the direction of the ray: the value of μ affects the speed of transmission of light; hence the two circular components will not proceed at the same pace, and the direction of vibration will infinitesimally rotate. The same thing is repeated at every half-swing, the elemental rotations being all in the same sense, and so the ultimate rotation of the plane of polarization in transparent bodies is accounted for.

[1] Continued from p. 13.

The Hall effect observed in conductors follows at once; for the rotation of a displacement is equivalent to combining it with a small perpendicular displacement; and it is this perpendicular or transverse E.M.F. exerted by a magnetic field which Hall discovered. At the same time, there are one or two facts which militate against this view of the Hall effect, chief among which is the singular behaviour of nickel, which rotates light one way and electric displacement the other way. For some time it was possible to hope for a way out of this through the usual convenient avenue of "impurity"; but now that both experiments have been performed on the same identical piece of metal, still with opposite results, this exit is closed. In this unsettled state, so far as I know, the connection between the rotation of light and the Hall effect at present stands.

It may be well here to repeat the caution, appended as a footnote to the last article, not to assume that this account of the magnetic rotation of light and the Hall effect is true. If true, however, it is convenient as linking the phenomena on to hysterēsis, and the direction of the effect in iron is correctly given—namely, a rotation against the magnetizing current.

Prof. Ewing has since pointed out, in a letter to me, that, attending more precisely to the instruction of his curves, we find the difference in μ for positive and negative magnetizing forces only lasts through a number of cycles for the time during which the final state has been approached, and does not persist after a steady state has been reached. This would make the magnetic rotation of light a function of time; and certain experiments by Villari on spinning a glass disk between the poles of a magnet, so that fresh and fresh portions of glass were continually exposed to the magnetic field, showed a marked falling off in the amount of rotation as soon as high speeds were obtained; thus proving, apparently, that a certain short time was necessary to set up the effect. This experiment, and other modifications of it, want repeating, however.

Prof. Ewing has subsequently expressed a doubt as to whether the kinematic resolution of a displacement into two equal opposite circular components is, under the circumstances, legitimate.

Prof. Fitzgerald has further pointed out that, although when attending to one element only the theory might possibly work, yet, as soon as one takes into account the whole wave-front, it breaks down; for all the main magnetic disturbance lies in the wave-front, as is well known, and the extra magnetic disturbance which I have postulated as a consequence of electrostatic displacement is annulled by interference of adjacent elements.

If I were quite sure that there were no vestige of truth in the suggestion I have made, I should, of course, withdraw it; but, as I do not feel perfectly sure either way, I leave it in a dilapidated condition for the present.

Another and apparently distinct account of the magnetic rotation can also be hinted at, which links the phenomenon on to the facts of thermo-electricity. It labours under worse disadvantages than the preceding, being more hazy.

Referring back to NATURE, vol. xxxvii. p. 12, we find that, to explain what is called the "Thomson effect" in metals, we were led to suppose a connection between one kind of electricity and some kinds of matter more intimate than between the other kind of electricity and the same matter. Thus, the atoms of iron were said to have a better grip of positive electricity than of negative; while copper, on the other hand, had a better grip of negative than of positive. All metals could be arranged in one or other of the two classes, with the exception of lead, which appears to grip both equally. It is the same phenomenon as was originally named by Sir W. Thomson, "the specific heat of electricity in a substance." Certain it is that vibrating atoms of iron push positive electricity from the more rapid to the less rapid places of vibration—that is, from hot to cold—and a whole class of the metals do the same; while another class, like copper, push it from cold to hot.

Permitting ourselves to picture this effect as a direct consequence of the Ohm's law relation between electricity and matter, combined with a special relationship between certain kinds of matter and one or other kind of electricity, a relationship which can exhibit itself in other ways also, we get a possible though rather hazy notion of a Faraday rotation in a magnetic field by supposing that the Amperian molecular currents in these substances consist not of precisely equal positive and negative currents, but of opposite currents slightly unequal; say, for instance, that the density of the positive constituent of the bound ether of a substance is slightly different from that of the negative constituent, so that on the whole the bound ether in a magnetized molecule is slowly rotating one way or the other, at a pace equal to the resultant rotation of its constituents. Suppose that in iron the positive Amperian electric current is the weaker of the two, then the ether, as a whole, will be rotating with the negative current, and accordingly an ethereal vibration entering such a medium will begin to screw itself round in a direction opposite to that of the magnetizing current. Whereas in copper or other such substance it would be rotated the other way.

According to this (admittedly indistinct) view, lead ought to show no rotatory effect at all; and of course, therefore, no Hall effect either. And the classes into which metals are divided by the sign of their Hall effect should coincide with the classes into which the sign of their Thomson effect throws them.

Hall finds that, of the metals he examined, iron, cobalt, and zinc fall into one class, while gold, silver, tin, copper, brass, platinum, nickel, aluminium, and magnesium fall into the other. Now, referring to the thermo-electric results of Prof. Tait, we find iron, cobalt, platinum, and magnesium with a negative sign to their Thomson-effect-coefficient, or with lines in the thermo-electric diagram sloping downwards; while gold, silver, tin, copper, aluminium, and zinc slope upwards, or have a positive sign to their "specific heat of electricity."

According to this, therefore, the discordant metals are zinc, platinum, and magnesium. The proper thing to say under these circumstances is that the metals used in the very different experiments were not pure. They certainly were not; but I do not feel able to conscientiously bolster up so inadequate a theory by help of this convenient fact.

In the *Philosophical Magazine* for May 1885, Mr. Hall gives some more measurements, showing that in bismuth the effect is enormous, and in the same direction as in copper, whereas in antimony it is also great, and in the same direction as in iron. All these things seem to point to some thermo-electric connection—whether it be of the sort I have vaguely tried to indicate, or some other.

Other Outstanding Problems.

Outstanding problems bristle all over the subject, and if I pick out any for special mention it will only be because I happen to have made some experiments in their direction myself, or otherwise have had my thoughts directed to them, and because they have not been so directly called attention to in the body of the articles.

Referring back to the end of Part II., "a current regarded as a moving charge," it is natural to ask, Is this motion to be absolute, or relative to the ether only, or must it be relative to the indicating magnetometer? In other words, if a charged body and a magnetic needle are flying through space together, as, for instance, by reason of the orbital motion of the earth, will the needle experience any deflecting couple?

It is one of many problems connected with the ether

and its motion near gross matter—problems which the experiments of Fizeau (showing that a variable part of ether was bound with matter and transmitted with it, while another constant portion was free and blew through it) began to throw light upon; aberration problems such as have been partially solved by the genius of Stokes; problems connected with the motion of ether near great masses of matter, like those which Michelson is so skilfully attacking experimentally: it is among these that we must probably relegate the question whether absolute or relative motion of electric charges is concerned in the production of magnetic field, and what absolute motion through the ether precisely means. It is doubtless a question capable of being attacked experimentally, but the experiments will be very difficult. I believe that Prof. Ayrton has attempted them.

Referring back to Parts I., II., and III., we find a number of questions regarding momentum left unsettled. Has an electric current any true momentum mechanically discoverable? Now, this question, before it can be answered in the negative, will have to be attacked under a great number of subdivisions. One may classify them thus. Two main heads: (1) When steady, Does a magnet behave in the least like a gyrostat? (2) When variable, Is there a slight mechanical kick on starting or stopping a current? With four or more subsidiary heads under each, viz. (*a*) in metallic conductors; (*b*) in electrolytes; (*c*) in gases; (*d*) in dielectrics.

Suppose the answer turns out negative in metals, it by no means follows that it should be negative in electrolytes too. In fact, as matter travels with the current in the case of electrolytic conduction, it is hardly possible that there is not some momentum, though it may be too small to observe—either a kick of the vessel as a whole at starting and stopping, or a continuous impact on an electrode receiving a deposit. The present writer has looked for these things, but after gradually eliminating a number of spurious effects the result has been so far negative. In a light quill vessel fixed to the end of a torsion arm, the main disturbance was due to variations of temperature which gradually introduced a minute air-bubble, and by kicking this backwards and forwards simulated the effects sought. In the case of the suspended electrode, convection currents in the electrolyte, caused by extra concentration or the reverse, seem determined to mask any possible effect.

One obvious though very troublesome source of disturbance in all cases is the direct effect of terrestrial magnetism on the circuit. To get over this, the writer not only made his circuits as nearly as possible of zero area, but also inclosed them in the iron case of a Thomson marine galvanometer, lent for the purpose by Dr. Muirhead.

In gases, the experiment of Mr. Crookes, where a stream of particles propels a mill inside a vacuum-tube—perhaps even the ancient experiment of the blast from a point—shows that momentum is by no means absent from an electric current through a gas.

To see if there are any momentum effects accompanying variation of electric displacement in dielectrics, the writer has suspended a mica-disk condenser at the end of a torsion arm, and arranged it so that it could be charged and discharged *in situ*. Many spurious effects, but no really trustworthy ones, were observed.

In the writer's opinion the subject is by no means thoroughly explored, and he only mentions his old attempts as a possible guide to future experimenters.

Then, again, there is the influence of light on conductivity. Annealed selenium, and perhaps a few other things, improve in conductivity enormously when illuminated. The cause of this is unknown at present, and whether it is a general property of matter, possessed by metals and other bodies to a slight degree, is uncertain; for the experiments of Börnstein with an affirmative result for the case of metals have been seriously criticized.

Even though metals show no effect, yet electrolytes might possibly do so, but the effect, if any, is small; and it is particularly difficult in their case to distinguish any direct radiation effect from the similar effect of mere absorbed radiation or heat.

The writer has found that a glass test-tube kept immersed in boiling water conducts distinctly better when the blinds of a room are raised than when they are lowered, though nothing but diffuse daylight falls upon it. But as the effect could have been produced by a rise in temperature of about the tenth of a degree, and as the absorption of diffuse daylight is competent to produce a rise of temperature as great as this in the glass of a thermometer-bulb even though immersed in boiling water, he feels constrained to regard the result, though very clear and distinct, as after all a negative one, and has accordingly not published it.

A few months ago I should have put in a prominent position among outstanding problems the production of electric radiation of moderate wave-length, and the performance with this radiation of all the ordinary optical experiments—reflection, refraction, interference, diffraction, polarization, magnetic rotation, and the like. But a great part of this has now been done, and so these things come to be now mentioned under a different heading.

Conclusion.

"Conclusion" is an absurd word to write at the present time, when the whole subject is astir with life, and when every month seems to bring out some fresh aspect, to develop more clearly some already glimpsed truth. The only proper conclusion to a book dealing with electricity at the present time is to herald the advent of the very latest discoveries, and to prepare the minds of readers for more.

Referring back to Part IV., vol. xxxviii. p. 418, we spoke confidently of a radiation being excited by electric oscillations, a radiation which travelled at the same rate as light, which is reflected and refracted according to the same laws, and which, in fact, is identical with the radiation able to affect our retina, except in the one matter of wave-length. Such a radiation has now been definitely obtained and examined by Dr. Hertz, of Karlsruhe, and in the last month of last year, Prof. von Helmholtz communicated to the Physical Society of Berlin an account of Dr. Hertz's latest researches. The step in advance which has enabled Dr. Hertz to do easily that which others have long wished to do, has been the invention of a suitable receiver. Light when it falls on a conductor excites first electric currents and then heat. The secondary minute effect was what we had thought of looking for, but Dr. Hertz has boldly taken the bull by the horns, looked for the direct electric effect, and found it manifesting itself in the beautifully simple form of microscopic sparks.

He takes a brass cylinder, some inch or two in diameter, and a foot or so long, divided into two halves with a small sparking interval between, and by connecting the halves to the terminals of a small coil, every spark of the coil causes the charge in the cylinder to surge to and fro about five hundred million times a second, and disturb the ether in a manner precisely equivalent to a diverging beam of plane-polarized light with waves about twice the length of the cylinder.

The radiation, so emitted, can be reflected by plane conducting surfaces, and it can be concentrated by metallic parabolic mirrors; the mirror ordinarily used being a large parabolic cylinder of sheet zinc, with the electric oscillator situate along its focal line. By this means the effect of the wave could be felt at a fair distance, the receiver consisting of a synchronized conductor with a microscopic spark-gap, across which the

secondary induced sparks were watched for. By using a second mirror like the first to catch the parallel rays and reconverge them to a focus, the effect could be appreciated at a distance of 20 yards. If the receiving mirror were rotated through a right angle, it lost its converging power on this particular light.

Apertures in a series of interposed screens proved that the radiations travelled in straight lines (roughly speaking, of course).

A gridiron of metallic wires is transparent to the waves when arranged with the length perpendicular to the electric oscillations, but it reflects them when rotated through a right angle, so that the oscillations take place along the conducting wires; thus representing a kind of analyzer proving the existence of polarized light. The receiver itself acted as analyzer, however, for if rotated much it failed to feel the disturbance.

Conducting sheets, even thin ones, were very opaque to the electrical radiation; but non-conducting obstacles, even such as dry wood, interrupt it very little, and Dr. Hertz remarks, "not without wonder," that the door separating the room containing the source of radiation from that containing the detecting receiver might be shut without intercepting the communication. The secondary sparks were still observed.

But the most crucial test yet applied is that of refraction. A great prism of pitch was made, its faces more than a yard square, and its refracting angle about 30°. This being interposed in the path of the electric rays, they were lost to the receiver until it was shifted considerably. Adjusting it till its sparks were again at a maximum, it was found that the rays had been bent by the pitch prism, when set symmetrically, some 22° out of their original course, and hence that the pitch had an index of refraction for these 2-foot waves about 1·7.

These are great experiments. As I write, they are but a month old, and they are manifestly only a beginning. They are very simple: I have repeated some of them already. They seem likely to settle many doubtful points. There has been a long-standing controversy in optics, nearly as old as the century, as to whether the direction of the vibrations was in, or was perpendicular to, the plane of polarization; in other words, whether it was the elasticity or the density of the ether which varied in dense media; or, in Maxwell's theory, whether it was the electro-magnetic or the electrostatic disturbance that coincided with that plane. This point has indeed by the exertion of extraordinary power been almost settled already, through the consideration of common optical experiments; but now that we are able electrically to produce radiation with a full knowledge of what we are doing, of its directions of vibration and all about it, the complete solution of this and of many another recondite optical problem may be expected during the next decade to drop simply and easily into our hands.

We have now a real undulatory theory of light, no longer based on analogy with sound, and its inception and early development are among the most tremendous of the many achievements of the latter half of the nineteenth century.

In 1865, Maxwell stated his theory of light. Before the close of 1888 it is utterly and completely verified. Its full development is only a question of time, and labour, and skill. The whole domain of Optics is now annexed to Electricity, which has thus become an imperial science.

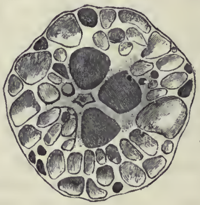
OLIVER J. LODGE.

A JAMAICA DRIFT-FRUIT.

IN 1884, I made a collection of drift-seeds and seed-vessels washed ashore on the spit of land inclosing Kingston Harbour, Jamaica, called the Palisadoes. The collection was sent to Kew, and it was utilized by Mr. Hemsley in the appendix to the "Botany of the *Challenger* Expedition," vol. i. pp. 277-304, when discussing the oceanic dispersal of plants. In the collection there was a fruit I had not seen before, and which was equally new to Mr. Hemsley and the other officers at Kew. There were several specimens of this fruit obtained, and these were afterwards placed in the Kew Museums amongst other drift-fruit, to wait until sufficient material was forthcoming to lead to their identification.

The general character of the drift-fruits collected at Jamaica points to the conclusion that they were brought by the Gulf Stream current from the mouths of the Amazon and Orinoco. Jamaica lies directly in this current, and for a long period fruits unknown in the island itself have been collected on its shores. The most striking of these is the fruit of *Manicaria saccifera*, a palm confined to Trinidad and the mainland of South America. Sloane ("Natural History of Jamaica," vol. ii. p. 186) noticed this fruit more than two hundred years

1.



2.

3.

Representation of a Jamaica drift-fruit (natural size). 1, external aspect; 2, cross-section; 3, longitudinal section.

ago, and states that "it is frequently cast up by the waves on the shores of this island, and it is one of those fruits thrown (also) on the north-west islands of Scotland by the currents and seas." None of these fruits appear to have germinated in Jamaica, for the palm, which is a most striking object, with entire leaves, could not fail to be noticed if it existed there. The fruits are known at Jamaica as *sea-cocoanuts*, while at Barbados they are called *sea-apples*. Other South American fruits found drifted at Jamaica were *Carapa guianensis*, *Dimorphandra mora*, and *Astrocaryum* sp. The collection of drift-fruits, although by no means a new subject, is one which has not received the attention it deserves. Since the publication of the "Botany of the *Challenger*," the active part played by the sea in the dispersion of plants has been more fully recognized. Mr. Hemsley has given a summary of results, in which many interesting facts have been brought to light, and doubtless observers in numerous parts of the world are now engaged in making observations.

But to return to the unknown drift-fruit. It is seldom that specimens remain at Kew for a long period without something occurring to call attention to them. It was so in this instance. In November 1887, Mrs. Hubbard sent Prof. Oliver a drift-fruit from the coast of Devonshire which was found to be exactly identical with the fruits collected at Jamaica. The specimen had the same water-worn appearance, and there was little doubt that it had travelled across the Atlantic in the drift of the Gulf stream.

This fruit, a representation of which is given opposite, possesses such distinctive characters that it can easily be recognized. It is evidently a drupaceous fruit, but the fibrous or fleshy outer layer (the sarcocarp) has either decayed or been worn away while drifting. What is now left is the woody indehiscent putamen or pericarp, externally marked by a mammillated surface corresponding, as shown in sections, with numerous cavities or resin-cysts existing in its walls. The fruit is normally five-celled, but two of these are suppressed, and only three remain. The seeds, as shown in Fig. 3, are solitary, and they possess abundant albumen. The presence of resin-cysts is a character of some value in seeking for the order or genus to which such a fruit could belong. In the Kew Museums, there are some fruits collected by G. Mann, on the Gaboon River, West Africa, which afford a clue. These are the fruits of *Aubrya gabonensis*, Baill, belonging to the natural order *Humiriaceæ* (Oliver, "Flora Trop. Afr.," vol. i. p. 275). They are smaller than the Jamaica drift-fruit, and are covered with a brown, fibrous or leathery epicarp 3 millimetres in thickness. The bony endocarp is, however, similarly developed and plentifully furnished with resin-cysts. The resemblance altogether is very close. The natural order *Humiriaceæ* is a very small one, and consists of genera entirely confined to Brazil and Guiana, with the exception of the single African genus already mentioned. There can be little doubt that the drift-fruit is derived from tropical America, and not from Africa. The American genera of *Humiriaceæ* are *Vantanea*, *Humiria*, and *Sacoglottis* ("Gen. Plant.," vol. i. p. 247). It is not necessary to give all the details, but I may say at once that Prof. Oliver is of opinion, and in this I agree, that the drift-fruit will doubtless be found to belong to a species of *Humiria*, and possibly to *H. balsamifera*, Benth. (Hook., *Kew Journ.*, vol. v. (1853), p. 102).

This species is said by Aublet (who figures the leaves and flowers only in "Plant. Guian.," p. 564, t. 225) to grow in all the forests of French Guiana, where it is known, from the colour of the wood, as *bois rouge*. Strange to say, the fruit of apparently so common a plant is unknown in European herbaria. Urban, who described it, with a figure, in "Flora Brasiliensis" (vol. xii. p. 439, t. 92), had not seen a mature fruit. The specific name is derived from the fact that the bark, when wounded, yields a reddish balsamic juice, possessing an odour like that of storax, and which after a time becomes hard and brittle. It is then used as a perfume. An ointment is also prepared from it.

For the present, therefore, we must leave the question open as regards the exact determination of this drift-fruit. There can be little doubt that it belongs to the genus *Humiria*, but until we obtain fruits of *H. balsamifera* we are unable to say whether it is that species or not.

D. MORRIS.

P.S.—Since the above was in type, I have gathered information which considerably increases the interest connected with this fruit. It is first figured and described (as a drift-fruit) by Clusius in his "Exoticorum libri decem," lib. 2, cap. 19. This work bears the date of 1605. The description adds nothing as to the origin of the fruit, except that it was received from Jacob Plateau. The figure given by Clusius, with the description, is reproduced by J. Bauhin, nearly eighty years afterwards, in "Historia Plantarum" (1680), tom. i., lib. 3, cap. cxi., Fig. 1. There is another figure, still from a water-worn and drifted specimen, given in "Petiveri Opera," tab. lxxi., Fig. 5 (1764), with the information that "it is a hard oval fruit with seed-holes [resin-cysts] round its surface. Cat. 605. Found on the shore of Jamaica." Finally, Mr. E. G. Baker, F.L.S., to whom I am indebted for the references to Bauhin and Petiver, has recognized the fruit in the Sloane Collection at the British Museum (Natural History), labelled "No. 1656." We are still, however, without information as to the origin of the fruit or the plant bearing it.

D. M.

HAZE.

I HAVE for some time given in my lectures an explanation of the common summer haze which appears to me to be very probable. I do not know whether it is new, but it has not been referred to in the discussion raised by Prof. Tyndall's letter on Alpine haze. Some time since I mentioned it to Prof. Lodge, and at his suggestion I send it to you, though its extension to other kinds of haze is somewhat speculative.

It is that haze is often due to local convection currents in the air, which render it optically heterogeneous. The light received from any object is, therefore, more or less irregularly refracted, and, through the motion of the currents, its path is continually varying. The outline of the object, instead of appearing fixed, has a tremulous motion, and so becomes ill-defined. At the same time, reflection occurs where there is refraction at the surfaces of separation of heterogeneous portions. Much of the light which, in a homogeneous medium, would come straight from the object, is thus lost for direct vision, and the contrast between neighbouring objects is lessened. The reflected light is diffused as a general glare. The combination of the quivering of outline, and the loss of direct light, with the superposition of the reflected light as a diffused glare, gives the appearance we call haze.

This explanation appears to me to accord well with the obvious facts of summer haze—the haze which is seen in the middle of a hot, cloudless, summer day. The lower layers of air, being heated by contact with the earth, rise in temperature till equilibrium is no longer possible, and convection begins, streams of the heated air rising, and streams of colder air falling to take its place. The variation of temperature and density gives optical heterogeneity. The existence of these streams is sometimes shown by the quivering of distant objects, looked at through the air close to the ground, but a telescope will often show the quivering of outline at higher levels, and when quite invisible to the naked eye. Accompanying this refraction, reflection must occur. We have a direct proof of its occurrence in the fact that the glare is greatest under the sun, where reflection occurs at angles approaching grazing incidence, for which it is a maximum; while it is least opposite the sun, where reflection occurs at angles approaching normal incidence, for which it is a minimum. The opening lines of the "Excursion" perfectly describe the resulting appearance:—

> "'Twas summer, and the sun had mounted high;
> Southward the landscape indistinctly glared
> Through a pale steam; but all the northern downs,
> In clearest air ascending, showed far off
> A surface dappled o'er with shadows flung
> From brooding clouds."

During the night the lower strata become colder than the upper ones, and the atmosphere passes into a state of stable equilibrium. We should therefore expect that, if the foregoing explanation is true, there would be

complete absence of haze, and it is well known that the air is peculiarly clear in early morning, when we get above the fog-level.

According to this account of heat haze, it stands in sharp contrast to fog, of which it is so often supposed to be a relative in reduced circumstances. While the one requires convection, the other usually occurs when the air is in stable equilibrium, the lowest strata being the coldest. In the fog, for example, which so frequently heralds or accompanies the break-up of a frost, the lower strata are still cold, while above the wind has changed, and the air comes up warm and vapour-laden. The vapour diffuses downwards into the lower, cold strata, and is there condensed, and it is possible that the more rapid diffusion of water vapour has something to do with the continuance of the fog, for it would diffuse downwards more rapidly than the rest of the air with which it has come.

There are other cases of haze which may, perhaps, be explicable by optical heterogeneity. In the dry east winds of spring we frequently have a haze when the air is far from saturation-point, and the clouds, if they exist, are at a high level. It appears possible that this haze is due to small convection currents of the cold air from above, the temperature falling too rapidly from below upwards for equilibrium.

Sometimes the heterogeneity may be due to water vapour. After rain, when the ground is still wet, the drying of exposed surfaces often shows that the air is not saturated, yet there is a haze or mist which is supposed to be thin fog, *i.e.* water-dust. Evaporation must be going on, and the air must certainly be unequally charged with vapour. With this inequality there must also be convection. I have never been able to detect, with certainty, quivering of outline either in this case or in the previous one of the east wind haze, though I have sometimes suspected its existence. Possibly someone who has used a high-power telescope for terrestrial objects might be able to give information on this point. But it is to be noted that the differences of density in both these cases are much smaller than in the case of summer haze, and the currents should therefore be on a smaller scale.

It seems worthy of inquiry whether the haze observed under cumulus clouds, referred to by the Rev. W. Clement Ley, may not also be due to water-vapour heterogeneity. The cumulus cloud indicates the existence of a large body of vapour-laden air extending no doubt below, as well as above, the condensation level. As this mass sweeps along, the lower part of it is retarded by the earth and by the lower strata, and more or less disturbance and mixture with the surrounding air will occur. There will therefore be heterogeneity. I do not know whether this would be at all sufficient to account for the haze observed, but the suggestion seems worth considering.

J. H. Poynting.

THE EARTHQUAKE AT EDINBURGH.

Though no earthquake of great destructive energy has passed across the area of the British Islands within historic times, the number of actual shocks which have been experienced and recorded amounts now to many hundreds. Scotland, being more generally mountainous than the other divisions of the United Kingdom, has hitherto enjoyed by far the largest share of these manifestations of terrestrial disturbance. Hardly a year passes without adding to the list. The latest addition is that which startled the inhabitants of Edinburgh, on Friday morning, the 18th instant, a few minutes before 7 o'clock, when a large part of the population was still in bed. It agreed in general character with the usual type of Scottish earthquakes, and might indeed be taken as an illustrative example of them—not strong enough to do damage to property or life, but yet quite sufficiently marked to arrest attention and to exhibit some of the more prominent features of seismic movements.

The earthquakes that visit Scotland so frequently are always singularly local in character. Now and then a more vigorous shaking may be felt across the breadth of the Highlands, but as a rule the tremor is confined to a comparatively circumscribed district. Again, not only are they local, but there is usually some centre or median belt of ground where the effects have been more distinctly perceptible than elsewhere. Some districts are specially liable to them. Thus, the tract around Comrie, in the south of Perthshire, has long been noted for the frequency of its earthquakes. Another area often similarly affected embraces the West Highlands up to Inverness. It is worthy of remark that this latter region was considerably disturbed by a series of shocks almost exactly a year before, viz. on February 2, 1888. If we look at the geological structure of these earthquake districts, we observe that they are traversed by some of the most important lines of fissure by which the crust of the earth within the area of Britain has been disrupted. Comrie stands on the line of a powerful fault which runs across Scotland from sea to sea, and which, by bringing the softer and less prominent sandstones of the low country against the harder and more precipitous schists of the hills, has been in some measure the origin of the line between the Lowlands and Highlands, and thus of the limitation of the Saxon and the Gael. Again, in the West Highlands, a profound dislocation has defined the line of the Great Glen from Inverness to the Linnhe Loch. The relation of the chief earthquake centres to these ancient lines of fracture in the terrestrial crust can hardly be accidental. The actual shock that starts the seismic wave is probably in these areas to be traced to some slipping of the rocks along these lines of rupture. Though the faults are of great geological antiquity, they doubtless remain lines of weakness, along which any changes due to the secular cooling and contraction of our planet may be expected to show themselves.

The area shaken by the earthquake of Friday, January 18, is not one which has been much subject to experiences of this kind, though a few shocks are spoken of as having been felt there in the past. But its geological structure shows how well fitted it is to become a theatre of disturbance of the usual feeble Scottish type. It extends from the edge of the Firth of Forth southwards into the interior across the site of Edinburgh, and thence along the chain of heights known as the Pentland Hills. These hills consist mainly of volcanic rocks belonging to the period of the Lower Old Red Sandstone. The beds of lava and sheets of tuff increase in thickness towards the north-east, until in the Braid Hills, which lie immediately along the southern outskirts of Edinburgh, they are replaced by the materials that fill up what seems to have been the chief vent from which they were discharged. These volcanic eruptions had long ceased when the Carboniferous rocks of the district began to be laid down upon their upturned and worn edges. During a prolonged period of deposition and depression they gradually sank and were buried under some thousands of feet of sedimentary strata. In later times the area was disrupted by a group of long parallel fractures running in a general north-east and south-west line. Vast denudation likewise took place. By degrees the deep cover of Carboniferous strata was worn away from the tops of the volcanic ridges which now once more appear at the surface as the chain of the Pentland Hills. Thus the site of the earthquake coincides with an ancient volcanic centre and with a belt of country which has been dislocated by lines of fault.

The area within which this earthquake was most perceptible is tolerably well defined by that of the geological features here described. It is rudely elliptical in shape, about fifteen or twenty miles along the longer, and from five to seven across the shorter axis. Outside these limits, the shock, though in some places distinctly felt, seems to have rapidly lost force, so that at Linlithgow, about ten miles away, it was hardly perceptible. The effects by which the passage of the seismic wave made itself sensible were of the usual kind. For the most part all that was noticed was a tremor or quivering movement of the ground or houses, accompanied with the rattling of any loose objects. I was myself awake, and about to rise, when I was aware of a peculiar grinding noise and the jangling of all the crockery and glasses on the wash-hand-stand. It seemed as if some heavy load had been discharged from a waggon on the ground immediately outside the house. But as the position of the house on the outskirts of the southern suburbs of the city made this impossible, I was at a loss to conjecture the cause of the disturbance. I thought of an earthquake, but found that no other inmate of the house had noticed anything peculiar. In the course of the day, however, accounts came from all parts of the district affected, which put the real nature of the event beyond any doubt. The undulation of the ground was experienced by many observers, and the general impression was that the wave moved from west to east, or from south-west to north-east. Some who were not yet astir felt first one end of the bed and then the other depressed and raised. To others who were already on foot the ground seemed to sink away from their feet and to rise upward again. Chairs appeared to slide forward and backward. Pictures, lamps, and other hanging objects were set swinging. In one recorded case, an eight-day clock, which had been standing at the time, and of which the pendulum swings in an east and west line, was made to go. On the other hand, the parish clock of Currie was stopped at the moment of shock. One boy is said to have been pitched out of bed, and was found immediately afterwards with a hammer in his hand ready to attack someone whom he supposed to be concealed under the bed. Numbers of witnesses spoke of the feeling of giddiness or nausea that so frequently accompanies earth-movements. Dogs barked or howled to mark their sympathy in the general alarm. No damage of any kind, however, seems to have been done, unless under that name be included the dislodgment of a portion of the plaster from the ceiling of a church at Portobello.

The most violent motion appears to have been felt along the north-west base of the Pentland Hills and thence in a north-easterly direction through the northern parts of Edinburgh. There can be little doubt that the source of the shock lay somewhere along the line of these hills. We may plausibly connect it with the failure of support, and consequent fall, of some part of the rocks along one of the main lines of fault that define the chain of the Pentlands.

The greater frequency of earthquakes in the winter half of the year has often been remarked upon. It is certainly during that season that they most generally occur in Scotland. With regard to the shock of last week, we find that a strong gale had been blowing for some time, and that the barometer had fallen four-tenths of an inch between Thursday and Friday. The position of the moon, according to some seismologists, conduces to the determination of those disturbances of the terrestrial crust that give rise to earthquakes. With regard to the disturbance of the 18th instant it is noticeable that full moon happened the previous morning, when there was a lunar eclipse. It is about the time of new moon and the first quarter that the chief earthquake-maxima are said to take place.

A. G.

DECOMPOSITION OF NICKEL AND COBALT.

CHEMISTS have recently heard with great interest that Dr. Krüss, of Munich, a well known and trusted worker, has succeeded in "decomposing" nickel and cobalt. Judging from the accounts which thus far have reached us, it would appear that his discovery consists in finding that cobalt and nickel contain about 3 per cent. of a new element which is common to both as ordinarily prepared. By the removal of this hitherto unrecognized "impurity," the properties of the cobalt and nickel salts are slightly modified as to colour, &c. It is to be expected that the discovery will serve to explain the discrepancies which are to be noted among the various determinations of the atomic weight of nickel and cobalt. We give the following details from a short note upon the subject in the *Chemiker Zeitung* of January 27:—

Dr. Krüss, in conjunction with Herr Schmidt, read a paper at the meeting of the Munich Chemical Society of January 11, upon the results of their attempted redetermination of the atomic weights of these two metals. Clemens Zimmermann, as the outcome of a determination made some years ago, found the atomic weight of cobalt 58·74, and that of nickel 58·56. The method followed by Krüss and Schmidt was a revival of the older process of Winkler, and consisted in determining the relative equivalents of gold and nickel, and of gold and cobalt. Such a method ought now to be very much more trustworthy, on account of the recent exceptionally accurate determinations of the atomic weight of gold made simultaneously by Dr. Krüss himself, and by Prof. Thorpe and Mr. Laurie in this country. The process simply consisted in precipitating the gold from a neutral solution of gold chloride or sodium gold chloride by weighed quantities of metallic nickel or cobalt, chlorides of the two latter metals passing into solution. The results, however, were not what were expected, and differed among themselves to a remarkable extent. It was found impossible to precipitate the equivalent in gold of the nickel or cobalt employed, owing to the inverse effects of polarization, small quantities of metallic nickel or cobalt being reprecipitated, and thus mixed with the finely divided gold. In order to determine the amount of metal which had been dissolved, the precipitate was weighed, dissolved in aqua regia, and the gold reprecipitated by sulphurous acid. The weight of gold thus obtained, deducted from the weight of the whole precipitate, of course gave that of the admixed nickel or cobalt. Even after making this correction, the method afforded such surprisingly untrustworthy values that it became necessary to seek for the disturbing cause. On washing the reprecipitated gold, it was noticed that the red colour of the filtrate due to chloride of cobalt gradually paled, and eventually took a greenish tint. On evaporating a quantity to dryness and igniting in a platinum dish, the small residue obtained was found to dissolve in warm concentrated hydrochloric acid forming a beautiful green solution. On cooling, the liquid again became almost colourless, and gave a white precipitate of hydrate on addition of ammonia, which on ignition gave a white oxide; and a brownish-black precipitate of sulphide with ammonium sulphide. A number of other reactions also show that the compounds of this metal, which was itself obtained as a black powder by reduction of the oxide with charcoal, are not to be identified with those of any known element. The most interesting fact, however, is that the washings from the gold obtained in the nickel determinations gave precisely the same indications; the same residue on ignition, a green solution on treatment with warm hydrochloric acid, and the same hydrate and oxide. Several other methods were also described in the memoir, which we hope shortly to see published, by which this same common ingredient could be extracted from both nickel and cobalt. It is very interesting that Dr. Krüss has also obtained a green double chloride of the

new metal and red cobalt chloride, which possesses all the properties of green nickel chloride, which has thus been decomposed into a red and a colourless salt.

NOTES.

THE Royal Society has recently entirely recast the regulations under which the Government fund of £4000 for the promotion of scientific research is administered.

MR. COMMON'S 5-foot telescope is now completed, and photographs of the moon and nebulæ have already been taken to test the figure of the silver-on-glass speculum. We hear the results are quite satisfactory. Congress is to be asked to vote 250,000 dollars for the purchase of a refractor of the same dimensions for the Washington Observatory.

MR. ISAAC ROBERTS, working on the lines laid down by Mr. Common, has recently, by exposures of over four hours, obtained most important additions to our knowledge of the nebulæ of Orion, Andromeda, and the Pleiades.

WE believe that the Royal Astronomical Society has this year awarded its medal to M. Lœwy, of the Paris Observatory.

PROF. CORFIELD has been elected an Honorary Member, and Dr. Louis Parkes a Foreign Associate, of the Société Française d'Hygiène.

LAST week's number of the *Electrician* contains a notice of the work of Sir William Thomson, accompanied by an admirable steel engraving.

THE new Laboratory at the Normal School of Science, built for the accommodation of the students in the practical courses in physics and astronomical physics, is now finished. It accommodates about eighty students.

THE Medals and Funds to be given at the anniversary meeting of the Geological Society on February 15 have been awarded by the Council as follows: the Wollaston Medal to Prof. T. G. Bonney, D.Sc., F.R.S.; the Murchison Medal to Prof. James Geikie, F.R.S.; the Lyell Medal to Prof. W. Boyd Dawkins, F.R.S.; and the Bigsby Medal to Mr. J. J. Harris Teall; the balance of the Wollaston Fund to Mr. A. Smith Woodward, of the British Museum; that of the Murchison Fund to Mr. Grenville A. J. Cole, of the Science Schools, South Kensington; and that of the Lyell Fund to M. L. Dollo, of the Royal Museum at Brussels.

AT the last meeting of the Mineralogical Society, there was described a new mineral species, an oxychloride of lead, to which the name of "daviesite" was assigned. This mineral was found as very minute crystals in a specimen from Sierra Gorda in Bolivia. The crystals are very rich in faces, and belong to the ortho-rhombic system; their parametral ratios are $a : b : c = 1·2594 : 1 : 0·6018$; they are elongated in the direction of the vertical axis, parallel to which there are faces of the prism (110) and the pinacoid (100), and they are terminated sometimes by a simple basal plane (001), sometimes by the domes (011), (031), (101), (301), (501), and the pyramids (211), (121), (221), (521). The optic axes are visible when the basal plane is normal to the axis of the convergent polarized light.

THE Scientific Department of the Scotch Fishery Board, in view of the approaching great spawning period of the marine food-fishes, have begun a series of systematic investigations at some of the more important fishing-grounds lying off the east coast of Scotland. From a report presented to the Fishery Board by Prof. Ewart, it appears that one of the Board's naturalists (Mr. T. Scott) has recently made some interesting observations on board the large steam-trawler *Southesk*, of Montrose, as to the spawning of the plaice (*Pleuronectes platessa*) at Smith Bank, a well-known ground in 20 fathoms of water, lying off the Caithness coast, where operations were carried on for several days. A great variety of fish were obtained; but, except a few gurnards, only the plaice, which were present in great numbers, were spawning. Specimens both quite ripe and partly spent were captured by the trawl, while the tow-net revealed the presence of countless multitudes of floating eggs on the surface—in all stages of development—as many as 10,000 being obtained in one haul. These were shown to be almost entirely the ova of plaice, the remainder being the ova of the gurnard. Such an opportunity of witnessing the spawning of a shoal of flatfish on so gigantic a scale, and of proving so clearly the relationship between the spawning fish and the pelagic ova, does not often occur.

A BOTANICAL STATION was established early last year at St. Lucia on the most unpretentious footing. A Committee appointed to supervise the work of the Curator, Mr. John Gray, reports that, "considering the difficulties incidental to the starting of such an undertaking, the peculiar nature of the ground, and the limited funds available for the purpose, the work thus accomplished is satisfactory." The Committee says that the most encouraging feature of Mr. Gray's report is the general appreciation shown by the agriculturists of the district in the success of the Station, as shown by their increasing disposition to seek advice from the Curator, and to try and obtain seeds from him. Already the demand for cocoa, coffee, and nutmeg plants is so great that additional land will have to be acquired for the extension of the Garden.

LORD WOLSELEY, who is not often caught tripping in making hasty statements, writes as follows in the current number of the *Fortnightly Review*:—"The battles of the future will be very different from even those of 1870. . . . One remarkable change will be the absence of nearly all that terrific noise which the discharge of five or six hundred field guns, and the roar of musketry caused in all great battles. . . . The sound of cannon will be slight, and will no longer indicate to distant troops where their comrades are engaged, or the point on which they should consequently march. Our sentries and advanced posts can no longer alarm the main body upon the approach of the enemy by the discharge of their rifles. The camp or bivouac will no longer be disturbed at night by the spluttering fire of picquets in contact with the enemy. Different arrangements for giving the alarm upon the approach of hostile columns will have to be resorted to. The main column on the march cannot in future be warned, by the shots of flanking parties, of the enemy's proximity, and a battle might possibly be raging within a few miles of it without that fact becoming at once apparent." Will some competent member of the "Scientific Corps" kindly explain, or are they all in civil employ?

WE make the following extract from a letter addressed by Mr. A. W. Tuer to a contemporary:—"The melodious hum of skating was perhaps never heard to greater advantage than through the crisp air of a bitterly cold morning little more than a fortnight ago—the first Sunday in the year. Almost as soon as Kensington Gardens were entered, one became conscious of a clearly-defined musical sound coming from the direction of the Round Pond—G as nearly as I could judge, but corrected to G sharp, when, half an hour later, I got to a piano. I had wished to compare the notes—probably lower—given forth by other and larger sheets of ice, but procrastination strangled an opportunity which perhaps others will take when it again offers. Comparing a sheet of ice to a taut string, and the countless skates to the hairs of a bow—scientifically, a poor comparison enough—the sound might be expected to have been like that produced by the scraping of a fiddle, but it exactly resembled the whistle of a distant locomotive."

Prof. J. H. Gore, of the Columbian University, has in preparation a bibliography of geodesy. During two trips to Europe he has collected about seven thousand tit'es, having examined nearly every large library except that at St. Petersburg. He begins with the first effort to ascertain the shape of the earth by triangulation in the seventeenth century. The work will be published soon by the Coast Survey. Prof. Gore is trying to make his service complete by personal application for data, he having written to all astronomers and other mathematicians in the world whose addresses he could obtain.

The American Society of Naturalists (*Science* reports) held in Baltimore, on December 27 and 28, one of its largest and most successful meetings. Methods of instructing large classes in botany were presented by Profs. Goodale and Wilson, and in geology by Profs. Niles and Williams. The Society fully approved the excellent work of its committee on education, in paving the way for better instruction in the natural sciences in all grades of schools, especially the lower ones. Mr. J. E. Wolff showed a photographic method of class illustration, and Prof. W. M. Davis explained a most interesting series of paper models, illustrating the development of certain topographic forms and their relation to base-levels of erosion. The Society is composed largely of teachers, and desires to so arrange its meeting next year that the members may be able to attend the meetings of specialists held about the same time.

We referred recently to the investigations in the Torres Straits of Prof. A. C. Haddon, of the Royal College of Science, Dublin. The *Ceylon Observer* now publishes extracts from some later letters from Prof. Haddon, from which it appears that he was anxious to spend some time in Ceylon, to work out the life-history of the Ceylon turtle and to add to his collections; but it is unlikely that he will be able to do more than call at Colombo on his way home. Writing in November from Thursday Island, Prof. Haddon says:—"I have now been out nearly three months, and have had a very pleasant time, and have seen and learnt much. I find that the anthropology is an untouched field, absolutely so as regards the manners and customs of the past, and I have taken some trouble and a great deal of interest in collecting what information I can in the short time at my disposal. In most of the islands the people are dying off; the younger men know nothing of the life of their forefathers, and there are but few old men left. In a few years' time it will be too late, so I have deemed it desirable to turn some of my attention to that subject, although I had no intention of so doing when I started. Experts at home must judge whether my information is of value. I have had a little peep at New Guinea for a few hours—Mowat—to this end. In April and May I am going to the Louisiades, Sudest and other islands of the south-east end, and also to Port Moresby and Motu-Motu. Mr. Chalmers strongly urged me to give an extra month to that end of New Guinea, promising to take me about, an opportunity which money could not purchase, and which falls to the lot of very few. So I shall conclude my stay in this part of the world with a good look at New Guinea under the best of guidance. It has been a great grief to me that I could not manage Ceylon as well, but I feel I have done quite right in not yielding to the strong temptation."

Experiments have recently been made (says *Science*) showing in what order a fatigued eye recovers the power of perceiving different colours. The important factor is what colour has been used to induce fatigue. If the eye has been fatigued by long exposure to red, the sensitiveness for green is the first to reappear, then for blue, then yellow, and finally red. After a "blue-fatigue," the order is yellow, red, green, blue; after a "green-fatigue," the order of recovery is red, blue yellow, green; after "yellow-fatigue," it is red, blue, green, yellow. The eye recovers last the perception of the colour by which the fatigue has been induced, and first recovers the sensitiveness for the complementary colour. The fatigue is in the retina, for it is an independent phenomenon in the two eyes. The point of finest vision, the fovea, requires a longer time to recover from colour-fatigue than the less sensitive lateral portions of the retina. The physiological process is considered to be related to the visual purple of the rods and cones. On the sense of taste, the same journal states that in the case of a patient whose entire tongue, including the large circumvallate taste-papillæ at the root of the tongue, had been removed, it was found that some power of taste remained. The sensations of sweet, bitter, and sour could be obtained by applying appropriate substances to the back of the pharynx or the stump of the tongue, though if applied to the tongue the taste was apparent only during swallowing. The taste of salt was not perceived. Though these results are not fully in harmony with previous experiments, they are helpful in localizing the tasting-powers of various portions of the mouth cavity.

The Indian papers report that a severe earthquake, lasting about four seconds, followed by slight momentary shocks at intervals, occurred at Quettah on the morning of December 28. The shocks were felt at intervals till December 31. No injury, beyond the destruction of a few native shops and bazaars, is reported.

Turkestan has again been the scene of earthquakes. On November 28 last, at 11.40 a.m., a shock of earthquake, much stronger than any lately experienced, was felt at Tashkent. After a feeble earth tremor, which lasted for four or five seconds, there was a violent shock; the houses cracked, windows rattled, and the inhabitants rushed into the street. The wave of the earthquake came from the east, and at Khojent some houses were damaged.

Prof. Mushketoff has made a gift to the Russian Geographical Society of a very interesting album of 175 photographs, showing the effects of the last great earthquake at Vyernyi. It illustrates with perfect accuracy, the damage done in the houses, as also several geological changes due to the earthquake.

A member of the Astrakhan Scientific Society has been taking photographs of fishermen at work at the mouth of the Volga, and of the inplements used by them. An album of 200 photographs gives a complete representation of the present state of these important fisheries, and a copy is to be deposited at the St. Petersburg Academy of Sciences.

In December last, a Chinese scientific expedition, under the learned functionary Miao, arrived at Irkutsk.

At a recent meeting of the Geological Society of Stockholm, Dr. N. O. Holst exhibited the forehead and part of the leg of the skeleton of a bison found in a bog near Vadstena. The discovery was made by a farmer as far back as 1865, but it has only recently been proved that the parts are those of a bison. Only two similar discoveries have been made in Sweden, viz. in the province of Scania. Baron de Geer maintained that recent careful researches disproved the theory held by some that a sound had in prehistoric times separated Scania from the rest of Sweden, and thus prevented the immigration of the bison thither.

In a recent British Consular Report on the Agriculture of the Department of the Maritime Alps, Consul Harris says that the reckless destruction of the forests had already considerably altered the climate and other conditions of that region in the first half of this century, and had caused a large portion of the soil, or the "flesh of the mountains," as Elisée Reclus calls it, to disappear from the summits, which are now only the most barren slopes. When the snows of winter melt off the higher mountains, devastating floods are very common, and the population has, within the past twenty years, decreased very

much on account of these floods. It has been calculated that in one year alone the amount of soil carried down by the two rivers, the Loup and the Paillon, was sufficient to have covered the whole department to a depth of 6 centimetres. The Consul adds that, though something has been done to encourage replanting, a more serious effort than has yet been made is needed to reafforest the country.

FROM a recent British Consular Report on the trade of Maranham, it appears that a large number of india-rubber producing trees were discovered last year in the district of Pinheiro. The principal traders, who were suffering severely from the depression in the sugar and cotton industries, formed themselves into a company to work up the new discovery, but up to the present the trees have produced little.

THE *Ceylon Observer*, commenting on the destruction wrought by the scaly insect on the cocoa-nut palm in the West Indies, says that it is most remarkable that in Ceylon the palm has been absolutely free from this and other such pests. This fact perhaps is due to the absence of those long-continued droughts which have so grievously affected Jamaica and its neighbouring islands. While the palm, however, has flourished so well in Ceylon, the coffee-plant is almost extinct in the island, a few isolated fields in each district being all that have survived the ravages of the green scale insect. Frequently the finest coffee-trees, with fresh and vigorous-looking bushes, and with stems as thick as a man's thigh, are so completely under the influence of the pest that no crop is produced. Experiments with soap, lime, kerosene oil, &c., have up to the present produced no satisfactory results. Tea seems to flourish where the coffee-plant dies, and even where the tea plantations are attacked by fungoid or insect pests, the plants can be pruned down till not a leaf is left; or, if the attack is a very severe one, the tea-garden can be burnt to the ground without suffering any permanent injury, for the roots and stems in a very few months again display their luxuriance as richly as before.

THE additions to the Zoological Society's Gardens during the past week include a Green Monkey (*Cercopithecus callitrichus* ♂) from West Africa, presented by Mr. Lishman; a Serval (*Felis serval*) from Malindi, East Africa, presented by Mr. H. C. Hunter; a Common Fox (*Canis vulpes* ♂), British, presented by Mr. E. Baldwin Cashel; a Common Fox (*Canis vulpes* ♀), British, presented by Lieutenant H. F. Sparrow, "The Buffs"; a Chough (*Pyrrhocorax graculus*) from Ireland, presented by Mr. A. Mudge; a Gold Pheasant (*Thaumalea picta* ♂), a Silver Pheasant (*Euplocamus nycthemerus* ♂) from China, presented by Mrs. Theodore Lloyd; a Sharp-nosed Crocodile (*Crocodilus acutus*) from the West Indies, received in exchange.

OUR ASTRONOMICAL COLUMN.

ROUSDON OBSERVATORY, LYME REGIS.—The observations at Mr. Peek's private observatory have been carried on during the past year. 163 nights were available for observations, as compared with 165 in 1887. As last year, the attention of the observers has been chiefly directed to transit-observations for time, and to observations of variables of long period. The object of the observations of variables is to determine the exact dates of maxima and minima, and, as far as possible, the light-curve of each star. The list of stars under examination is gradually being revised, circumpolar stars being substituted for those withdrawn, in order that uninterrupted observations may be made throughout the year. Owing to the lengths of the periods of the stars taken, the complete observations are not yet ready for publication. The importance of these light-curves cannot be over-estimated, as they will undoubtedly throw much light on the origin of the variability.

A sidereal clock, by Grubb, has been added to the equipment of the observatory.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 FEBRUARY 3–9.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on February 3

Sun rises, 7h. 36m.; souths, 12h. 14m. 7·4s.: sets, 16h. 52m.: right asc. on meridian, 21h. 9·6m.; decl. 16° 22′ S. Sidereal Time at Sunset, 1h. 48m.

Moon (at First Quarter February 7, 21h.) rises, 9h. 25m.; souths, 14h. 58m.; sets, 20h. 43m.: right asc. on meridian, 23h. 54·3m.; decl. 5° 49′ S.

GEOGRAPHICAL NOTES.

THE paper read at Monday's meeting of the Royal Geographical Society was on the Gran Chaco of the Argentine Republic and its rivers, by Captain John Page, of the Argentine Navy. The Gran Chaco, Captain Page said, is a vast central tract of country lying between the southern tropic and 29° S. lat., bounded on the north by Brazil and Bolivia, on the south by the Argentine province of Santa Fé, on the east by the Paraná and Paraguay Rivers, and on the west by Santiago del Estero and Salta. It contains about 180,000 square miles, or considerably more than the superficies of Great Britain and Ireland. About one-third part of this vast area belongs to Paraguay. The Gran Chaco has been called, particularly in allusion to the low-lying Paraguay section, the *oceano firme*, or solid ocean. This section and the central section of the Argentine rise from the Paraguay River towards Bolivia almost imperceptibly, having numerous and very extensive marshes and jungle, which are drained by many small streams likely to become, as the country progresses, important local waterways. The monotonous level of these sections is relieved by various prominent points of great beauty along the Paraguay River. Both are well wooded, although the predominating woodland

feature is the great and almost interminable palm forests, which, singularly enough, in the Chaco are a sure indication of marshy lands subject to inundation, although in the province of Entre Rios, and other parts of the world, they are the exact contrary. On the northern and eastern borders of the River Bermejo the Central Chaco rises sensibly, as if to form a barrier to the waters of that river in their easterly progress. The Chaco Austral of the Argentine is the most favoured in natural riches of the three great sections. Its surface rises gradually from the Paraná River, and is intersected by several small streams, which are even now useful as a means of water-carriage to the many colonists settled along their courses; after rising thus up to the parallel of 25° 40′ S., the ground dips towards the valley of the San Francisco, sending its waters with those of that river to the Bermejo, sometimes in untimely floods. This depression extends across the Central into the Paraguayan Chaco, taking in the sections of the two rivers that are subject to yearly overflows between long. 61° and 62° W. of Greenwich, thus making a point of analogy between the two. The Austral is favoured with extensive primæval forests, notably that on the north-western border extending into Salta and covering a superficies of many hundreds of miles, quite unexplored, and sometimes designated by the name of "impenetrable." The principal water-courses of these territories are the Pilcomayo and Bermejo, which are undoubtedly destined to become highways of commerce. The waters of these rivers differ in colour, those of the Pilcomayo being dark and sometimes brownish, and those of the Bermejo red, as its name indicates; both are long, narrow, and tortuous, as are most of the interior rivers of the La Plata system; both run in a general south-east direction, preserving a remarkable parallelism throughout their entire course, running distant from each other as nearly as possible 180 miles. Neither of these streams receives tributaries of any kind over the greater part of their course, and their waters are consequently subjected to a great and constant drain from evaporation, in a climate whose average temperature is 80° F., as well as from absorption by the deep alluvial covering overlying the compact argillaceous bed, which is a geological characteristic of the whole Chaco subsoil. The impermeability of this bed probably arrests the effect of absorption, and in a great measure accounts for the non-diminution of the wealth of waters delivered into the Paraguay; such a geological formation may also account for the saline properties of the waters found in the Chaco, wherever wells have been made. The density of the Bermejo water is greater than that of the Pilcomayo; the amount of sediment it brings down is enormous, and it is deposited with such extraordinary rapidity that it cannot but be considered a peculiarly strong feature of the mechanical work of this river, by which its geological formations are rapidly made, and, indeed, unmade as well; this swift precipitation of its detritus, which it replaces by an increasing abrasion of the banks, may be caused, to some extent, by the quantity of salt contained in its water. This constant precipitation goes on in the Bermejo, even when at its height, and when in the exercise of its greatest carrying power, with a speed quite equal to the square of its normal current; a fact which would seem to say that its currents are swifter on the surface than over its bed. Captain Page has seen this river eat away an entire point of land, and, by way of compensation, deposit, just a turning below, an amount of detritus sufficient to form a similar promontory, which, in one season of low water, became covered with a thick and luxuriant growth of red willow. The Pilcomayo—the Piscumayu, as it is called in the Quichua tongue, signifying Bird River—is to a great extent unknown. The section that is *quite* unknown, and that is surrounded by a certain mythical halo which it will be a geographical triumph to dispel, is that comprised between long. 61° and 62° W., and the parallels of 22° and 23° S.; the river at this point was said, by theorists who forgot to account for its reappearance immediately below, to disappear altogether. Captain Page then gave an historical sketch of the various expeditions which have explored the Gran Chaco, concluding with an account of an expedition in a steamer up the River Bermejo, which he himself led, amidst many dangers from banks, and snags, and wrecks, as well as from the widespread flood that suddenly overtook him.

WITH the first number for 1889 a useful modification has been introduced into *Petermann's Mitteilungen.* For the last few years, in addition to the classified list of geographical publications each month, there has been a separately paged supplement containing critical analyses of the more important works. These were often carried to such length that many of the notices were from six to twelve months behind date. Now, the two lists are to be amalgamated, the notices are to be greatly reduced in length, and thus it is hoped that new works in the various departments of geography will be promptly made known to the readers of the *Mitteilungen.* In the first number of this year is an important paper on valleys of erosion, by Dr. V. Hilber. The paper consists mainly of an analysis of the nine theories that have been advanced to account for the formation of such valleys. The author himself favours the regression theory, according to which valleys have mostly been formed by retrogression, through the erosion of a river from its mouth backwards.

CAPTAIN VAN GÈLE, the explorer of the Mobangi-Wellé, was to leave Antwerp on the 29th for the Congo, to undertake a special mission. He is accompanied by Lieut. Le Marinel, Lieut. De Rechter, and M. Ferd. Meunier, as naturalist.

M. MAUREL, who has explored French Guiana, recently described the results of his observations and investigations to the Geographical Society of Toulouse. From the orographical point of view, he stated, French Guiana comprises four zones, rising in stages to the Tumac Humac Mountains. The first consists of a broad band of alluvial country. The second zone is hilly, covered throughout by a series of hillocks and bluffs, not exceeding 650 feet in height, and frequently separated by shallow valleys. The third zone M. Maurel describes as mountainous, with an irregular surface, abrupt slopes, and deep valleys. The Tumac-Humac chain constitutes the fourth zone, and it rises by a series of gradations to a height of about 4000 feet. M. Maurel has collected a number of flint objects, which he believes belonged to a pre-historic race that must have inhabited the country before the alluvial period. He accounts for the present formation of Guiana by two long-separated volcanic outbursts, acted on subsequently by a large river, which he believes gave origin to the deposits of the first zone.

MR. J. Y. BUCHANAN, PROF. A. H. KEANE, AND MR. J. T. WILLS, are candidates for the Lectureship in Geography at Cambridge, vacant by the resignation of Dr. Guillemard.

THE Russian Geographical Society has just brought out, as an appendix to the nineteenth volume of its Memoirs, an atlas containing all the measurements made by A. Kaulbars in the delta of the Amu-daria. These measurements, which will be invaluable to those who may hereafter study the changes going on in the delta of the great Central Asian river, could not be embodied in M. Kaulbars's capital work "The Old Beds of the Amu," published by the Society in 1887. Now they are given partly in the atlas (on the scale of 1 : 1,500,000), and in full in the text which accompanies it.

THE PRESENT STATE OF SEISMOLOGY IN ITALY.[1]

THIS group of papers affords the reader a very fair means of forming a mental estimate of what Italy has been doing to study her earthquakes during the last year or eighteen months.

Signor E. Brassart, for some years the Mechanical Constructor of the Central Office of Meteorology and Geodynamics, has produced a seismoscope in which a small slug perched on a thin column was overturned by the earthquake, and fell into an umbrella-like balance-pan surrounding the peg. In this way the direction of the shock was supposed to be indicated by the

"Il Sismometrograph a Tre Componenti con Una Sola Massa Stazionaria," Nota di Ermanno Brassart. "Sulla Sistemazione delle Osservazioni Geodinamiche Regolari," del Prof. Giulio Grablovitz. "Relazione della Sottocommissione Incaricata di Studiare alcune Proposte per l'Ordinamento del Servizio Geodinamico nell' Italia Meridionale e nelle Isole," del Prof. T. Taramelli. "Relazione alla R. Sottocommissione Geodinamica sulla Distribuzione delle Aree Sismiche nell' Italia Superiore e Media," del Prof. T. Taramelli. "Il Terremoto nel Vallo Cosentino del 3 Dicembre, 1887," Studio del Dott. Giovanni Agamennone.—All these papers are published in the *Annali dell' Ufficio di Meteorologia e di Geodinamica*, vol. viii. Parte 4, Anno 1886. (Rome, 1888.)
"Alcuni Risultati di uno Studio sul Terremoto Ligure del 23 Febbraio, 1887," Nota di T. Taramelli e G. Mercalli, *Rendiconti d. R. Accad. dei Lincei*, vol. iv. fasc. 1. (Roma, 1888.)

fold in which it fell, and its weight disturbed the equilibrium of the balance, which by making contact gave notice of the shock. Many of these are at present in use in Italy. A recent improvement is to suppress the balance, the contact is made by the slug being caught between the supporting style and surrounding umbrella-shaped grooves. The author of the paper experimented on earthquake alarms for vertical shocks, and found that, with three wire spirals, two supporting different weights and one without, the last gave less repeated oscillatory movements after the shock, returning more quickly to rest; and he therefore suggests this as an improvement on the old spring and bob seismoscope.

The next point discussed is whether it is preferable to stop or start a clock at the moment of an earthquake, and is in favour of starting one, as the few minutes between the shock and the arrival of the observer could afford little time-error, whereas there is no means of correcting the time-error of a clock stopped by the shock.

Following an observation of Prof. J. Milne on the facility with which light objects, such as pens, pencils, &c., when propped up nearly vertically, fall by the slightest movement, the author has constructed a seismoscope. A long thin bar, standing in a concavity, is supported by a small prop that can be regulated so as to put the bar almost in a vertical position, which is surrounded by an isolated ring of brass. On the occurrence of a shock, the bar falls and completes a circuit with the brass ring so as to ring a bell, start a clock, &c. Experiments made by the inventor and Prof. Tacchini showed the extreme sensibility of this seismoscope compared with others placed on a marble wall-bracket upon which small weights were allowed to fall. Drawings and descriptions are given of a method of using this seismoscope to start a clock, the pendulum of which is retained ready to vibrate by a short catch. The ring surrounding the falling bar is supported on a jointed base and the falling bar displacing it, and acting on a system of jointed levers the catch falls out of the way of the clock pendulum.

Next, Signor Brassart alludes to the different ideas current about the best method of connecting seismic apparatus to the ground, and shows the necessity of a series of experiments to determine this by using stakes, walls, &c., and employing seismographical instruments of different types.

In the next memoir by the same author, a description and drawings of the principal apparatus used in seismological research in Japan is given, together with a criticism of each. He concludes the review of these instruments by pointing out that it is only those in which a pendulum is employed, together with those possessing a rolling base, either spherical or cylindrical, that do not require adjustment, beyond rendering the base horizontal. His own choice would be a vertical pendulum, because not only does it not require adjustment and is constantly ready to indicate the shock, but is always in the same condition; and then adds, "In other arrangements it is possible greater stasis or neutrality of the mass is obtained, but notwithstanding that, for the above-mentioned reasons I should show a propensity for pendulums." This is a preference I fear few other seismologists would share with the author, since he undoubtedly alludes to vertical forms. The floating seismograph of Gray is favourably mentioned, but troubles from evaporation of the liquid, &c., pointed out. This is similar to the opinion expressed by the writer of this article, some years since, in a paper on seismographs published in NATURE.

Signor Brassart then proceeds to suggest an instrument consisting of an annular pendulum suspended by a silken cord 1 metre long, attached at its upper end in the middle of another horizontal cord made taut by side screws in the frame. In the middle of the bob, near the centre of gravity, is a pin which slides in two slots placed at right angles to each other. These slots are cut in the ends of levers of the first order, one being bent at right angles so as to bring the opposite ends of the levers side by side, to which are attached writing needles. These are made to trace on a smoked glass plate held on a truck, which by a seismoscope is liberated and drawn along at a uniform and known rate by a clock. This proposition was soon carried out with some modifications, and at the end of the paper is an appendix describing it. The changes of design consist of the suspending silk cord being attached to a stage supported on three vertical cork cylinders, the object of which is not very evident, except, perhaps, to absorb a part of the vertical component. This latter is registered by a Gray's compensated bob attached to the same frame, and by means of levers made to trace side by side with those of the two horizontal component styles on the same plate, or, as the author suggests, in some suitable cases upon an endless band of paper. This seismograph has many defects which it will be more convenient to discuss later on. This paper is dated December 1887.

It has doubtless been the ambition of most inventors of seismic instruments to be able to register the three components of an earth-movement employing but one steady-point or mass. Anyone who makes such an attempt, however imperfect be his result, deserves much credit for trying such a herculean feat in mechanical construction.

Signor E. Brassart's later production is described in February of this year, and, in so far as the registration of the horizontal components goes, is quite similar to that described in December 1887. Inserted in the suspending cord is a spiral spring inclosed in a tube, which consequently also allows the bob movement up and down. The peg or rod then slides in the slots of the horizontal component levers, is prolonged downwards a suitable distance, and terminates in a ball, which is engaged in a short tube or cup at the end of a bar. A gimbal is a mechanical arrangement by which a bar supported in its centre can rotate around any theoretical axis in the horizon of the gimbal, whilst any motion along a line normal to the horizon or plane of the gimbal would be resisted; or, if the gimbal be suspended to a lever, this will be moved in proportion to the vertical movement applied to the gimbal arrangement. (The writer of this article believes the gimbal was first applied by himself in seismological instruments, but he is open to correction.)

Signor Brassart takes advantage of this, and makes the sphere at the end of the peg from the pendulum, form a ball-and-socket joint with the tube or cup bar of the gimbal arrangement which is supported horizontally at the end of a lever. Now all horizontal excursions of the peg, joint, and gimbal bar, are quite free, but vertical excursions will disturb the whole gimbal system with its lever, the motion of which by suitable mechanical arrangements is traced by the side of the horizonal component styles.

It will be convenient now to examine the favourable points and disadvantages of these instruments. In the first place, we have the well-known defects of the vertical pendulum for registering the horizontal components of an earthquake. Then, the author's method of the peg sliding in the two slots of levers introduces an amount of friction, even where the finest workmanship and materials are adopted, as to modify the results to an important extent. In regard to the gimbal arrangement, that answers perfectly during vertical without horizontal movement; but the moment that lateral displacement takes place, the bar of the gimbal, and the pendulum length, form two sides of a triangle instead of a straight line. On the principle that two sides of a triangle are always greater than the third, the more the horizontal components are, the less would the vertical component be registered. And even there is a point in which the motion of the pendulum bob would simply resolve itself in a greater tilt of the gimbal bar.

The next study by Prof. G. Grablovitz is a kind of programme of seismological observations to be made in Italy. The paper shows a clear conception of the known or probable relationship of different seismic phenomena, and apparently the best methods to adopt for their study. One most favourable point about the author's writing is a total absence of that long-winded style, charlatanism, and seismic magic, which has characterized the writings of many Italian seismologists up to quite recently. Very little, however, is new: similar suggestions may be found scattered through the writings of many other seismologists, and part, at least, were thrown out by the writer of this article in many of his papers relating to Ischia. It is, in fact, in organizing the new observatory on that island by Prof. G. Grablovitz that has led that gentleman to the considerations contained in his paper. From observations made with the mercury cup in the temporary Ischian Geodynamic Observatory, passing carriages and numbers of people could be detected at a distance of 100 metres; therefore the author considers this as the minimum distance of isolation such an observatory should possess.

The next is a report of a sub-committee, drawn up by Prof. T. Taramelli, dated December 1886. It consists of a review of the principal earthquakes that have affected different regions of Southern Italy, and the means then in existence for their study. This was preceded by another report referring to Northern and Central Italy. The author opens his report by discussing the views of different writers as to the causes of earthquakes, with-

out adding in any way to those views. Chapter ii. is a review of the earthquake parts of Italy referred to in the report, together with an attempt to separate the country into seismic provinces, a work already in part carried out by Mercalli, and where observatories are wanting to suggest the establishment of them. Appended to this memoir is a map of Italy coloured in nine tints, showing the seismic intensity in different regions. If the reader compare this with a geological map of the country, he will be struck with the relationship of earth-movements and the rocks. We notice intense foci near Sienna, north of Florence, and the alluvial flats of the mouths of the Po, another in Umbria, and a very intense one between Aquila and Solmona, where the Apennines reach their greatest elevation. There are the two volcanic centres of Naples and Melfi, with the intervening of Benevento and Ariano, a district in which comparatively recent rocks are much metamorphosed, whilst to the south-west of Potenza we observe a large but only moderately intense focal area. The toe of the Italian boot looks very dark with the two intense centres of Cosenza and Aspromonte, together with the Messina district in Sicily. In these we have granite, gneiss, and other crystalline rocks, covered chiefly by more or less friable Tertiary deposits, much eroded into many narrow deep valleys, and sharp crumbling intervening ridges. One cannot but be struck by the striking relationship between the distribution of seismic areas and the alluvial flats, the volcanic regions and more active points of mountain-building in the geologically-speaking young country of Italy. In fact, this map constitutes the most important part of the report.

The last two memoirs are descriptive in character, dealing with the two recent destructive earthquakes. Of these two, the first, by Dr. J. Agamennone, refers to the earthquake which occurred on December 3, 1887, in the Cosenza Valley. Besides the topographical, a geological map is given, with a description from which we learn that this strip of mountainous land lying between the Gulfs of Taranto and of Policastro is composed principally of granite and allied rocks with gneisses and schists. The depression constituting the valley is filled by clays, sand, marls, and other more or less incoherent rocks of Tertiary age, which have been eroded by innumerable side valleys into pinnacles, and tongues of land with more or less perpendicular sides very liable to slips. Bisignano, which suffered most severely, is situated on some of these pinnacles or almost isolated tongues of molasse. Although the town has been destroyed by nine or ten earthquakes, many of these had their foci at some considerable distance. This last earthquake occurred during a barometric maximum corresponding to a marked centre of high pressure that crossed Europe from December 1-3, and three days after full moon. The author could find no relationship between increase or decrease of microseismic movements in Italy and this earthquake. As there were probably three shocks, the first being comparatively feeble, the people had already escaped from their houses when the second arrived, so that, comparatively to the ruin, few lives were lost. These are the results of the statistics: houses down or threatened ruin, over 900; deaths, 22; wounded, 60; and damage done to the value of 1,000,000 lire.

It appears that here stone must be brought from some distance, and building materials are very dear, hence bad construction and ruin. This but too well recalls the appalling scenes that passed under the eyes of the writer of this article after the earthquakes of Ischia [1] which might have been far less destructive, had it not been for the horribly bad walls, &c.

From the exceedingly incorrect time kept and the few approximately accurate records, the calculations afford for the *velocity of propagation* from 650 to 3300 metres per second.

The author shows that the epicentre was near the station of Mount Grassano, and that the greatest damage was on the loose unsupported friable rocks resting inclined against the sloping faces of the older compact rocks—conditions of effect identical with what occurred in the great Calabrian earthquake of 1783, and noticed by Mallet in 1857. The intensity of this earthquake the author calculates, on somewhat flimsy grounds, at eleven times less than the Andalusian, and four times less than that studied by Mallet in Italy in 1857. The sound seems to have been communicated to much greater distances through the compacter and more elastic rocks than through the loose detritic deposits. What, however, is strange, is the manner in which the author talks of one shock being subsultory and another, in the same locality, as undulatory, as if they were two entirely different kinds of earthquakes.

In fine, we pass to the consideration of the Ligurian earthquake of February 23, 1887 (described by Prof. Taramelli and Mercalli), which drove so many people away from the towns of the Riviera. The first eight pages are devoted to the geology of the district, which may be said to be composed of a range of compact fairly elastic rocks close to the shore-line. The valleys that incise the cliff along the coast extend not only to the sea line, but some distance beneath the water, whilst near the coast they are partly filled by platforms of late Tertiary, and very incoherent deposits. It is on these small somewhat triangular planes that most of the towns are met with. The region is one of the most disturbed by earthquakes of Upper Italy, no less than twelve, more or less destructive, occurring since the thirteenth century.

The authors sent out 1100 circulars to different localities, and from the answers were able to obtain much information. It appears that, as on former occasions, slight shocks were felt over the whole district, and preceded the great one, no less than four occurring during the previous night to February 23, 1887. The area affected extended southwards to Rome, Mount Ferru (Sardinia), east to Pordenone, west to Perpignan, and north to Lyons and Basle. The mesoseismic area was crescentic in shape, 100 miles long between Mentone and Albissola. The form was due to the focus being beneath the sea, and to the region occupied by the elastic crystalline rocks. The effects of geological structure in affecting the limitation of isoseismal areas was beautifully illustrated in the Ischian earthquakes described by the reviewer. It is not customary to call the region above mentioned the mesoseismal area, which should be limited to that space around the epicentre and above the focal area: a better definition would be that of almost total destruction. The zone of severe injury extended to the Langhe of Piedmont and Astignano. The limits of severe shaking reach Turin and the lower Canovese, whilst the earthquake was strongly felt as far as Como, Arona, Parma, Leghorn, Marseilles, and nearly all of Corsica.

The main shock seems to have had two maxima, and to have lasted about 30 seconds. The authors calculated the *velocity of projection* at 9·4 m. at Oniglia, 3·53 m. at Faggia, and 4·7 m. per second at Nice. As in other cases of localities not epicentral, the rumble preceded the shock, the more, the farther the observer was from the focus.

Azimuths point to the epicentre being 15 miles from the beach, midway between Oniglia and San Remo, which is confirmed by the isoseismals being concentric to a point 20 kilometres south of Porto Maurizio. The shock appears to have started at about 6.19 a.m. The velocity of propagation was calculated at 1452 m. per second westward, and 584 m. per second towards Genoa: this the authors consider to be due to a main and secondary focus, whilst the depth obtained from emergence angles appears to be 18 kilometres. Little disturbance of the sea occurred, but it is said to have remained at a lower level for some days at Loano and Porto Maurizio. Dead fish of deep-sea character were found along the coast some days after. No meteorological phenomena of importance were noted, but strong telluric currents were set up at the moment of the earthquake. After nine minutes, another destructive shock occurred, another at 8.53 (M.T. Rome), and in the ruined area there occurred another twenty-two slight shocks, and others continued to occur with diminished force to March 11, so that at Savona fifty were perceptible in all.

The first three earthquakes killed 640 persons, and wounded as many, and the damage in the provinces of Porto Maurizio, Albenga, and Savona, was valued at 21,500,000 lire.

The greatest damage occurred on thin layers of incoherent rocks superposed on the more elastic and crystalline ones, at sharp boundary lines of different rocks, and unfavourable topographical positions. The effects were augmented by bad and unscientific construction of the houses, or badly repaired buildings, that have suffered in former shocks.

In this article, already of inordinate length, fair justice has hardly been done to the works reviewed, but the reader will see that Italy is awaking to her duty towards humanity and science in organizing the study of her seismic phenomena, and shaking off that conservatism and isolation which ruled her in this department up to the year after the great Ischian earthquake.

H. J. JOHNSTON-LAVIS.

[1] H. J. J.-L., "Monograph of the Earthquakes of Ischia: a Memoir dealing with the Seismic Disturbances in that Island from Remotest Times, with Special Observations on those of 1881 and 1883." (Naples: Furcheim, 1885.)

FRIENDLY SOCIETIES AND THEIR FUNDS.[1]

M. DE LAFITTE is the Vice-President of a Friendly Society numbering some 150 members and of a somewhat advanced type. He has evidently discharged his duty as Vice-President with exemplary devotion to the work, and has extended his studies and observations over the wider area covered by the French Friendly Societies generally. From a Report of the Minister of the Interior, it appears that the number of these Societies on December 31, 1885, was just upon 8000, that the average number of members in each was 136, and that, consequently, the total number of members whose names were inscribed in their rolls at that date was more than a million.

The volume before us is professedly an elementary treatise on Friendly Society finance. The author, in the opening chapter, selects, as the typical Society, one which possesses no other resources than the contributions of its members, and which, in return, undertakes to provide three distinct benefits: viz. (1) an allowance during sickness, (2) an old age pension to commence at a specified age, and (3) a sum of money to be paid to the relatives, on the decease of a member, to cover funeral expenses. He deals, throughout the book, with the various conditions under which contributions are levied and benefits conferred; but as a rule he assumes that new members are admitted at the age of 16, that the contributions cease at age 70 (or thereabout), when members become pensioners, and that sickness allowances, so far as money allowances go, are, at the same time, also discontinued.

The author, at the outset, urges the desirability of apportioning the total contribution of each member into three parts, corresponding to the three kinds of benefits assured to the member; and of keeping an exact account of the fund accumulated, from year to year, out of each part, *i.e.* of keeping an exact account of the resources available, at any moment, for each kind of benefit.

He points out, what is indeed obvious enough, that the share of contribution allotted to pensions must accumulate for many years; in fact, till the age for commencing pensions is attained by the members of the Society. He points out that, of the share of contribution allotted to meet sickness claims, a fraction of it only is required in the earlier years of life, when periods of sickness are less frequent and less prolonged, the remainder of it forming a provision against the heavier disbursements of later years, when the periods of sickness have become more frequent, more protracted, and more costly. Also, he points out that with the share of contribution intended to secure funeral moneys, there is likewise a gradual accumulation going on from the earlier years of life, when deaths are fewer in number, to the later years of life, when they are doubly and trebly as numerous. In respect of all three kinds of benefits, then, each member of the Society, during his years of active membership, has an increasing interest in the adequate accumulation of the funds of the brotherhood. These funds are trust funds, a collection of deposits confided to the Society by its members, and for which it remains accountable till the time arrives for restoring them, in the shape of aid to the members in sickness, or old age, or to the relatives upon the occurrence of decease. The preceding considerations show that every Society has not only accumulating funds fed by unused portions of the contributions received year by year, but also, and on the other hand, growing liabilities, and it has therefore to take care that the liabilities do not grow faster than the funds accumulate.

Every Society renders accounts year by year, but they are of the usual form, and that is not enough: at the same time that it exhibits its resources, it should know how to calculate with exactness its actuarial liability under current contracts with its members. By actuarial liability we mean the obligation of the Society to gradually accumulate a fund out of which future benefits may be paid as they mature. By inserting the amount of such actuarial liability in its balance-sheet, the Society completes its statement of liabilities and assets, and shows conclusively whether its accumulated funds are more or less than they should be. Such a balance-sheet, if the liabilities and assets are shown separately for each of the three kinds of transactions—sickness allowances, pensions, and death payments—is a perfect balance-sheet. It should be made out every year, and carefully studied by those responsible for the management of the Society.

The author's chief object in writing the present treatise is to give tables of actuarial liability, and to enunciate, prove, and illustrate rules by which such liability may be calculated. He proposes to explain to Friendly Societies how two or three of their constituted officials, in the course of an afternoon, may determine the liability of the Society with precision, and without possessing any preliminary knowledge other than that of the elementary rules of arithmetic, such as are taught at the primary schools to children of between ten and thirteen years of age.

Considering the labour usually expended on actuarial valuations, and the special knowledge and skill usually regarded as indispensable in such investigations, these are brave words. Impressed, as we are, with the immense amount of good that would accrue from the accomplishment of the author's design, we wish him whatever success is possible. There is nothing so much needed for the stability of Assurance Companies as well as Benefit Societies as a fuller acquaintance on the part of the public with the nature of actuarial liability. If such knowledge were general, we should hear little more of the insolvency of such associations, and see little more of the sad spectacle of a group of dependent and helpless persons finding in sickness or old age that the savings of long years of self-denial have been sacrificed.

In the calculations of Friendly Societies the average mortality and sickness found to have been experienced under more or less similar conditions must form the basis of all reasoning, and the effect of compound interest, combined with mortality and sickness, must, in some form or another, be introduced as further necessary preliminary information. The author lays before us, as giving such necessary preliminary information, several tables. In addition to two tables of mortality, viz. the table of the Caisse des Dépôts et Consignations, and the table of the English Institute of Actuaries, known as the H^M (healthy males) table, and a sickness table, showing the average number of days of sickness per head at each year of age, we have two tables of a somewhat unusual kind for the present purpose. These tables embody new rates of the Caisse Nationale des Retraites pour la Vieillesse, of whom pensions are bought, and show, for any present age, the amount of deferred annuity, to commence at age 50, 55, 60, or 65, corresponding, in the first table, to a payment, cash down, of 100 francs, and, in the second table, to a payment of 10 francs a year until the pension commences. A table of the present values of temporary annuities, terminable at any one of the four ages first mentioned, completes the group of fundamental tables.

The fact that both the above-named tables of mortality are frequently used in one and the same solution is, as the author appears to be conscious, open to criticism; and so is the fact that contributions are sometimes assumed to be payable at the beginning of the year and sometimes at the end of it. In a particular case, instanced by the author himself as showing that the consequent error is insignificant, the error amounts to 4 per cent. of the true figure, and this is hardly to be regarded as an insignificant difference. With respect to the tables themselves, they display appreciably different rates of mortality, and if one is found to be suitable for a particular Society, the other can hardly be suitable also. The H^M is a table of which English actuaries are justly proud; but a record of the mortality experienced by the middle and upper classes of this country is hardly to be accepted as a measure of the mortality to be expected amongst the artisans and mechanics and the mechanical and agricultural labourers of France. It might not, possibly, be inapplicable to some of the rural districts of that country, but if so, it would probably not be applicable to the districts of the large towns and the cities. Strictly speaking, no one table of mortality is suitable in all the varying conditions of locality and occupation to be found within the boundaries of French territory; and herein lies an obvious objection to the application of stereotyped results, such as those prepared for general use by the author, to the circumstances of all the Friendly Societies of an entire country, indiscriminately.

In selecting a sickness table on which to base the calculations of sickness liability, the author very properly observes that sickness tables, when compared one with another, often present discordant results. This is explained to be due to the limited number of observations or individual experiences on which the tables are based, and partly to the difficulty of saying exactly when a period of sickness begins or ends—of drawing, with precision, the line of demarcation between positive sickness and mere indisposition; besides, chronic and incurable maladies have been

[1] "Essai d'une Théorie Rationnelle des Sociétés de Secours Mutuels," par Prosper de Lafitte. (Paris: Gauthier-Villars et Fils, 1888.)

dealt with differently in the tables compiled for publication. Of the tables at the author's command, he has chosen that given by M. Hubbard as being, in his judgment, the best representative of the circumstances with which he is immediately concerned.

We cannot, at this point, do better than compare M. Hubbard's figures with those we are familiar with in England, viz. those of the Manchester Unity of Oddfellows and the Foresters. We give, then, the average number of days of sickness per annum at each of the undermentioned ages, as shown by the several tables specified. In the cases of the Oddfellows and the Foresters, the total average sickness in the year is shown in two parts—sickness within six months of its commencement, and sickness counting only beyond this limit. The rules of French Societies generally do not continue aid in money beyond the term of six consecutive months, a large proportion of them not beyond three.

Age.	M. Hubbard	Manchester Unity of Oddfellows: first six months and subsequently.		Foresters: first six months and subsequently.	
20	4·4	4·6	0·3	5·6	0·3
30	5·6	5·2	0·9	5·4	0·9
40	6·0	6·4	1·8	6·9	2·0
50	7·1	9·1	4·8	9·1	4·5
60	11·7	15·0	13·2	13·8	13·1
70	17·1	25·8	44·8	24·0	48·6

A glance at the above table affords sufficient evidence that the author is right in his assertion that sickness tables present very discordant results; and we should be somewhat failing in our duty if we did not utter a word of caution as to the use of M. Hubbard's tables by unskilled persons, more especially so as the author is inclined to advocate the continued payment of the sickness allowance in prolonged sickness rather than its curtailment. The experience of the Oddfellows and the Foresters may not supply a suitable basis for the calculations of *les Sociétés de Secours mutuels*; but this experience is extensive, has been carefully tabulated by competent actuaries, and is, at least, worthy the attention of anyone proclaiming, as our author does, the narrowness of existing and available data.

We have not the space to follow the author in detail through the numerous rules and explanations given by him in connection with the calculation of actuarial liabilities and kindred matters. We must content ourselves with an examination of one only, and that a simple one. We propose to consider the method recommended for the calculation of the actuarial liability attaching to the receipt of contributions on account of pensions. As an example, the author takes the case of a member of 47 years of age, who has contributed 10 francs a year since the age of 16, and who is looking forward to a pension of 294 francs 11 centimes to commence at the age of 65. He then proceeds on the basis of the Caisse des Retraites tables, substantially, as follows:—

According to the second of the two tables, an annual contribution of 10 francs, the first payment being made at age 47, secures a pension, to commence at age 65, of 41 francs 35 centimes a year. Whilst, for the same annual contribution, the first payment being made at age 16, the pension is one of 294 francs 11 centimes a year. The equivalent at age 47 of the earlier contributions (from age 16 to age 47) is, therefore, a pension amounting to the difference of the two preceding ones, 252 francs 76 centimes a year. But, according to the first of the two tables, the cost, at age 47, of a pension of 34 francs 53 centimes a year is 100 francs. It follows that the cost of a pension of 1 franc is $\frac{100}{34·53}$ francs, and of 252 francs 76 centimes is $\frac{100 \times 252·76}{34·53}$, *i.e.* 732 francs.

We do not think the tables on which this calculation is based are more convenient in form than those in general use, or that they lend themselves more readily to a simple presentation of the theory of the subject; and we do not think the method of arranging the calculation is any improvement upon that commonly adopted. Annuity tables intended as aids to arithmetical computation are usually constructed to the unit of annuity, and not to the unit, or ten, or hundred, of contribution or purchase money. A common form of annuity table gives, for each year of life, the present value of a temporary annuity, payable to one of certain ages, say to age 65, accompanied by the present value of a deferred annuity to commence immediately thereupon, the two present values added together giving the present value of a life annuity to run during the whole of the annuitant's life. The ordinary calculation, which may be called the method of present values, then proceeds to estimate the liability of the Society to provide the future benefit, on the one hand, and the claim against the member to provide future contributions on the other:—

Present value, at age 47, of a pension of 294 francs 11 centimes a year, after age 65, is the tabular number (2·90) × 294·11	853 francs
Present value of contribution of 10 francs, payable from age 47 to age 65, is the tabular number (12·10) × 10	121 francs
Leaving the actuarial net liability as before ...	732 francs

The principle of present values which distinguishes the usual method of calculating actuarial liabilities, is quite as easy for the general public to understand as the inverted method of using tables, proposed by M. de Lafitte; indeed, easier, because of the uniformity with which it is applicable to all cases of annuity, assurance, or sickness contracts. M. de Lafitte himself makes reference to it in explaining the calculation of sickness liabilities. We are of opinion, however, that there is a still simpler way of explaining to the general public the calculation of actuarial liabilities than that depending on the principle of present values. The latter looks to the future, the former to the past. The latter is a prospective method of procedure, the former is sometimes described as a retrospective method. It consists in imagining a number of persons, equal to the number in the table of mortality or sickness, to have actual existence, and to live and die as indicated in the table of mortality, and to fall ill as indicated in the table of sickness, and for the periods mentioned therein. By supposing contributions to be received year by year from all who live to pay them, and the various benefits to be paid out as they accrue due, the amount of money remaining in hand, as thus shown, is the sum that a Society of the tabular number of members should have in hand, and therefore the amount also of the Society's actuarial liability as required. For any other number of members than that suggested by the table, the amount of the actuarial liability would be proportional.

We have confined our observations, in the main, to the subject of actuarial liability, the use of tables of such liabilities, the mortality and sickness experiences on which they are based, and the principles on which they are explained, because the chief object of the book is to deal with this subject and to popularize it. There is, however, a chapter on the due, or fine, or fee, to be charged new members who join at other than the age for which the rates of contribution are arranged; another chapter on raising the contributions of existing members to provide increased benefits or to meet a deficiency; another on the mission and the proper sphere of Friendly Societies; and others beside, all affording excellent reading, and on which, had space permitted, we should like to have said a few words; but we must conclude this notice. The author manifests an enthusiasm in the work he has undertaken, has expended a great deal of time and thought upon it, and evidently has the welfare of Friendly Societies at heart. If one may judge of literary composition in a language which is not one's own tongue, we should like to express the opinion that the author's writing is clear and attractive. In his efforts to promote and encourage a wider knowledge of the somewhat abstruse subject of actuarial liabilities or valuation reserves, he has our very best wishes.

WATERSPOUTS IN THE HUGHLI.[1]

ON Tuesday, the 4th instant, a fine waterspout was projected from the level vapour-plane of a silvery-edged towering cumulus cloud—or, as our American cousins would term it, a "thunder-head"—over the western side of Kulpee anchorage, and near the village of Jiggerkolly, which, by the aid of a good telescope, showed well the downrush on the inside of the tube, and its counterpart the whirling uprush on its outside, twisting and coiling round and round against the watch-hands (face upwards).

[1] Reprinted from the *Englishman* of September 13, 1888.

The day had been close, hot, and breezeless, so far as the surface was concerned, and the cloud in question formed a grateful screen to the afternoon's sun, which was shining brightly north and south of our position; and continued to do so until old Sol hid his face for the night in lower clouds later on. At about 5 p.m., a well-formed waterspout was observed trailing away north-eastward from the cloud's northern verge; then about 40° or 30° high. Near the dense cloud from which it grew its mass was dark and opaque; but from half way down its length to below where it terminated in an unfinished turmoil of jags and rags, it was semi-transparent, the clouds beyond in the background being distinctly seen through it; and there was a light-coloured tube within its gauzy mass which at times was very pronounced and conspicuous.

There seemed to be no commotion on the river or the shore, over which its lower part hung at a height of five or six hundred feet, from the time when it was first observed until it began to wane and draw itself upwards. It was then, when it had shrunk and shortened, that the inside downrush was seen to advantage, and the simultaneous upward whirl around the dense remains of the tube, which, so far as I was able to make out from the motions of the cloudlets, I cannot do better than liken to the turning inside out of a coat sleeve or of a stocking, only the end of the tube was always ragged; and here, where this reversing process was taking place, there was great commotion in the air currents, more especially after the tube had withdrawn itself up to its opaque head.

I had a good telescope, observed these phenomena very carefully, and was on the alert for optical illusions; and, as the upper part of the spout remained intact for a long time after the gossamer-like lower continuation had melted into invisible vapour, I had an opportunity of studying it well.

It was very remarkable to see two or three common kites hovering high up in the vapour plane round and round the dense tube, every now and then becoming hidden behind it as they performed their gyrations, and in the same direction as the ragged fragments of rack or scud which were rushing round and upwards towards the dense head of the spout, until they were actually lost to sight in the very cloud itself.

The "thunder-headed" cloud, from the lower part of which the spout issued, gradually melted away, and grew less gaudy as it dwindled, without, as is usual under similar circumstances, pouring forth a torrent of rain. But there was a double rainbow projected on the clouds banking up over to the eastward, and evidently rain was falling in the space between them and the sun for some time after the last remains of the spout had disappeared, and all was again tranquil aloft.

The following evening, during a heavy thunderstorm and severe squall from the north-east, some twenty miles further down the river, a flash of lightning revealed the existence of a grand waterspout close by. This thunderstorm was remarkable, as it stretched south and north from the pilot station to far north of our position off Kedgeree, and struck both places at nearly the same hour, 7 p.m. Possibly all these phenomena had some connection with the small whirl reported in Mr. Pedler's useful weather bulletin issued daily from the Meteorological Office. The squall itself was seen from an early hour in the evening as a tract of dark streaks hovering ominously high up behind the accumulating white clouds away in the north-east and east, and threatening to quench the light north-west wind blowing in the estuary.

Subsequent information concerning this sudden thunderstorm shows that it was one of the class, referred to lately in NATURE by the Hon. Ralph Abercromby, which extend in an almost straight line for maybe hundreds of miles. It was felt at nearly the same hour all the way from Titighur on the north, to a point forty or fifty miles south of the Hughli Pilot Station—or, say, nearly 200 miles. S. R. ELSON.

SCIENTIFIC SERIALS.

Journal of the Russian Chemical and Physical Society, vol. xx. fasc. 8.—On the properties of allene, by G. Gustavson and N. Demianoff. The existence of this isomer of allylene ($CH_2 : C : CH_2$) was foreseen since 1872; now, it has been obtained by the action of zinc dust and alcohol on $C_3H_4Br_2$. It is an uncoloured gas, the smell of which resembles that of allylene. It smokes freely when burning.—A note on the atomicity of bore, by G. Gustavson.—On unorganized ferments, by N. Kravkoff, being an inquiry into the properties of pure vegetable diastase.—On a general law of contraction during the formation of solutions of salts, by A. Geritsch. The author comes to the conclusion that the contraction (δ) is proportional to the produce of the respective percentages of water and salt in the solution $\delta = C(100 - p)p$; for Na_2CO_3 the constant C is $= 0{\cdot}0086$, and the contraction calculated by means of the formula for solutions at from 3 to 13 per cent. are very near the contractions directly measured by Gerlach and Mendelejeff.—On the solutions of sulphuric acid from the molecular point of view, by M. Teploff.—On the heat of combustion of stilbene, the mononaphthenes, and some organic acids, by J. Ossipoff.—An apparatus for the demonstration of thermic conductibility, by O. Chwolson.—On a new method of measuring the index of refraction, used by E. Forsch for measuring the same in the lenses of the Pulkowa refractor.—A note on the mutual influence of electrized bodies, by A. Stepanoff.

SOCIETIES AND ACADEMIES.

LONDON.

Linnean Society, January 17.—Mr. W. Carruthers, F.R.S., President, in the chair.—On behalf of M. Buysman, of Middleburg, Mr. B. D. Jackson exhibited a series of careful dissections of *Nymphæa cærulea* collected by Dr. Schweinfurth in Egypt.—Mr. D. Morris exhibited specimens of drift fruit from Jamaica, where he had collected no fewer than thirty-five different kinds brought by the Gulf Stream from the mouths of the Orinoco and Amazon. Although the species exhibited had not been determined with certainty, it was believed to be probably *Humiria balsamifera*, Aud., the flower of which is figured by Eichler ("Flora Brasiliensis," vol. xii. part 2, p. 440, pl. xcii. fig. 1), but the fruit undescribed. It was commonly known in French Guiana as *bois rouge*, and from it was obtained a gum used medicinally and burnt as incense. An interesting discussion followed, in which Mr. J. G. Baker, Mr. Rolfe, and Mr. Breese took part.—Mr. T. Christy exhibited a material felted from Manilla hemp, and waterproofed, very strong and light, and particularly useful for surgical bandages, for which purpose it was highly recommended by army surgeons.—Mr. F. Crisp exhibited some specimens of agate so curiously marked as to lead to the erroneous supposition that they inclosed fossil insects and Crustacea.—A paper was then read, by Mr. J. G. Tepper, on the natural history of the Kangaroo Island grass-tree, *Xantharrhœa Tateana.* This tree grows abundantly in Kangaroo Island, South Australia, in poor gravelly and sandy soil, intermixed with ferruginous concretions, and attains a height of from 6 to 14 feet, with a diameter of 6 to 18 inches, and a floral spike of from 10 to 19 feet. It is thus a most conspicuous plant, and lends a peculiarly weird aspect to the country it occupies. Its rate of growth is described as very slow, old settlers having remarked but little change in individual trees after thirty years' observation. The most remarkable feature in the structure of the stem is the formation of a dense ligneous central core immediately above and connected with the roots, exhibiting numerous annular zones traversed by transverse (medullary) fibres. The flowers are borne in a dense spike upon a smooth peduncle. Individually they are inconspicuous, of a whitish colour, and develop a strong odour and abundant nectar during the warmer part of the day, when they are visited and fertilized by Hymenopterous insects, the most remarkable being a large metallic-green carpenter-bee (*Xylocapa*), which tunnels out cells in the dead flower-stalks. An interesting discussion followed upon the botanical position of the grass-trees, and the antiquity of the type, in which the President, Mr. A. W. Bennett, Mr. J. G. Baker, Mr. Morris, and Mr. Rolfe took part.

EDINBURGH.

Royal Society, December 17, 1888.—Sir W. Thomson, President, in the chair.—Mr. R. Kidston read a paper on some fossil plants from Teilia quarry, Gwaunyscor, near Prestatyn, Flintshire.—Dr. G. Sims Woodhead communicated an abstract of the results of an inquiry into the causation of Asiatic cholera. The first part (general) was by Dr. Neil McLeod and Mr. W. T. Milles. The second part (with special regard to the reproduction of the disease) was by Dr. McLeod. The disease was shown to be due to the comma bacillus. In forty out of forty-four cases this bacillus was present; while, in a large number of spurious cases, it was only once or twice detected. It was found that symptoms similar to those accompanying cholera in

man followed injection of the comma bacillus into the stomach of the guinea-pig, care being taken to neutralize the acid products which are fatal to the organism.—Prof. Tait described some preliminary observations with a large rotatory-polarization spectroscope. In this apparatus the light passes through a slit and collimator, a Nicol's prism, a train of cylinders of quartz, a double-image prism, and an ordinary direct-vision spectroscope. The instrument is so arranged that the two spectra produced are in exact juxtaposition side by side, each spectrum being alternately crossed by dark interference bands corresponding to successive rotations of the plane of polarization through 180°. A scale is thus applied to the spectrum, and the interval between successive bands can be subdivided to any required degree of accuracy. Wave-length is thus measured with extreme accuracy by the amount of rotation of the plane of polarization. When the apparatus is used, not with bright-line spectra but, with continuous spectra, the excessive loss of intensity by dispersion which occurs in ordinary spectrometers may be avoided.—Dr. Woodhead communicated a paper by Mr. G. Brook, entitled "Preliminary Remarks on the Homologies of the Mesenteries in Antipatharia and other Anthozoa." After describing the arrangement and musculature in the common shore anemone, *Edwardsia*, Cerianthidæ, in Alcyonaria, Madreporaria, Mr. Brook pointed out that the Antipatharia are generally supposed to be degenerate forms, and to have lost a considerable number of the mesenteries that were present in their ancestors. Mr. Brook, who is examining the *Challenger* collection of Antipatharia, has been able to make sections of twenty-three species, from which he finds that the arrangement, number, and relative development of the mesenteries cannot be explained in accordance with the views current on the subject. With the exception of two pairs of directives the mesenteries do not appear to show the paired arrangement usually looked for. He gives the arrangement of the mesenteries in *Cladopathes* (six mesenteries), *Antipathes* (ten mesenteries), *Leiopathes* (twelve mesenteries), and points out that the arrangement in these forms receives its explanation by a comparison with the order in which the first twelve mesenteries are, according to Lacaze-Duthiers, developed in Hexactiniæ. In *Actinia* and *Sagartia* the first twelve mesenteries are developed in pairs which are not adjoining mesenteries, but are situated one on each side of the stomodæum. The order in which they are developed in *Sagartia bellis* (and in *Actinia equina*?) precisely corresponds *with their relative length* in *Leiopathes*. The first pair to be developed are those corresponding to the transverse mesenteries in Antipathidæ; next follow the two pairs of directives, and afterwards the three pairs which he has termed "secondary" in Antipathidæ. The shortest mesenteries in *Leiopathes* are the last of the six pairs to be developed in *Sagartia*. Evidently, then, the mesenteries forming a pair are originally opposite mesenteries and not adjacent ones. We thus have, in forms with an elongated stomodæum, a true bilateral symmetry. The two pairs of directives limit an anterior and a posterior unpaired chamber. Between these two the cœlenteron may be imperfectly divided into any number of paired lateral chambers. On this interpretation the arrangement in Alcyonaria, *Edwardsia*, Cerianthidæ, *Madracis*, &c., is also easily understood: all are modifications of one plan. In the Hexactiniæ the simple bilateralism is masked, but a careful study of the order in which the mesenteries are developed shows clearly how this is brought about. In all types the mesenteries of a pair are originally on opposite sides of the stomodæum. The two pairs of "directives" come to be *adjacent* mesenteries, for the reason that no new mesenteries are ever formed between them, and with a further development of mesenteries they come to be pushed closer together. As is clearly seen from Hertwig's figures of the embryonic condition in *Peachia*, the other so-called "pairs" of primary mesenteries are not pairs developmentally, as they consist of mesenteries of different ages. They are called pairs because they are arranged in couples, having the retractor muscles on their inner surfaces. In Hexactiniæ the further increase in the number of mesenteries takes place in a modified way. Buds appear which are on opposite sides of the stomodæum between existing "pairs," but, instead of giving rise to a single mesentery as before, each gives rise to two, with the retractor muscles on their inner surfaces. The general plan of development Mr. Brook considers to be as follows. The mesenteries have a radiate arrangement in forms with a round stomodæum; this arrangement becomes bilateral by an elongation of the stomodæum in one axis—the sagittal. In this case the anterior and posterior pairs (directives) come to consist of adjoining mesenteries, whilst the intermediate pairs consist of opposite mesenteries. So long as the folds of the body-wall give rise to only one mesentery each, the simple bilateral arrangement is retained, as in Cerianthidæ (this refers to bilateral arrangement of parts, irrespective of the outline of the polyp). In case the mesenterial rudiments give rise (after the formation of the first twelve mesenteries) to two mesenteries instead of one, the Hexactinian type is reached. In certain Madreporaria (*e.g. Lophohelia*, *Mussa*, and *Euphyllia*) the radiate arrangement appears never to be lost. At any rate, according to Fowler and Bourne, there are no mesenteries distinguishable from the others as "directives," and there is a perfectly radiate symmetry. Such a general plan of development is also found in *Peripatus* and in Vertebrata. In *Peripatus* the blastopore becomes elongated and closes in the centre, but its two extremities remain open as the mouth and anus. The mesoblastic somites are formed in the region in which the blastopore has closed, and these become more numerous as the two extremities become more and more separated. At present, Mr. Brook is only able to indicate the bearing of these views in outline. He hopes, however, shortly to make a more detailed communication on the subject.

January 7.—Prof. Chrystal, Vice-President, in the chair.—At the request of the Council of the Society, Prof. Tait gave an address on the compressibility of water, salt-solutions, glass, and mercury. His address was illustrated by experiments.

PARIS.

Academy of Sciences, January 21.—M. Des Cloizeaux, President, in the chair.—On a point in the question of homogeneous elastic plaques, by M. H. Resal. In this note the author proposes to base the hypothesis relative to the expressions of the tangential dilatations on a supposition of a more general character than that hitherto assumed by geometricians.—On the Hæmatozoa detected by M. Laveran in the blood of the inhabitants of marshy districts, by M. Bouchard. Attention is called to the great importance of the discovery made by M. Laveran ten years ago, and now placed beyond all doubt, that marsh fevers are of parasitic character. They offer the first known example in man of an animal parasitism in which the pathogenic agent appears to be placed at the lowest scale of animal life. While most infectious maladies in man and animals are due to vegetable microbism, the most important and widespread infectious disease in man is now shown to depend on animal microbism. The parasite observed by M. Laveran in Algeria has since been found in France, Corsica, Italy, Russia, Madagascar, Tonquin, and America, and is identical with the organism more recently detected by Marchiafava and Celli in the blood of people inhabiting marshy districts.—On the elementary terms in the co-ordinates of a planet, by M. Hugo Gyldén. Supplementing his recent communication on this subject, the author here points out that, the convergence of the terms in question being established, their numerical values may be determined by the methods proposed in the paper on the determination of the radius vector in the absolute orbits of the planets inserted in the *Monthly Notices* of the Royal Astronomical Society, London.—On the distribution of the aqueous vapour in the atmosphere, by M. A. Crova. In a previous note (*Comptes rendus*, cviii. p. 35) MM. Crova and Houdaille communicated the results of the observations made last August at Bedoin and on the summit of Mont Ventoux. From those results M. Crova here deduces the mode of distribution of the aqueous vapours at various altitudes. Although only approximate, the calculations show how rapidly the quantity of vapour must decrease with the increase of altitude. The quantity itself also varies greatly from day to day, which is again explained by the fact that the vapours are mainly confined to the lower atmospheric regions, which are most directly influenced by meteorological phenomena.—Note on the new meridian of France, communicated by the Minister of War. The Geodetic Section of the Service Géographique de l'Armée concluded in 1888 the measurement of the angles for the new meridian begun eighteen years ago. The present note embodies a summary report of the main results, from which it appears that the meridian of Delambre and Méchain, useful in their day, can no longer serve as a base for the triangulation of France, or for further researches on the form of the globe. For these purposes the new meridian offers all the necessary elements except for the south-west region, where fresh measurements are required to secure complete accuracy.—Observation

relative to M. Vaschy's recent note on the propagation of the current in a telegraph line, by M. L. Weiller. The author questions on theoretical grounds some of M. Vaschy's conclusions, on which has been based an application for a patent. M. Weiller submits a specimen of a telephonic cable with two conductors constructed for the purpose of obtaining by self-induction the compensation of the electro-static capacity. In this apparatus the increase of the coefficient of self-induction is obtained by inclosing the chief copper conductor in a covering of soft iron wire.—Observations of the partial lunar eclipse of January 16, 1889, made at the Observatory of Lyons, by M. G. Le Cadet; and at the Paris Observatory, by MM. D. Eginitis and Maturana. The observations at Lyons were made with the Gautier equatorial *coudé*, and at Paris with the west equatorial in the garden. In the latter place the atmospheric conditions were favourable at the commencement and towards the close of the eclipse; but during the middle period the sky became overcast, preventing the complete observation of all the phases.—Experimental verification of M. Charles Soret's method for measuring the indices of refraction in crystals with two axes, by M. Louis Perrot. In a previous note (*Comptes rendus*, cvii. p. 176), M. Soret showed that the three chief indices of refraction in a crystal with double axis may be deduced from the limiting angles of total reflection on any given faces. M. Perrot has now verified this method by experiments with ordinary tartaric acid, employing a Liebisch refractometer for the purpose.—On the electric conductibility of salts in solution, by M. Lucien Poincaré. The author finds that the high polarization of a silver electrode plunged into a saline solution, such as the nitrate of potassa, falls immediately to zero by adding a trace of the nitrate of silver. From this phenomenon follows a means of greatly simplifying in certain cases the method hitherto employed by MM. Bouty and Poincaré for measuring the electric resistances of saline solutions.—Papers were contributed by M. Ch. Antoine, on the expansion and compression of atmospheric air; by MM. C. Vincent and Delachanal, on the extraction of sorbite; by M. J. Meunier, on the dibenzoic acetal of sorbite; by M. A. de Lapparent, on the relation of the acid eruptive rocks to the phenomenon of the solfataras; and by M. H. Morize, on the Widmanstätten figures, illustrated by two photographs obtained in direct and diffused light.

Berlin.

Physical Society, December 28.—Prof. Kundt, President, in the chair.—Dr. Ritter demonstrated, with the help of an electric arc-lamp, the action of the ultra-violet rays on the electrical discharge at the negative pole.—Dr. Lummer spoke on photometers, and deduced, from the experiences gained with the existing instruments, the following as requirements in their construction: in the first place, the surfaces whose brightness of illumination is to be equalized must not be separated by even the narrowest intervening space; and in the second, the outline of the surfaces must be sharply defined. The first of the above requirements is satisfied in Bunsen's grease-spot photometer, but not the second. A further drawback arises from the fact that the grease-spot reflects light, and the paper allows some to pass through, so that both the spot and the surrounding surface are always illuminated by both sources of light. An ideally perfect photometer ought to reflect no light from its grease-spot, and be impermeable to light over the rest of its surface. The speaker, working in conjunction with Dr. Brodhun, had obtained the above desiderata by purely optical means. When two total-reflection prisms are placed with their hypotenuse surfaces in juxtaposition, and two of the surfaces of the glass-cube thus formed are illuminated by light from bright surfaces, then on looking through the combination of prisms the only light which reaches the eye will be that which enters laterally, whereas that which enters from the opposite side cannot reach the eye. When a drop of Canada-balsam, whose refractive index is very nearly the same as that of the glass, is placed between the opposed hypotenuse surfaces, total reflection is done away with at the place where the drop lies, and thus by illumination from *one* side only either a bright spot is seen on a dark ground or a dark spot on a bright ground. When the illumination is made from *both* sides, equality of illumination can be easily established by adjusting the relative distances of the sources of light until the spot disappears entirely. The drop of Canada-balsam very soon loses its sharply-defined edges, hence some other mode of procedure became necessary. The central portion of the hypotenuse surface of one of the total-reflection prisms was left untouched, while the rest of the surface was ground to a slightly spherical shape. When the surfaces of the prisms were now firmly pressed together, light passed without hindrance across the point of close contact of the surfaces, whereas it was totally reflected at all other points. By this means an ideally perfect "grease-spot" was obtained, which was permeable to light, but reflected none, while the surrounding area reflected light completely and allowed none to pass through. A third method for obtaining an ideally perfect grease-spot consisted in etching figures on one of the reflecting surfaces of the prisms; the etched portions were perfectly transparent, the rest of the surface reflected light completely. The speaker exhibited photometers constructed according to the above methods, and proved theoretically that the ideally perfect grease-spot bears to the real one the ratio of 1 to 2, according to the constants determined in the Imperial Physico-Technical Institute. The sensitiveness of the new photometer is about 1 per cent.

EARTHQUAKES.

Les Tremblements de Terre. Par F. Fouqué, Membre de l'Institut (Académie des Sciences), Professeur au Collège de France. (Paris: J. B. Baillière et Fils, 1888.)

IN the introduction to his little volume on earthquakes, Prof. Fouqué observes very justly that it is only in recent years that seismology has begun to shape itself to the lines of an exact science. Its students have of late concentrated their attention on questions susceptible of direct attack by observation and experiment. The older seismologists made the mistake of attempting to take the citadel by storm, and failed. The younger school of investigators, proceeding more gradually, have at least succeeded in showing how enormously complex the problem of earthquakes in their origin and propagation really is. The older seismologists were for the most part men with little knowledge of mechanics, and their fundamental mistake was that they under-estimated the difficulty of the problem in its mechanical aspect. Setting to work with a preconceived and quite false idea of its simplicity, they used such observational data as were at their disposal to build up an elaborate structure of inference and hypothesis—a structure very ill adapted to bear the shock of the first earthquake that formed the object of scientific measurement. The foundation on which the new school builds its science is exact seismometry; and so far, little, if anything, more than the foundation is laid. It is less than ten years since instruments of precision were introduced, capable of giving complete information as to the manner of motion of the ground. We now have sufficiently full and exact knowledge of the nature of the motion which takes place at one or another point of the earth's surface in the affected region while an earthquake is going on. The elaborate recording seismographs which have been brought to something like perfection by a few enthusiastic workers in Japan have analyzed this motion as completely as can be desired. But beyond this we as yet know next to nothing with any certainty about the real character of an earthquake. The relation which exists between the motion at one point and that at another, the manner of the motion below the surface, the transformations which the seismic waves undergo *en route*, are subjects hardly touched; and no seismometric observations have as yet been made, in a single case, from which conclusions may be drawn with any certainty as to the position of the origin and the nature of the originating disturbance. These are matters which used to be glibly settled by reference to a few projected stones or cracked walls, or to the stoppage of some village clocks: if the new seismometry has not yet thrown much light on them, it has at least shown how gross was the former darkness.

It is, then, not a little surprising to find Prof. Fouqué write a book on earthquakes without so much as a chapter on seismometers. He excuses himself from taking up this branch of the subject on the curious ground that its extreme importance makes it deserve a special treatise, and further, that, as the instruments are being improved from day to day, "nous pensons que la description des séismographes et microséismographes gagnera singulièrement à n'être exposée en détail que dans quelques années." Readers of NATURE, who have had the opportunity from time to time in these pages of seeing what present-day seismographs are able to do, will scarcely agree with the author; and granting, as we very well may, that many improvements have still to be made, the results already achieved in exact seismometry are surely such as not only to justify but to demand some description of these appliances in any new treatise on earthquakes.

In fact, however, M. Fouqué has been better than his word, for, in speaking of the "intensity" and the components of earthquake motion, he has given some slight account of seismographs and seismograms. But the account is far from adequate, and is not free from serious errors. We find the old fallacy restated, that the position of the "epicentre" can be determined by observation of the azimuths of the oscillations; that the bearing of the origin is given by the direction in which pendulums are set oscillating or objects are thrown down. Anomalous cases are spoken of, but not a word is said to explain that the cases which are styled anomalous form, not the exception, but the rule, because the chief oscillations are in general not of the normal but of the transverse type. With regard to the mechanical theory of seismographs, the author is completely at sea. It is now well known that the first essential in seismometry is to secure a point of reference by having a steady mass pivoted or hung in nearly neutral equilibrium; that a stably-hung mass like a common pendulum will not do, because it acquires oscillation through the more or less close agreement between its period of free swing and the period of the successive seismic impulses. Nothing could be worse than a pendulum with the period of which these impulses happened just to agree. Nevertheless, M. Fouqué says, without hinting dissent:—

"M. Cavalleri admet, d'après ses observations, que, dans un tremblement de terre, le meilleur pendule au point de vue de l'indication des intensités est celui dont les oscillations sont synchrones avec la durée de l'ondulation du sol; les pendules à fil long donnent le tracé le plus étendu quand les mouvements du sol sont lents; l'inverse a lieu quand les vibrations sont rapides. Par conséquent, pour obtenir un tracé, qui soit l'image aussi fidèle que possible de l'intensité de la secousse, il faudrait avoir une série de pendules d'inégale longueur, et considérer exclusivement, parmi les tracés obtenus, celui qui offre les dentelures les plus allongées."

Nothing could be more complete than the misapprehension shown in this last sentence. Other indications lead one to conclude that the author's acquaintance with seismometry is not intimate, and that it has not been formed at first hand. His references to original sources of information are rare. He gives a fairly good account of the work of Milne and Gray on the measurement of the speed of propagation of artificial disturbances through the soil—a subject the author has himself investigated—but of the work of Ewing in measuring natural earthquakes, and of the continuation and extension of it by Sekiya, he is apparently ignorant. Ewing's horizontal pendulum seismograph is not described, and his duplex pendulum seismograph, although mentioned, is wrongly classed as an instrument that records the phases of the

motion in their relation to the time. The account that is given of the labours of Italian observers in the field of microseismometry is meagre and unsatisfactory, and the work of M. d'Abbadie and the Darwins in this connection is not so much as alluded to.

The only part of M. Fouqué's book which can be said to make any addition to existing knowledge is that which deals with the experiments conducted by the author and M. Michel Lévy on the speed of propagation of artificial disturbances through the earth's crust. In the first instance their method was the same as that used by Mallet and by Abbot; the seismoscope was a basin of mercury, in which the observer detected the arrival of the shock by watching in a telescope for the disturbance of the reflected light. In a second series of experiments, the personal equation of the observer was got rid of by causing a convergent pencil of light reflected from the basin to fall on a revolving photographic plate. The light was intercepted by a shutter which opened, through electric connection with a seismoscope at the origin of the shock, when the blow was given which caused the disturbance to be propagated. Then, until the arrival of the earth waves blurred the image, a sharply defined circular arc was photographed on the plate, the length of this arc serving to measure the time of transit of the waves. In other instances, where the explosion of dynamite formed the source of disturbance, the explosion was produced by an electric discharge which was made to photograph itself on the plate, thus registering the instant at which the disturbance originated more sharply than by the method of the shutter. Besides observations on the surface of the ground in various localities, and with various qualities of vibrating medium, some were made entirely underground. The author and his colleague made use for this last purpose of a mine at Commentry, by causing the explosion to take place in one gallery, 470 feet below the surface, while the seismoscope was set first on the surface of the ground and then in a second gallery 280 feet below the other. As a general result, it was noticed in all cases that the first thing to reach the seismoscope was a series of very small vibrations, which preceded the arrival of the principal shock. In surface propagation this principal shock was not unique: it was followed by several others, although the initial disturbance at the distant source had consisted in a single blow.

Notwithstanding the care and pains which have evidently been bestowed on the author's experiments, the results, as regards speed of propagation of seismic waves, seem to be subject to some uncertainty. The intervals of time actually measured were too small, and what may be called the personal equation of the apparatus was too large. The whole amount by which the record lagged through inertia of the apparatus and other causes is estimated to be 0·301 seconds. Taking one set of experiments (at Creuzot), the recorded time-interval, when the seismoscope was 490 metres from the source, was 0·105 seconds; but to this small quantity we have to add the above large error of 0·301 seconds before deducing the velocity. It should be added, however, that observations made at a more distant station gave results according well with the velocity so deduced. The velocities ranged from about 3000 metres per second in granite to 300 metres per second in sand. The results as to rocky soils are of the same order of magnitude with those of Abbot, and with the velocities which have been inferred from laboratory experiments on the density and elasticity of rocks. The figures given refer to the rate of propagation of the group of waves, as measured by the arrival of the first sensible motions—the motions, namely, which form the advancing edge of the group. But the group widens as it travels, and a much smaller speed would be deduced by reference to the passage of the principal wave or waves.

The first and main part of M. Fouqué's book, entitled "A General Study of Earthquakes," concludes with an interesting detailed account of these experiments. The second part will appeal to a wider circle of readers. It is a narrative of the principal earthquakes which have been felt from 1854 to 1887, including those of San Salvador in 1854, 1873, and 1879; of Simoda, in Japan, in 1854; of Ischia in 1883; of Andalusia in 1884; and of the Riviera in 1887. The account is pleasantly written, and is embellished by a number of photo-engravings showing the mischief wrought by these destructive shocks.

PERIPATUS.

Studies from the Morphological Laboratory in the University of Cambridge. Vol. IV.—Part 1. A Monograph of the Development of *Peripatus capensis.* Part 2. A Monograph of the Species and Distribution of the Genus *Peripatus.* By Adam Sedgwick, M.A., F.R.S. (London: 1888.)

IN these two numbers the editor has reprinted the five papers from his pen on *Peripatus*, which have appeared in the *Quarterly Journal of Microscopical Science* between 1885 and 1888. From the patient detail with which he has followed the developmental changes, and from the power of generalization from observation which he displays, this research may well be regarded as a model for those who are beginning embryological study. Memoirs such as these, on the other hand, are rarely distinguished for clearness of expression and lucid phrasing, and the one before us forms unfortunately no exception to the generality.

Since the observations of Moseley and Balfour, it has been anticipated that several difficult morphological problems presented by the Arthropoda would receive their solution from a study of the ontogeny of *Peripatus*, and in Mr. Sedgwick's hands this hope has been largely realized. The only other recent workers in this field, Miss Sheldon, Mr. Sclater, and Dr. von Kennel, have studied forms from New Zealand and the West Indies; and while the observations of the latter are in many points at variance with those before us, some of the disagreement is undoubtedly due to the different development of the different species. Like most of such primitive types, the species of *Peripatus* are widely and discontinuously scattered, and exhibit considerable structural and embryological discrepancy. Such a discrepancy occurs at the outset. The ovum of the New Zealand form is large, and consists mainly of deutoplasm; that of the Cape species, the subject of the present memoir, is smaller, and, while now actually devoid of yolk, forms a loose reticulum of protoplasm which appears to imply its former presence between the meshes: in both of these

segmentation is meroblastic. The ova of the West Indian *Peripatus*, again, are yet smaller, and totally devoid of yolk, and the segmentation is apparently complete. In other words, the reduction in size of the ovum, due to loss of yolk, which is still in process in *P. capensis*, has been achieved in the West Indian forms, and its effect shows how easily the phylogenetic significance of segmentation-types may be lessened.

We can only mention a few of the more important facts and generalizations of Mr. Sedgwick's memoir. Of great interest is the observation that the embryo, at any rate at and until the gastrula stage, is a syncytium, *i.e.* the various cells of which it is composed are only incompletely marked off from one another, being connected by radiating protoplasmic strands. Such a syncytial condition the author regards as more primitive than the complete separation of the segmentation-spheres from each other. Another point in the early ontogeny is that no part of the nucleus of the unsegmented ovum enters that central portion of the syncytium which becomes differentiated into endoderm; and in this connection some recent observations of Hickson on segmentation in *Millepora* are of value. The ovum in *Millepora* is almost devoid of yolk, while those of the Hydrozoa generally possess a large quantity; and we venture to think that an earlier yolked condition probably occurred in *Millepora*, though Mr. Hickson has pronounced to the contrary. The segmentation-nucleus breaks down into a number of deeply-staining fragments, which become scattered through the cell, and eventually arrange themselves as the nuclei of the blastula; and it is at any rate possible that a similar phenomenon occurs in the formation of the endoderm of *Peripatus*, since Mr. Sedgwick describes (p. 26) "small particles of a deeply-staining matter, which are neither visible in the unsegmented ovum nor in the gastrula stages, and which are not to be distinguished from nuclear chromatin." From whatever source, amitotic nuclei presently appear in the endodermal vacuolated protoplasm, and the enteron is formed by the confluence of these vacuoles. A solid gastrula is thus produced. These facts lead Mr. Sedgwick to discuss the course of the evolution of Metazoa from Protozoa. He pronounces in favour of a "nucleated Infusorian-like animal, with possibly a mouth leading into a central vacuolated mass of protoplasm," for the transition-type, as against a colonial Protozoan; and declines to accept Metschnikoff's hollow blastula as an even more primitive form than the solid gastrula.

The nephridia, the existence of which is one of the most remarkable features of *Peripatus*, present two special modifications, those of the third somite becoming the salivary glands of the adult, and those of the twenty-first functioning as generative ducts. The generative glands themselves are formed as two continuous tubes from the dorsal sections of somites 16-20 by a separation from the ventral sections and absorption of the septa. With reference to the cœlom, Mr. Sedgwick comes to several important conclusions. The mesoblastic bands appear as a proliferation of nuclei at the lips of the blastopore, which arrange themselves in groups round a succession of cavities to form the future somites; a mode of connection generally taken to imply an obscured enterocœle. This primary enterocœlic system of cavities is represented in the adult merely by the generative glands and the nephridia; the latter are, as the author insists, not connected with, but actual parts of, the cœlom, and open each into a hitherto undescribed vesicle in the leg, which at no period communicates with the perivisceral space. Heart, pericardium, and perivisceral cavity are the outcome of spaces *secondarily* excavated in the mesoderm in connection with a vascular system, and are best designated by Lankester's term hæmocœle. Such a hæmocœle is characteristic of Mollusca and Arthropoda, and Mr. Sedgwick's deductions tend to show that in the latter group also the generative glands and ducts and the excretory antennary glands are the sole remnants of the true cœlom.

In the second part, which deals with the genus from a systematic stand-point, Mr. Sedgwick criticizes the various forms hitherto described. He recognizes nine good species, of which two are new: four from South Africa, two from the Australian region, and three from the Neotropical. The coloured plates which illustrate this section are most creditable to the lithographers of the Cambridge Scientific Instrument Company. In future volumes of the "Studies" an *exact* reference to the place where the original paper is to be found would often spare trouble to the student of zoological literature.

THE TEACHING OF CHEMISTRY.

The Fundamental Principles of Chemistry practically taught by a New Method. By Robert Galloway, M.R.I.A., F.C.S. (London: Longmans, Green, and Co., 1888.)

THE first thing that strikes one in taking up this volume is that it requires cutting. This is a considerable drawback to the student working from it, especially in those cases where the description of an experiment is continued on the next page, and to the mere reader it involves a trouble that ought not to be imposed upon him. But a far more serious fault is the absence of even an attempt at an index. Whether the author, the publisher, or the binder is to blame for this omission is not obvious, but the fact remains that the book is incomplete.

The difficulty as to where the beginner shall begin must have presented itself in some form or other to every earnest teacher. Shall the facts come first in their then necessarily isolated condition? or shall the student begin with theories, making for himself so many mental pigeonholes into which the facts as they come may be put away in an orderly manner?

The majority of teachers at the present day prefer to have something to classify before they attempt a classification with their pupils, and in so doing we think they adopt a perfectly sound and natural method. The earnest student is anxious to get on from the very first day of his course, he craves to get hold of something tangible; and the teacher who treats him like an empty reservoir, that is to be elaborately prepared and carefully tested as to perfection of soundness before any water is admitted to it, will ignominiously fail.

Probably every teacher of chemistry has found difficulty

in getting his students to understand in a satisfactory way the effects of changes of temperature and pressure upon gases individually and in general, after the student has performed the ordinary elementary experiments upon the principal gases. But turning to this subject in the present hand-book, we find that the student has to study these effects before he has seen or read of any gas whatever, unless we suppose that "the gas" at gas-works, or the air mentioned in earlier chapters, will be retained in the student's mind and applied by him to the rules given. In the questions set on this part of the subject, "a gas" is the vague expression almost always used, for fear, we presume, it should be imagined that the rules given are more intimately connected with oxygen than with hydrogen, &c.

In the early pages the learner is introducd to gases by the statement that gas-holders are "employed at gas-works for holding the gas," and is then instructed, without even the suggestion of an experiment, how to collect gases over water and in other ways, how to transfer gases to the lecture table, how to burn substances in gases, to burn gases themselves, to generate gases when heat is required and when heat is not required, and so on. The student, having got this abstract information in all its minuteness of practical detail, is expected to keep it in his memory, and to work and study through nearly two hundred pages dealing fully with, to him, a vast variety of complex subjects, before he can apply it to practical use in relation to hydrogen. By dint of much searching (for there is no index, and hydrogen does not appear to be mentioned at all in the meagre contents table) we have found a paragraph headed "Hydrogen" at p. 213. In this page no experiments are set down to be done, and the first suggestion of any practical exercise is the statement that "it can be obtained, as has been shown (Experiment 400), by electrolyzing water." The past and future are here confused, for Experiment 400 is twenty-two pages further on. This is apparently an unintentional memory exercise for the student. A few lines below, it is stated that "it is usually obtained by the action of H_2SO_4 or HCl on Zn or on Fe (see note, p. 183)." At this page we find a jar of hydrogen is required for an experiment (to extinguish burning phosphorus with), and in a note a method by which hydrogen "may be prepared" is given, with far too little description for a beginner and far too much for anyone else. We venture to predict that before many students have worked through this volume, one will be found to march off with a jar to the "gas-works" to get it filled with hydrogen, with the full conviction that he is carrying out, if not the specific instructions before him, at least an alternative way set down in the book to get his hydrogen to extinguish his phosphorus with.

There is a large measure of truth in the old saying that "example is better than precept," and this when translated into chemical language tells us that "experiment is better than theory." Theories in chemistry are of no use whatever to the student except as they enable him to remember, classify, and utilize his facts; and if the theories are to be divorced from the facts, or if the facts are only to be introduced as if they were accidental illustrations of the theories, then the study of—so-called—chemistry becomes as useless as the study of the dead languages. We consider that any method of teaching that tends to lead the student of chemistry to regard the theories he has to learn as anything more than suggestions that will be of assistance to him, is calculated to injure whatever of scientific capability he may possess. Good and useful theories have been believed in, and they have had to be modified, enlarged, or rejected as the growing richness of facts has demanded more extensive ideas. To teach the theories without the facts is to teach the fallible side of the science, and to make the theories more important than the facts is to attempt to balance a pyramid upon its apex.

OUR BOOK SHELF.

Treatise on Meteorological Apparatus and Methods. By Cleveland Abbe, A.M. (Washington: Government Printing Office, 1888.)

METEOROLOGICAL observations have been made more or less continuously since the days of Ferdinand II., Grand Duke of Tuscany, who first organized systematic observations in the year 1653. A full account of the progress which has been made since then in securing data of greater accuracy is contained in the book before us, which forms the forty-sixth appendix to the Report of the Chief Signal Officer to the United States Government. There are five different sections, one being devoted to temperature, one to pressure, one to atmospheric movements, one to aqueous vapour, and the last to the measurement of rain and snow. Each section commences with a general statement of the object to be attained, then the formulæ for correction are discussed, and finally there are descriptions of the most accurate instruments which are at present available. Every form of meteorological instrument hitherto conceived seems to find a place in this wonderfully complete treatise. Besides the ordinary instruments, all the self-recording arrangements are described, and their relative merits discussed. Diagrams of most of the instruments are also given. Those who have but a slight acquaintance with the subject will no doubt be surprised at the number of different methods of determining the same data, and at the number of corrections which it is necessary to make before the results can lay claim to scientific accuracy. The methods and standards adopted by the International Bureau of Weights and Measures are fully considered in every case where they are applicable.

The treatise will be invaluable to all meteorologists, and will undoubtedly do a good deal towards extending the usefulness of meteorological observations generally. Other treatises on optics, electricity, and actinometry are to follow.

New Zealand of To-day. By John Bradshaw. (London: Sampson Low, 1888.)

Round about New Zealand. By E. W. Payton. (London: Chapman and Hall, 1888.)

IN each of these books there is a full and interesting account of the present condition of New Zealand. Mr. Bradshaw's indignation has been excited by some of the hasty judgments expressed by Mr. Froude in "Oceana," and "New Zealand of To-day" may be regarded as to some extent an answer to Mr. Froude's criticisms. Mr. Payton's book consists of "notes from a journal of three years' wanderings in the Antipodes," and the impression produced by his narrative is not essentially different from that of Mr. Bradshaw's more polemical work. Both writers believe strongly in the future of New Zealand, and express warm admiration for the great results already achieved by the colonists. Yet it cannot be said that

either writes extravagantly, or that, in describing the social, industrial, and other characteristics of the colony, they have allowed themselves to be unduly swayed by mere feeling. They have, of course, a good deal to say about the Maoris, and it is worth noting that each refers to habits and physical conditions which cannot but tend to hasten the decay of that interesting race. A strong liking for whisky is unfortunately characteristic of most Maoris, and Mr. Payton remarked that the state of drunkenness appeared to have a great fascination for them. "I once saw a Maori that I knew," he says, "walking up and down the veranda of an hotel, and looking very much disgusted about something. On my asking him what was the matter, he told me he had had thirteen glasses of whisky, and *couldn't* get drunk!"

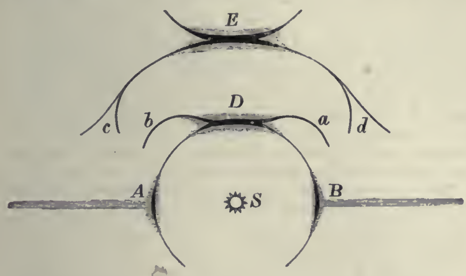
Solar Halo.

BETWEEN 1 and 2 p.m. of January 11, a solar halo, so remarkable as to deserve some notice in the columns of NATURE, was observed and sketched by myself and several of my pupils. The mock suns A, B, and D (see diagram below), appeared to be at the usual distance of about 22½° from S, and the halo at E about the same distance from D.

A and B were quite bright, but D and E were nearly twice as brilliant, and blazed with gorgeous prismatic colours.

The parhelic circle—observed by Prof. William Ellis on April 1, 1886 (NATURE, vol. xxxiii. p. 535)—was very bright. It extended only from the mock suns A and B outwards from S to about 120° from the latter; and on the right branch of this circle was another mock sun (not shown in diagram) at the distance of about 90° from B. This last sun, as well as the visible portions of the parhelic circle, was formed of pure white light, and the latter was everywhere parallel with the horizon.



But perhaps the most remarkable part of the phenomenon was the forking of the arc *c* E *d* at the ends *c* and *d*, and the concave recurving of the arc *a* D *b* (convex to S at D) at the ends *a* and *b*. These forkings and recurvings were very distinctly visible at about 1.30 p.m., traced in fainter prismatic hues.

There was a light cloudy haze covering the southern two-thirds of the sky, while the remainder was clear. Calm moderate weather both preceded and followed the phenomenon for some days.

EVAN MCLENNAN.

Brooklyn, Iowa, U.S.A., January 14.

[The altitude of the sun is not given, but (according to Bravais) it must have been less than 30°, because of the extreme vividness of the tangent arc to the halo of 46°. This also accounts for the "recurved" appearance of the tangent arc to the halo of 22°. The apparent bifurcation of the halo of 46° is too rudely drawn to afford the means for a rigorous investigation. As sketched, it may be due solely to diversity of inclination (*balancement*) of the axes of the ice-crystals.—ED.]

Seismic Disturbance at Venezuela.

ABOUT the middle of November 1888, there was a notable seismic disturbance in several places of Northern Venezuela. On the 13th, at 4h. 30m. a.m., a rather heavy concussion was felt at Caracas, and eastward as far as Rio Chico, where it caused some damage. On the 17th, two shocks were noticed at Cumaná, viz. at 5h. 8m. a.m. and 2h. p.m. It is reported that their force diminished towards the east, so that they were scarcely perceptible at Carúpano. On the same day two shocks (1h. 45m. and 5h. 15m. p.m.) damaged in a somewhat serious manner a large number of houses at Guanare (69° 20′ W. of Greenwich, 8° 45′ N. lat.); two more were felt at the same place on the 18th at 3h. p.m., and on the 19th at 1h. 10m. a.m. The ultimate sign of the paroxysm was observed at Caracas on the last-named day, a few minutes before five o'clock in the afternoon. The zone of disturbance extended from Carúpano to Escuque (63° to 70° W. of Greenwich), and embraced the whole mountainous part of Northern Venezuela. In some cases the wave-motion is said to have been plainly north-east to south-west; but the maximum of disturbance (first shock at Guanare) showed decidedly a direction from north to south, as results from the numerous cracks in damaged walls and the way in which free-standing objects were thrown off their bases. The clock at the telegraph station, which hangs on a wall running east to west, was likewise instantly stopped. Dr. Lisandro Alvarado, a physician who resided at Guanare, who communicated these facts to me, informs me at the same time that the cracks emerge in an angle of from 75° to 80°. It is therefore very likely that the centre of the shock was not far from Guanare towards the north, where the crystalline schists of the Cordillera break through the overlying clay-slates and Cretaceous rocks, which form the northern margin of the great plains or *llanos* of Venezuela. Guanare lies on the very edge of these plains (185 metres above the sea), where the Cretaceous formation rather abruptly is met by the extensive deposit of conglomerate which covers the plains. Any disturbance in the raised strata forming the southern slope of the Cordillera will thus manifest itself with particular intensity in the vicinity of this border-line. The whole disturbance belongs, of course, to the class of tectonic earthquakes, as, indeed, do all those which happen now and then in this country.

Caracas, January 6.

Opportunity for a Naturalist.

CAPTAIN JUAN PAGE, of the Argentine Navy, who is now in London, and read a paper on the exploration of the Rio Vermejo and Rio Pilcomayo at the last meeting of the Royal Geographical Society, has undertaken a new expedition for the survey of the Pilcomayo from the Paraná to the frontiers of Bolivia. Captain Page would be glad to give a place on the staff of this Expedition to a naturalist, who would thus have an opportunity of investigating the almost unknown fauna and flora of the Gran Chaco, through which the Pilcomayo runs. The Expedition will start from Buenos Ayres in June next, and be absent about six months. The naturalist would have to find his passage out to Buenos Ayres, and home, and his own equipment and collecting-materials, but on joining the Expedition would be free from charges. I should be glad to put any qualified person who might wish to avail himself of this excellent opportunity of exploring a most interesting country in communication with Captain Page.

Mass and Inertia.

DR. LODGE (NATURE, January 17, p. 270) seems to have misunderstood the bearing of my letter on mass and inertia (January 10, p. 248).

I was careful to point out that my remarks on the advantages of a *force*-time-length system of units had reference solely to *procedure in teaching*. Dr. Lodge, failing to observe this, objects to the suggestion because it does not immediately afford an absolutely permanent, universal unit of force. It was not intended to do so. Anyone who has learnt dynamics and attained clear ideas, appreciates the convenience of the *inertia*-time-length system for the purposes of the record. But the teacher's business is with those who have not yet learnt, but who, knowing nothing

yet of inertia, are—in this country, at any rate—already accustomed to pounds or ounces as the practical units of force. My suggestion is simply, "Don't swap horses while you are crossing the stream."

Dr. Lodge appears to object to my using the word inertia in the sense of the coefficient *m*. But he does exactly the same in his own book on "Mechanics" (p. 49); and the usage is, I think, quite common.

A. M. WORTHINGTON.

R.N.E. College, Devonport, January 26.

As a student and teacher of physics who has come much into contact with engineers and other artisans, I venture to say a few words on the vexed question of dynamical units now under discussion in your pages. It seems to me that it would be a distinctly retrograde step to adopt the proposals which Mr. Worthington makes in a recent number of NATURE. It would amount virtually to a return to the cumbrous and discredited system of units in use in British text-books of dynamics before the appearance of "Thomson and Tait," and the introduction of the Gaussian units of mass, force, &c.

It is certain that, whether the word "pound" be properly used to denote a unit of force or not, a common usage of the term is to denote a certain quantity of matter—that which has the same gravity at the same place as the so-called standard of weight. This is a standard quantity of matter and is a constant. Now in dynamics the primary property of matter is inertia, and inertia alone. When we compare the masses of bodies dynamically, we compare only their inertias; and that the forces of gravity on different bodies are proportional to their masses we have from Newton's pendulum experiment, &c. It seems natural and convenient, therefore, starting from this primary property of matter, to take the unit of mass as we find it defined, and give to that unit the unit of inertia. Then if the numeric of mass of a particle be m, of its acceleration dv/dt, the numeric of the inertia-reaction is $m \cdot dv/dt$ simply. The plan proposed by Mr. Worthington would introduce quite gratuitously the relation of his "unit of inertia" to the unit of mass, a relation which has been in the past—and would, I fear, be again—a great source of confusion to the student.

It is to be remembered, further, that the Gaussian system of units has been adopted by most civilized nations for practical electrical work. Certain units are constantly used in electrical engineering, which are simple multiples or submultiples of the various derived units in this system. It is too late in the day to change all this, and thereby run the risk of throwing things into the state of chaos from which with great labour and trouble they have been rescued. Hence the engineer, whatever units he uses for steam-pressures, &c., must, if he is taught dynamics at all, be taught how to express results given in gravitational units in terms of units independent of locality, or any other varying circumstance. It seems to me desirable, therefore, on the ground that the Gaussian system of units is in use in a great and growing department of engineering, to adopt it in our teaching at the outset. The true relations of other units is then got at once, and unfailingly.

My experience as a student and as a teacher is all in favour of the system and nomenclature followed by the persons whom Prof. Greenhill (I think) called "precisionists." Words are, of course, used in more senses than one in popular language; but if a popular word, such as "pound" or "weight," is to be adopted for scientific use, a restriction of its meaning to one sense is absolutely necessary if confusion is not to result. This, at any rate, is the principle on which scientific nomenclature has proceeded hitherto. This precision in the use of terms is absolutely necessary in teaching, and confusion of thought cannot be avoided without it. Of course there is want of consistency—no teacher can be perfectly precise; but that is hardly an argument for throwing precision overboard altogether.

Methods of teaching, after all, must stand or fall by their results, and I should like to join my testimony to that of those who say from experience that the Newtonian method in its original simplicity, with the system of units which Gauss gave, and which has produced so great and far-reaching scientific results, is the best way of approaching the study of dynamics. Students properly taught in this way have no difficulties beyond those inherent in a confessedly difficult subject.

ANDREW GRAY.

Use of Sucker-Fishes in Fishing.

WITH reference to Mr. Sclater's note in NATURE of January 24 (p. 295), on the use of the *Remora* in fishing, I would like to call attention to the use of sucker-fishes by the aboriginal inhabitants of Cuba. Ferdinand Columbus ("Churchill's Voyages," 1704, vol. ii. p. 616) says these people used the sucker-fish to catch both other fish and turtles. These fishes when tied "by the tail run themselves against other fish, and by a certain roughness from the head to the middle of the back, they stick so fast to the next fish they meet, that, when the Indians perceive it, drawing their line, they draw them both together."

Lightcliffe, Yorkshire, January 26. H. LING ROTH.

Remarkable Rime and Mist.

THE extraordinary rime described by your correspondents was also experienced here (at 425 feet above sea-level) in January.

Though not an unusual occurrence in severe weather, this has never been equalled in my recollection.

The freezing fog lasted three days, each succeeding one appearing to add to the thickness of the rime, which culminated on the 6th, when it was difficult to believe that the trees were not covered with snow. On that date I measured one of the sheaves of spiculæ attached to a terminal shoot of a beech-tree, and found it very nearly $2\frac{1}{2}$ inches in length. This, of course, was rather exceptional. E. BROWN.

Further Barton, Cirencester, February 1.

IT seemed to me scarcely necessary to mention the amount of what may be called, for the sake of brevity, "sooty matter," in the rime referred to by Mr. Maw (p. 295). Some of the products of combustion are frequently restored to the ground without contact with water particles; but many are carried about in the atmosphere for a considerable time, and are returned to the earth through aqueous precipitation. I am not sure that the subject of the varying results of analyses of rain-water, obtained under various conditions of weather, has received the amount of attention which it deserves. The heavy rains of our summer thunderstorms seem to contain less sooty matter than is brought down in drizzling rain, when we have made the necessary allowances for direction and force of wind, hygrometrical and thermal conditions, type and quantity of previous rainfall, &c. This is probably due to the fact that rain-drops of the thunderstorm fall from the greater altitude and fall more vertically through the lower strata of the atmosphere. I should, however, like to learn from some readers of NATURE whether the larger rain-drops may not also, from the motion of air which they produce, treat some of the particles of sooty matter with the kindly neglect shown by them to the midges. Snow (as, I suppose, most people have observed by the sense of taste, without chemical analysis) contains, when melted, more sooty matter than rain, and I should have expected the inhabitants (including, of course, the tobacconists) of certain localities on our globe to feel rational gratitude to those slanting flakes which, in their voyage through our air, cleanse it of its sooty particles at those seasons when we are most fertile in producing the latter. But the drifting fogs which traverse a considerable area of land where there are factories, chimneys, &c. (their water-particles moving in lines nearly concentric with the earth's surface, and at no great height above it), should give the air a more thorough washing than is provided by the more common forms of precipitation. The ice-crystals produced by such fogs necessarily furnish, when melted, a maximum of sooty matter.

The letter from Mr. Lowe (p. 319) confirms what was anticipated, that the fog and rime were considerably less in the west of England than in the Midlands. It is perhaps contrary to the rules of good taste for me to criticize the words of so great an observer as Mr. Lowe, but is it not a contradiction of the laws which govern atmospheric phenomena, considering the great distance between true cirri and the fog described, to suppose that the upper surface of the latter "rapidly changed to cirri clouds"?

Speaking of mist, it is almost impossible not to refer to the very interesting article by Prof. J. H. Poynting, F.R.S. (p. 323). May it not be possible that the quivering so often seen in a summer haze is, after all, the result of evaporation, as Wordsworth, the poet of Nature, himself seems to have thought in his use of the word "steam," in "The Excursion."

ANNIE LEY.

PENETRATION OF DAYLIGHT INTO THE WATERS OF THE GENEVAN LAKE AND INTO THE MEDITERRANEAN.

A SPECIAL COMMISSION appointed by the Society of Physics and Natural History to study the colour and transparency of the waters of the Lake of Geneva have investigated the extreme limit reached by daylight in the depths of the lake.

Many naturalists have investigated this interesting subject Amongst others, Prof. F. A. Forel, of Morges, spent much time in investigating the Lake of Geneva. Using paper specially prepared for photography, M. Forel arrived at very interesting conclusions as to the greater transparency of the water in winter than in summer. But the paper was not sufficiently sensitive to permit of the determination of the exact limit to which the light of day extends in the depths of the lake.

Another Swiss naturalist, M. Asper, engaged in the same research, and examined several lakes, especially Zürich and Wallenstadt, for the extreme limit of the penetration of daylight. He made use of dried photographic plates of gelatine-bromide of silver. Proceeding in the same way as M. Forel, he put his plates in in the night, and took them out the following night, thus neglecting the action exercised on the sensitive plate by the light which still exists in the sky, even on a moonless night, at the moment of putting in and taking out.

This action, however, should not be neglected, and its neglect is the source of considerable error. The researches of M. Asper were carried out in lakes where the waters are less pure, and therefore less transparent, than those of the Genevan lake; they are therefore special to the lakes which he studied, and do not bear upon our lake. M. Asper, having found light at the lowest depth to which he immersed his plates (140 metres), could not answer the question as to the limit of penetration.

1. *On the Extreme Limit of the Penetration of Daylight into the Waters of the Lake of Geneva.*

The recent work, like that of M. Asper, consisted in exposing photographic plates at various depths in the deepest parts of the lake. The rapid gelatine-bromide plates of Munkhoven were used. A special apparatus, warding off from the sensitive plate all light other than that which really penetrated at the depth to which it was plunged under the water, was added. This apparatus, constructed by the Genevan Society for the Construction of Instruments in Physics, consists of a box of rectangular shape, of brass, 40 centimetres in length and 20 in breadth, containing in the middle a sensitive plate fixed by wedges. This frame is closed in the upper part by two brass shutters, gliding into grooves with double borders, separated from each other by means of a strong spring contained in the bottom of the box, so as to leave the plate entirely uncovered. At the bottom of the frame a strong shaft is fixed in the form of a ⊥, which bears the axes of rotation of two levers coupled in the form of scissors. Each of the levers ends in the upper part in a fork whose teeth pass from one side of the frame to the other, and lean against two branches which each of the shutters bears. Under the action of the inner spring the shutters separate, and with them the two arms of the lever. A weight is suspended at the opposite extremities of the two levers, and acts on them like the pressure of the fingers closing a pair of scissors; the two forks approach one another, and with them the two shutters, which then cover the plate entirely and defend it from any luminous action from without. A hook fixed to one of the shutters, turns on the apparatus when it is shut, and hangs in the groove of the other shutter, preventing them thus from separating during the transport from the dark chamber to the site of the experiment; it is raised only at the moment that the apparatus is attached to the sounding-line and worked on by the weight; as soon as the sounding-weight reaches the bottom, it opens under the action of the antagonistic spring; it closes again immediately it is withdrawn, and the weight leaving the bottom recommences to act. The depth having been ascertained by previous sounding, the length of the cord is regulated by which the weight is suspended to the apparatus, 100, 200, 300 metres for instance, at the distance desired from the surface of the water. After exposure for a certain time, the apparatus is withdrawn and carried into the dark room established on the ship in order to change the plates, and, if necessary, to develop them immediately.

The duration of the exposure has been about ten minutes. The development has been effected by means of oxalate of iron, with which the workers acted on each plate for ten minutes. The plates were all covered by the same emulsion.

Experiments have been made near Evian, where the lake presents a pretty wide plain at 310 metres depth. M. Marcet was twice kind enough to put his steam yacht, the *Heron*, at the disposal of the Commission; and Prof. Forel, of Morges, was kind enough, not only to lend his sounding-line, but to aid by his advice and his experience.

August 16, 1884, weather clear, sun bright: (*a*) at 237 metres, two plates, one at 12.30, the other at 1.7; (*b*) at 113 metres, a plate at 2.30; (*c*) at 300 metres a plate at 2.44.

September 23, 1884, dull, but very clear weather, thin, pretty luminous clouds, light wind varying from east to north, we exposed: (*d*) at 147 metres, a plate at 1 o'clock in the afternoon; (*e*) at 170 metres, a plate at 2.26; (*f*) at 113 metres, a plate at 3.3; (*g*) at 90·50 metres, a plate at 3.34.

For the sake of comparison, M. Fol had, on August 15, at 10 p.m., exposed on a clear but moonless night: (*h*) a plate in the open air for ten minutes; (*i*) a plate in the open air for five minutes.

It was found that plate *c* (300 metres in depth) had received no luminous impression whatever. It was the same with plate *a* (237 metres). Plate *e*, at 170 metres, was lightly veiled, almost like plate *i*, exposed for five minutes during the night. Plate *d*, at 147 metres, had been vividly impressed, more than plate *h*, exposed in the night for ten minutes. Of the two plates at 113 metres, the plate *f* of the second day is much darkened, whilst plate *b* of the first day is no more impressed than plate *d* of the second day. Plate *g*, exposed at 90 metres, is so impressed that characters which had been traced on the back are only incompletely reserved on the dark background of the developed layer.

On comparing the results obtained in the two days of experiment one is struck by the fact that the photographic effect was much stronger on September 28 than on August 16.

From these two attempts the conclusions are drawn:—

(1) That daylight penetrates into the waters of the Lake of Geneva in September at 170 metres depth, and probably a little beyond that; that at this depth the amount of light in the day is almost similar to that perceived in a clear moonless night.

(2) That at 120 metres the action of transmitted light is still very strong.

(3) That in September, in dull weather, light penetrates in greater abundance and more deeply into the water than in August in fine weather.

Later experiments will show us whether this difference is to be attributed to the greater transparency of water in autumn and winter, which the experiments of M. Forel ascertained beyond doubt, or if the light diffused by the clouds penetrates more deeply than the more or less oblique rays of the sun.

Before these experiments M. Asper had exposed plates of gelatine-bromide in the Lake of Zürich at depths be-

tween 40 and 90 metres, in the Lake of Wallenstadt from 90 to 140, and he obtained an effect from all. He put them in in the night, left them exposed a whole day, and took them out the following night. But, as the exposures of plates *h* and *i* have shown, the darkest night is still light for a plate of rapid gelatine-bromide.

2. *On the Extreme Limit of the Penetration of Daylight into the Waters of the Mediterranean Sea.*

After being assured by the experiments in the Genevan lake that their apparatus worked well, the Commission desired to make similar experiments in the sea, in which the greater transparency of the water would lead one to suppose that the extreme limit of the luminous rays would be at a still lower level.

No satisfactory experiments had yet been made in regard to this, for the experiments of the *Porcupine* were not carried out, M. Siemens's apparatus refusing to work.

Owing to the kindly mediation of Dr. J. Barrois, Director of the Zoological Station of Villefranche-sur-Mer, the *Albatros* was put at the disposal of the Commission for several days in the spring of 1885.

The method of procedure was the same as for the experiments in the lake, only that it was important to preserve the sensitive plate against the chemical action of the salt water by adding a thick layer of varnish to the bitumen. The luminous impression was made by the back of the plate and through the thickness of the glass. Repeated washings with essence of turpentine and alcohol sufficed to remove the varnish before proceeding to the development. As before, oxalate of iron was used.

The experiments took place on March 25 and 26, 1885, and were favoured by calm and fine weather. The depths wanted were found near Cape Ferrat, from 400 to 600 metres.

A. From 10.30 to 10.40, plate exposed at the depth of 200 metres to start with.

B. From 12.45 to 12.50, at a depth of 280 metres.

C. From 11.30 to 11.40, at a depth of 345 to 350 metres.

D. From 10.55 to 11.5, at a depth of 360 metres.

E. From 10.15 to 10.25, at a depth of 380 metres. This experiment took place under exceptionally favourable circumstances; there was no breeze, the ship remained perfectly stationary, and the line perfectly vertical.

F. From 1.20 to 1.30, cloudy but pretty light, at a depth of 405 to 420 metres. All these plates except F were exposed during bright sunshine.

Plates A and B were found to be very much impressed. On the plates C, D, and E the strength of the impression diminishes very regularly with the increase of depth. On plate E the strength of the impression is notably inferior to that of an exposure of the same duration in the air, on a clear moonless night. It may be compared to that of a shorter exposure, five minutes only, in the latter conditions. Plate F does not bear the least trace of any impression whatever. It is no doubt to be regretted that this last experiment did not take place, like the others, in clear weather. But the degree of the impression of plate E, of 380 metres, is already so weak that it may be pretty safely concluded that the extreme limit could not be more than 20 metres lower. On the other hand, the experiments in the Lake of Geneva have shown that the dispersion of the sunlight by a light layer of clouds does not bring about a notable diminution in the depth which it may attain in the water.

It is concluded, then, from these experiments, that in the month of March, in the middle of the day, with a bright sun, the last rays of daylight stop at 400 metres from the surface in the Mediterranean.

3. *Effects of the Seasons on the Limit of Penetration of Daylight in the Waters of the Lake of Geneva.*

The experiments of M. Forel, mentioned above, showed that photographic paper dipped in the lake is blackened in winter to a depth of 100 metres, whilst in summer it is not blackened beyond 45 metres. It is interesting to know whether this variation of transparency with the season belongs only to superficial layers, or if the same law holds good also at lower levels.

March 18, 1885, the Commission went into the middle of the lake on the *Sachem*, steam yacht of M. E. Reverdin, which its owner put at their disposal. As in former experiments on the lake, M. Forel was present. The weather was pretty clear; a light layer of clouds dispersed the light without arresting completely the direct rays of the sun. The following plates were exposed: (*k*) from 9.20 to 9.30, at 158 metres; (*l*) from 10.0 to 10.10, at 192 metres; (*m*) from 10.30 to 10.40, at 235 metres; (*n*) from 10.10 to 11.20, at 240 to 245 metres; (*o*) from 11.48 to 12.23, at 280 to 300 metres.

The duration of exposure was uniformly ten minutes for all, save the last, which remained uncovered, at 280 metres, for 35 minutes. In spite of that, not the least trace of impression was visible either on this plate or on plates *m* and *n*. The plate *l* was very faintly impressed, almost like plate E, of 380 metres in the sea. Plate *k*, at 158 metres, is of nearly the same force as C.

These experiments show that the extreme limit of the action of daylight in the lake in winter is a little beyond 200 metres.

A comparison between this series of experiments and the preceding shows that the light only descends 20 or 30 metres lower in March than in September; the difference is perhaps a little more considerable in the month of August. The layers of water situated below 100 metres escape the law of variation of transparency established by M. Forel for the more superficial layers; the variations of temperature accompanying the seasons, on the effect of which M. Forel bases his theory, not being sensibly felt beyond a certain depth.

Compared to the series of plates exposed in the lake, the series brought from the Mediterranean is striking by its slower and more regular gradation. This gives rise to the idea that whilst in the lake the light is promptly intercepted by deep layers more or less troubled, in the Mediterranean the absorption of the pure water would be the principal if not the only factor in the arrest of the luminous rays.

4. *On the Penetration of Light in the Depth of the Sea at Different Times in the Day.*

The preceding experiments led to very exact determinations of the extreme limit of the penetration of daylight in the waters of the Lake of Geneva and in those of the Mediterranean.

The following year, pursuing the same kind of experiments, the relations which exist between the depth to which light reaches in the water and the inclination of the sun or the variations in the amount of light were investigated.

The Report continues:—

"As we no longer sought a single limit, but a series of limits at fixed times during the day, we required a series of plates exposed at the same instant at different depths and capable of comparison with one another. Instead of a single large apparatus, like that which we had been using, we used twelve small ones, constructed on the same principle, which we placed at regular intervals of 20 metres along the cord. These apparatus were also furnished by the Genevan Society for the Construction of Instruments in Physics. They consist of a little rectangular frame of brass, in which glides in double grooves the drawer containing the sensitive plate, and which an interior spring tends always to open. The frame is fixed by two rings of brass, which at their upper part allow the axis of rotation of a lever to pass. The apparatus is suspended to the sounding-cord by an arm of this bent lever, whilst the lower arm acts on a spring fixed to the

drawer. The lower part of the cord is attached to a cross-bar which unites the bottom of the two rings. When the cord is stretched under the action of the sounding-weight, the upper arm of the lever falls into the prolongation of the cord, in a vertical position, and the lower arm keeps the drawer close. When the action of the sounding-weight ceases, the drawer opens under the action of the antagonistic spring. The process is the same as in the large apparatus, but in a slightly different form, permitting a much smaller and lighter order, which is more suitable to the superposition in series. To avoid the lower apparatus interfering by their additional weight with the opening of the higher ones, when the action of the sounding-weight ceases, each apparatus and the corresponding cord were exactly counterbalanced by a floater of glass in the form of a vial, inclosed in a net and attached to the cord immediately below the apparatus which is wished to be free. Under these conditions the apparatus all open simultaneously, immediately that the sounding-weight touches the bottom, and also close all together at the moment when the cord is drawn up and the sounding-weight begins again to act on them. The simultaneous exposure of several plates at various depths is thus obtained, and it is possible to follow the decreasing action of the light with the depth in one and the same experiment, all circumstances being equal."

The sensitive plates used in these experiments were those of extra rapid gelatine-bromide of M. Lumière, at Lyons. They were protected by a varnish from the action of the sea-water. The duration of the exposure and that of the development were both ten minutes, as in the preceding experiments.

They were carried on in a locality presenting a depth of about 500 metres, so that the purity of the water and the limit of the light were not influenced by the nearness to the bottom. The place chosen was 1300 to 1500 metres from the Cape of Mont Boron, separating the strand of Villefranche from the Gulf of Nice.

Amongst the series of plates obtained the following succeeded well and are particularly instructive.

Series A.—Between 1.15 and 1.25, April 7, 1886, the sun being about 60° above the horizon. The sky was very clear and the sun brilliant; a moderate breeze from the east made little waves.

Plate 1. Exposed at 430 metres: no trace of luminous impression.

Plate 2. Exposed at 390 to 393 metres: a very faint trace, but yet a clear one.

Plate 3. Exposed at 350 metres: a still faint impression.

Plate 4. Exposed at 310 metres: a strong impression.

Plate 5. Exposed at 270 metres: a very strong impression.

Plate 6. Exposed at 230 metres: completely blackened, as were the following.

The limit of light is, then, very exactly towards 400 metres in April, in the middle of the day, in fine weather. This is as complete a confirmation as possible of the conclusion arrived at in the preceding experiments.

Series B.—Between 8.20 and 8.30, April 5, 1886. Sky veiled by a uniform layer of white clouds thick enough for the sun to project no shadow. Moderate breeze from the east.

Plates 1, of 450 metres, and 2, of 415, have no impression.

Plate 3, of 350 metres, presents a very slight impression, a little less strong than that of plate 3 (390 metres) of Series A.

Plate 4, of 315, is of the same force as plate 3 of Series A.

Plate 5, failed by accident.

Plate 6, of 245, and the following, are completely blackened.

Series C.—Between 6.5 and 6.15, April 8. The setting sun was hidden by a bank of black clouds. The rest of the sky was pretty clear, with some little cirro-strati with a faint white light. The light was altogether faint, and like that which is generally found when the sun has just set. The surface of the sea was little agitated, with a slight breeze from the west.

Plates 1, of 400 metres, 2, of 340 metres, and 3, of 300 metres, have no trace of impression.

Plate 4, of 260 metres, is of almost the same force as plate 3 of Series A.

Plate 5, of 220 metres, similar to plate 4 of Series A.

Plate 6, of 180 metres, like plate 5 of Series A.

Plate 7 and the following, completely blackened.

The limit in this last series may be placed with all probability at 290 to 295 metres from the surface.

We see from these experiments that the layers situated at 300 metres are lighted every day, not for a very short time, but all the time that the sun is above the horizon; at 350 metres the light penetrates at least during eight hours daily.

According to the tables that M. Holatschek has drawn up for the latitude of Vienna, especially after the photochemical experiments of MM. Bunsen and Roscoe, the actinic intensity of the light of the blue sky would be on April 21, 33 at 8.30 in the morning; 38·07, at noon; and 14·18 at 6 p.m.; that of the sky and the sun at once would be on an average, in April, 75 at 8.30 a.m., 133 at noon, and 15 at 6 p.m.

According to these figures, the depth that the actinic rays attain in the sea after the setting of the sun is very remarkable. The Commission wait, however, to have more numerous experimental proofs to try to calculate a formula of absorption of which they have to determine the constant for sea-water.

5. *New Experiments on the Effect of the Seasons on the Limit of Penetration of Daylight in the Lake of Geneva.*

The results of these, which require to be confirmed under better conditions, seem to indicate that the difference of transparency between the waters of the lake in winter and in summer is greater than one would have thought. On the other hand, the want of agreement with the experiments of Series 3 leads one to think that the distribution in extent and depth of the layers of troubled water brought by the affluents of the lake is subject to variations difficult to foresee and to appreciate.

The Report concludes by referring to certain improvements in the apparatus.

THE REPORT OF THE KRAKATÃO COMMITTEE OF THE ROYAL SOCIETY.

PART IV. of this Report, on the optical phenomena, by the Hon. F. A. Rollo Russell and Mr. E. Douglas Archibald, comprises 311 pages of letterpress, or the major portion of the work. Owing to the enormous mass of material which went on accumulating for nearly four years from the date of the eruption, as well as the complexity surrounding the optical phenomena, which in some cases were entirely novel, and in others differed both in quality as well as intensity from their normal analogues, it was plainly a work of some considerable difficulty to decide how best to arrange and discuss the data, as well as to avoid arriving at hasty conclusions from the first indications of appearances which continued in part right up to the beginning of 1887. When the wonderful sunsets appeared in this country, the idea of their being connected with the eruption of Krakatão was first suggested and traced out with remarkable clearness by Mr. J. Norman Lockyer, F.R.S., in his article in the *Times* (December 8, 1883).

From the results of certain experiments by himself, he

had concluded that, while under ordinary circumstances aqueous vapour preferentially stops by absorption the more refrangible blue rays, under certain circumstances somewhat analogous to the conditions under which the blue and red solutions of gold were obtained by Faraday, aqueous molecules exist which stop the red rays and transmit the blue. Such so-called "red molecules" were found to be larger than the "blue molecules."

Combining this with the facts which indicated an unusual extension of volcanic dust and vapour into the air by Krakatão, as well as the succession of dates, the occurrence of white suns in the Indian Ocean and blue suns at a distance and at noon, and the initially rapid progress of the coloured suns and twilight glows round the equator, and their gradual spread to the extra-tropics (at first only faintly realized through lack of sufficient data), he constructed the hypothesis that all the optical effects witnessed in England in November and December 1883 were, like those which preceded them, nearer the equator, traceable to the products of the August eruption of Krakatão, carried thither by the upper currents of the atmosphere. Although, in one or two minor details, such as a supposed south-to north line of coloured suns over India, the vastly greater mass of evidence ultimately collected by the Committee enabled them to arrive at a more correct conclusion, yet, in its main features, such as the east-to-west current along the equator, and the concatenation of such at first apparently unconnected phenomena as a sunset in London and a volcanic eruption in Java, the work of the optical section of the Committee has practically resulted in filling in the framework sketched out by Mr. Lockyer. As time progressed, fresh data came pouring in, which not merely testified to the universality of the phenomena over the north and south temperate zones, but helped to fill up the gaps which necessarily occurred over the oceans and near the equator.

In spite of all these links in the chain of circumstantial evidence, many persons still continued to doubt the connection of the extra-tropical twilight glows with the analogous appearances in the tropics. In the case of the blue and green suns, the evidence even at first, was too strong to allow much doubt that they were in some way or other connected with the eruption. Yet even so, the rate at which they travelled (from 70 to 80 miles an hour) along the equator was too much for some persons, whose powers of imagination could hardly grasp the enormous scale on which the operations were conducted; while in the case of the extra-tropics, all sorts of queer and gratuitous hypotheses were put forward to account for what they beheld from their own windows.

Now, a very cursory glance at the general data and evidence, as well as at the maps given in Section III., will, we think, convince the most sceptical that the grand series of optical appearances which were first seen in the neighbourhood of Krakatão on the day of its great eruption, extended themselves, at first rapidly in longitude, and then slowly in latitude, until they finally embraced the whole earth. It will also show that their arrival in Europe was but a mere incident in their spread over a region *fifty times as large*. All this, however, has had to be put forward in detail.

Other points which have had to be described or discussed were—

(1) The proximate cause of the abnormal twilights, and an explanation, as far as was possible, of the way in which they differed from ordinary twilights, both in quality and intensity.

(2) The coloured suns, large corona round the sun and moon, and the sky haze or eruption cloud which evidently caused them.

(3) Then came the geographical distribution, the height and duration of the glows, a list of analogous phenomena on former occasions, opinions put forward to account for the present series, and finally a general analysis of their connection with the eruptions of Krakatão in detail, each of which demanded a separate section.

To give some idea of the principal facts and conclusions of this part of the work, we will commence with the abnormal twilights, considered as local phenomena.

The phases of ordinary twilights have been investigated with much attention by Kepler, Le Mairan, Dr. Hellmann, and Dr. von Bezold,[1] of whom the last discussed them with wonderful clearness in 1863, and showed that certain sequences of colour and intensity take place normally, which have apparently been entirely overlooked until the present series brought the subject again into notice.

Thus the normal sunset consists chiefly of a series of bands of colour parallel to the horizon in the west in the order, from below upwards—red, orange, yellow, green, blue, together with a purplish glow in the east over the earth's shadow, called the "counter-glow." As the earth's shadow moves upwards towards the zenith, and passes invisibly across it, a reddish or purplish glow suddenly appears above the coloured layers in the west, in a spot which previously appeared of a peculiarly bright whitish colour. This purple glow is substantially the "primary glow," or, more definitely, "*erste purpurlicht*." It is peculiar in appearing *above* the horizontal colours, and in not extending far on either side of a vertical plane through the sun and the spectator. As this glow sinks on the horizon and spreads out laterally, it forms the first red sunset. After its disappearance, under *favourable conditions*, a second edition of twilight colours analogous to the first commences, with a similar bright spot (*dämmerungschein*) out of which a second purple light appears to be suddenly developed, and sinks on to the horizon as the secondary or "after-glow."

These are the normal phases of a complete sunset according to Dr. von Bezold, and the present series only appear to be abnormal in exhibiting certain peculiar yellow and greenish tints, a less-defined boundary of the earth's shadow, together with a much greater brilliancy, extension, and duration of the first, and particularly of the second, purple glows. The horizontal layers were less conspicuous than usual, and the abnormal extension of the purple light made it appear as though there was an inversion of the usual order of tints from below upwards.

In order to explain these and other peculiarities which we have not scope to describe, Mr. Russell starts with the observed fact of a sky haze which, in the tropics, tended to transmit blue or green rays in preference to red, and assuming that all the usual elements which are included under the term "optical diffusion" were present, viz. diffraction, refraction, and reflection, describes what should be the effects (1) assuming a haze composed of opaque particles, and (2) one composed of very thin reflecting plates into which condition a large proportion of the pumice ejected from Krakatão is shown to have been transformed. His conclusion is that the distinctive features of the Krakatão glows were due mainly to reflection from these fine laminæ, of rays already tinted in a certain order, by diffraction through the dust of the haze layer and the lower atmosphere, as well as by the selective absorption which ordinarily takes place in the more humid horizontal layers near the earth's surface. The direct as well as diffuse reflection by the plates and opaque dust, which lay, as Mr. Archibald has shown in Section IV., at a height of from 50,000 to 100,000 feet, of rays tinted in succession as both the direct and reflected twilight boundaries followed the descending sun, and the peculiar transmissive quality of the stratum for the more refrangible rays, appear to afford a reasonable explanation of the peculiar silvery glare, the unusual colouring, and the unusual extension of the purple glows.

It is admitted that diffraction played an important part, as it does in ordinary sunsets (Lommel, for

[1] *Pogg. Ann.*, Bd. cxxiii. (1863), pp. 240–76.

example, attributes all the red tints to this cause); but both in this section and those that follow, many considerations are urged against the view held by Prof. Kiessling that the development of the primary glow is chiefly due to diffraction, while the secondary glow is as confidently asserted to be due to reflection. One of the principal objections to the reflection hypothesis in explanation of both the ordinary as well as the present extraordinary development of the purple glow, is its limitation at first to a narrow band, a fact which cannot be explained by absorption, and which is equally at variance with Fresnel's law of reflection from small globular dust, which would be equal in all directions. On the lamina, and particularly the vitreous lamina assumption, however, it is intelligible, since the maximum reflection would then be like that from the sea, in the vertical plane through the sun and the eye.

Moreover, the richly coloured and prolonged secondary glows, which were the most characteristic feature of the Krakatão twilights, are shown by Mr. Archibald, in Section IV., when dealing with their secular duration, to have reached a distinct minimum when the large diffraction corona round the sun, from Prof. Riccò's observations,[1] appeared at its greatest brilliancy; while the curve of their duration on Plate XXXIX., representing Dr. Riggenbach and Mr. Clark's observations, shows that they never again reached the same brilliancy or duration as in the two or three months immediately succeeding their first appearance in Europe. Both these facts aid the conclusion arrived at by Mr. Russell, and indorsed by Prof. Kiessling, that they were reflections by the haze stratum of the primary glows. But if these were reflections, the question naturally arises, why not the primary also? and until more effective arguments are brought against this view, as well as Prof. Riccò's objections to Prof. Kiessling's theory of diffraction alone, which are detailed in Section I. (*c.*), p. 250, Mr. Russell's view of the origin of both glows seems to be the more probable as well as reasonable of the two. The haze stratum appears to have been capable of exerting two influences: one, diffraction of the sun's rays by its smallest particles, which, with the absorption and diffraction usually effected by the dust and vapour present in the lower atmosphere, caused the horizontal tinted layers; the other, reflection by its larger particles or laminæ of the horizontal layers, particularly of the lowest red one, when the earth's shadow had arrived at about 25° above the western horizon, and into a position whence the maximum reflective effect could be seen unmasked by a diffusely illuminated background.

The question of the blue and green coloration of the sun is next discussed by Mr. Archibald, particularly with reference to its intrinsic characteristics and physical origin. In Section VII., in which the distribution of the twilight glows and the blue suns on their first circuit of the globe is compared, it is shown that the mean limit of the band of coloured suns was about 11° north and south of the latitude of Krakatão right round the equator, while that of the glows lay 5° beyond this on either side. Along the latitude of Krakatão the colours were mostly white or silvery, and in one or two cases coppery. The colours thus evidently depended on the density of the stream, the glows appearing on its borders or fringes where it was less dense. A similar relation to density appears from a study of the diurnal changes with varying solar altitude, the sun appearing to change from blue near the zenith, through green, to yellow, or disappearance on the horizon. No direct physical explanation of such a phenomenon appears forthcoming, since, according to the physical laws enunciated by Lord Rayleigh and Prof. Stokes, the diffraction of light by particles of the same order of magnitude as a wave-length tends to sift out the shorter blue, and preserve the longer red waves of light. Repeated reflections by small particles tend to the same result.

[1] Section I. (*c.*), p. 241.

The explanation proposed by Mr. Norman Lockyer in his article in the *Times* attributed the blue colour of the sun to differences in absorbing power of particles of different sizes, the larger particles being supposed to transmit more of the rays near the red end of the spectrum and the smaller those of shorter wave-length. The difference of size has been shown by Prof. Kiessling to be inoperative so far as scattering is concerned, since for particles whose magnitude is of the same order as that of a wave-length of light, the only case to which Prof. Stokes's law applies, the intensity of the scattered blue rays will be always sixteen times that of the red rays. It can therefore only be explained as an effect of absorption, due to some particular absorptive property of the materials which composed the haze. The phenomenon of a blue or green sun has been observed under natural conditions, many of which are quoted, and in most cases where the air was filled with fine dust from a great variety of sources. It has also been artificially reproduced by Prof. Kiessling with dust-filled air and vapour of water, and particularly of sulphur. Several accounts are given in Section V. of blue suns seen in connection with former eruptions, and Mr. Whymper's observation during an eruption of Cotopaxi is conclusive as to the ability of the finest volcanic ejecta to cause such an appearance. The problem which still awaits solution is, What was the precise nature of the particles or gases which produced the absorption? It seems probable that they were metallic sulphides.

Mr. Archibald next deals with the sky haze and its peculiar effects, more particularly on astronomical definition. Here again it seems to have possessed a selective absorption of the red rays, for in two separate lunar eclipses, 1884 and 1885, the usual coppery tint of the moon was conspicuously absent. He then passes on to the peculiar large corona round the sun and moon, which was first observed by Mr. Bishop at Honolulu on September 5, and which, though less striking than the twilight glows, was, if anything, more uncommon, more constant, and more prolonged in duration. It was a true diffraction corona with a reddish border, and of almost exactly the same size as the ordinary ice-halo, viz. 45° in diameter. It lasted from September 5, 1883, up to October 15, 1886, since which date it has entirely disappeared. Its diameter has afforded an approximate determination of the mean radius of the smaller dust-particles composing the haze, which Mr. Archibald calculates to be 0·00006 of an inch. Its connection with, and independence of, the glows is discussed at length, but we have not space to refer to it.

In Section II., Mr. Russell gives a list of the first appearances of all the optical phenomena from the beginning of 1883 to the end of 1884, from which date the local duration of the glows is carried on by Mr. Archibald in Section IV. up to the end of 1885.

In Section III., Mr. Russell works out the geographical distribution of the optical phenomena, including blue suns and glows, up to the end of 1883, by which time they had virtually covered the whole earth. The general conclusion is, that the phenomena all propagated themselves (with the exception of a narrow offshoot towards Japan) at first due west from Java, at a rate of about 76 miles an hour right round the earth parallel to the equator, and in a band symmetrically disposed for 16° on either side of the latitude through Krakatão. A second circuit with wider limits, 30° north and south of Krakatão, was traced at the same rate, after which the motion became indistinguishable. They then gradually spread in latitude, and ultimately the haze which caused them appears to have invaded our latitudes, like the anti-trade, from south-west to north-east. These circumstances may be best realized from a survey of Mr. Russell's maps, especially that showing the successive limits of the appearances for the first nine days succeeding the eruption.

When Mr. Lockyer first pointed out his lines of coloured suns converging towards Krakatão, the data were too scanty for him to recognize that the apparent line through Ceylon, Ongole, and Madras, was due to a widening of the main east to west stream after its first circuit of the globe. As far as the motion of this stream was indicated by African and South American observations, he was perfectly correct, though nothing was previously known as to its velocity or even actual existence. The march of the optical phenomena which is shown in Mr. Russell's maps is indeed the only direct evidence we have of the fact that at 100,000 feet above the earth in the immediate vicinity of the equator, the air in August, and probably, as Mr. Archibald shows, at other times, moves in a rapid and constant current from east to west. Both in Section III. (*b*) and Section VII. he discusses this question in detail, and shows its agreement with the theory of the general circulation of the atmosphere, as well as the motions of the upper clouds as far as they have been observed.

In Section IV., Mr. Archibald investigates the height of the stratum, from observations in all parts of the world where the durations of the primary or secondary glow have been recorded with any attempt at accuracy. Proceeding on the hypothesis that the primary glow was a first reflection of the sun's rays by the stratum, and the secondary a reflection of the primary glow, for which ample evidence is adduced, he concludes that the height of the upper or middle part of the stratum above the earth, diminished from 121,000 feet in August 1883, to 64,000 in January 1884, the lower limits being practically indeterminate. Also, since from Dr. Riggenbach's and Mr. Clark's observations, the glows continued less brilliantly and less prolonged after the first few months right up to the end of 1885, while a decided minimum in the duration, and therefore presumably the height of the reflecting layer, was reached in April 1884; the important conclusion is arrived at, that by that date the larger and more effectively reflecting particles had descended to a lower level, leaving the finest particles suspended at nearly the same elevation as at first. This is further corroborated by the remarkable fact that the large corona reached its maximum intensity during the same month.

In Section V., Mr. Russell gives an interesting list of former eruptions and accompanying atmospheric effects, similar in many respects to those under discussion. During 1783 and 1831, the dates of the famous eruptions of Skaptar Jökull and Graham's Island, &c., and the two years of perhaps the greatest eruptive activity antecedent to that of Krakatão, the *after-glows* and other optical effects were most conspicuous, and from an examination of other eruptions and sequelæ, the general correspondence between the two phenomena seems fairly proven.

Section VI. is a *résumé* of opinions collected by Mr. Archibald, against and in favour of the volcanic origin of the phenomena. Besides its value in exhibiting every aspect of the question, it affords a curious illustration of the narrowness and breadth of human imagination, especially when dealing with phenomena whose universality and minor details were at first only partially realized.

Finally, in Section VII., Mr. Archibald gives a general analysis of the connection between all the optical phenomena and the eruptions of Krakatão both in May and August, in which the various objections on the ground of the initially rapid transmission of the appearances, insufficiency of fine solid ejecta, length of time of its suspension, and the occurence of *apparently* similar phenomena on dates previous to the great August eruption are discussed in turn. The time of suspension of the finest dust in particular, is shown—by an application of Prof. Stokes's formula,[1] $V = \frac{2g}{9\mu'}\left(\frac{\sigma}{\rho} - 1\right)a^2$, for the velocity of a small particle descending in air, and in which viscosity is properly considered—to be *over two years* between 50,000 and 100,000 feet, even assuming the particles to be spherical, which is the most unfavourable supposition. If, as is most probable, they were thin plates, the time would be much longer. A final summary is then given of the direct and local connection between the optical phenomena and the eruptions both of May and August, which the subsequent discovery of the relative though minor importance of the May eruption rendered necessary.

[1] Where σ, ρ, are the densities of the particle and the fluid respectively, a the radius of the particle (supposed spherical), and μ' the index of friction $= \frac{\mu}{\rho}$, where μ is the coefficient of viscosity. Its value is either $(0{\cdot}116)^2$ or $(0{\cdot}14)^2$.

In Part V., Mr. Whipple discusses the somewhat sparse data which show that a magnetic disturbance was generated by Krakatão and travelled round the world at a rate varying from 760 to 900 miles per hour, but the data are too uncertain to allow any definite conclusions to be drawn.

We cannot conclude without drawing attention to the fact that the study of the Krakatão sequelæ has not merely enlarged our conceptions of volcanic powers and the continuity of atmospheric circulation, as well as yielded positive information of great value to different branches of science, but has opened up fresh problems in optical and meteorological physics, the attack and solution of which will stimulate research as well as materially advance the boundaries of our present knowledge of these subjects.

SCIENCE AND THE REPORT OF THE EDUCATION COMMISSION.

THE Final Report of the Commissioners on the Elementary Education Acts, which has excited so much attention of late, deserves to be noticed from a point of view other than any that has yet been taken—that is, the attitude of the Commission towards the teaching of science in elementary schools. In a rather lengthy chapter on "Manual and Technical Instruction," the ground taken by the Commissioners is very clear. The teaching of science in our elementary schools, they say, is yet in its infancy. The importance of science teaching has been so far recognized that simple object-lessons are obligatory in all infant schools. This is a mode of teaching which the Report recommends to be extended. Thus in agricultural districts arrangements could be made for giving practical instruction of the simplest character in the principles of agriculture, the growth and food of plants, and their diseases; and similar instruction in the elements of dairy work might be given to the girls in these districts. The point here laid stress on is one that everybody who knows anything of former attempts to teach science to the children in Board-schools will feel the need of. Science, the Commissioners emphatically say, can never be taught to children out of books alone. No doubt much useful and entertaining knowledge is taken from text-books on science by children; but, to use the words of the Report, the true learning of science cannot be said to begin till the learners are taught to use their own senses in the study, and to rest their acceptance of scientific truth, even the most elementary, not on what they are told, but on evidence supplied by their own observation. To show the curious system of instruction pursued in our schools, it is worth while mentioning that though those simple object-lessons which lie, we are told, at the foundation of scientific instruction are compulsory in infant schools, yet immediately the child leaves the infant school they are discontinued until he reaches Standard V., after which, if he ever gets any scientific teaching, it is out of books alone. One witness considered it ridiculous that English is compulsory and elementary science optional, for, he said, English includes grammar and recitation for boys, the latter of which, he thinks, is far less likely to be useful in a manufacturing district than

elementary science. The preponderance of opinion amongst the teachers examined is that no subject is better calculated to awaken the interest and the intelligence of the scholars than science. So far as the present teaching of elementary science is concerned, it is in a most unsatisfactory condition. Mr. J. F. Buckmaster says that, in comparison with forty years ago, this department of school work has retrograded; and Sir Henry Roscoe agrees with the statement that the teaching of this subject is falling off. According to the latter witness, our system of education is intended to form clerks and not artisans: it is purely a literary system; and if we wish to preserve our manufacturing supremacy it must be changed. In fact, whatever has been done by the manufacturers and artisans of this country is owing in no degree whatever to the educational system, which rather retards industrial progress than otherwise; whilst on the Continent, where manufactures have made such strides of late, everything is owing to the technical schools and the scientific training of those intended for artisans. The vast majority of Board-school boys are intended for the workshop rather than the office: why, then, not fit them for the ordinary duties of life? If this be the object of elementary education—that is, the fitting of scholars in general for those duties which they will most probably be called on to perform—then, the Report says, elementary instruction in science is only second in importance to elementary instruction in reading, writing, and arithmetic. But the fact is, that though girls get some kind of training in, for example, needlework and cookery, there is no such thing as technical instruction for boys. Science, especially mathematical, mechanical, and physical science, is not only the foundation, but an essential part of technical instruction. With regard, however, to the teaching of science, certain warnings are necessary. In the first place, science teaching should not be allowed to interfere with the scholar's general instruction—that is, it should not be introduced too early in life. In the next place, the average teacher is useless as a science master. Even when by previous training the teacher is suited, he has scarcely time to devote to the preparation necessary to lecture clearly and to perform experiments accurately and neatly. Therefore, the Report suggests, the example of London, Liverpool, and Birmingham should be followed by School Boards, in engaging the services of a skilled science lecturer, who will go from school to school in a specified district. For example, in Birmingham, according to the evidence of Dr. Crosskey, the Chairman of the School Management Committee of that town, the demonstrator or an assistant visits each boys' and girls' department once a fortnight. He takes four departments a day, two in the morning and two in the afternoon. Two and a half hours a fortnight are given to science. The class teacher is present during the lecture, and recapitulates it to his scholars, who are bound to bring him written answers to questions thereon. Mechanics or elementary natural philosophy are the favourite subjects with boys,—sometimes they are taught electricity and magnetism; and the girls, domestic economy, considered as the application of chemistry and physiology to the explanation of matters of home life, and sometimes animal physiology. Not only have very great results been achieved by this system in the percentage of passes, but it is noticeable that the attendance is always largest on "science" days. Three years ago a lecturer was appointed for the East End of London, and he had at one time as many as two thousand boys under instruction in mechanics alone. The work has been so successful that three assistants have been appointed. Many witnesses justly complained of the kind of examination papers set in elementary science. One paper of questions is given at length in the Report. It is for boys of the Fifth Standard—that is, for boys between eleven and twelve—and consists of seven questions, of which a specimen, taken at random, may be given: "Quest. 2. In what bodies may you say that molecular attraction is balanced by the repulsive force of heat?" and written answers had to be given. Hence the suggestion of many experienced witnesses that younger children should be examined orally is taken up and recommended by the Commission.

Our system, or rather want of system, of education in elementary science is spoken of by the Commission as introductory to the wider subject of manual and technical instruction, to which they devote many pages of their Report. Into this we shall not follow them, but content ourselves by quoting a few sentences from the Report. "If it should be thought that children ought to receive some instruction in manual employment, other than that which the elementary schools available for their use can give, we are of opinion that the best way of meeting the need would be through the establishment of a workshop in connection with some higher institution, which might be willing to receive into the workshop boys of exceptional ability, or others to whom it was considered desirable to give this instruction. One such central institution could do its work better and cheaper than a number of scattered institutions, whilst nothing could be easier than to make arrangements for attendance at this central workshop being substituted on one or two afternoons in the week for attendance at the elementary school." To illustrate what might be done in this way, the case of the Seventh Standard School at Birmingham is quoted. This is to some extent a technical school, and no pupil is admitted unless he has previously passed in Standard VI. The subjects taught are reading, writing, and arithmetic, according to the Code; and, in addition, mathematics, plane geometry and projection, machine construction and drawing, magnetism and electricity, theoretical and practical chemistry, freehand drawing, and the manipulation of wood-working tools. These subjects are not generally taught to all pupils, but are divided into three divisions, to one of which, as a rule, the student confines his attention. The first division is the machine construction division, and includes mathematics, projection, machine construction, electricity, freehand drawing, and workshop; the second division is the chemistry division, and includes mathematics, projection, chemistry (theoretical and practical), freehand drawing, and workshop; the third division, the electricity division, includes mathematics, projection, theoretical chemistry, electricity, freehand drawing, and workshop. In the second year (the course is three years in duration) the scholars spend three hours a day in the workshop. This system, it is said, has produced excellent results.

NOTES.

The Council of the Royal Meteorological Society have arranged to hold at 25 Great George Street, Westminster (by permission of the Council of the Institution of Civil Engineers), on March 19-22 next, an Exhibition of Instruments connected with atmospheric physics invented during the last ten years, especially those used for actinic and solar radiation observations. The Exhibition Committee invite the co-operation of all who may be able and willing to send contributions. The Committee will also be glad to show any *new* meteorological instruments or apparatus invented or first constructed since last March; as well as photographs and drawings possessing meteorological interest.

We learn that Prof. Fitzgerald and Mr. Trouton have been conducting experiments confirmatory of Hertz's magnificent work. Lately, using parabolic mirrors after the manner Hertz recently described, they have observed the phenomenon of the polarization of radiations by reflection from a wall 3 feet thick. They observed long ago, and exhibited publicly at the opening meeting of the Experimental Science Association last November, that stone walls are quite transparent to these radiations, as they

should be, and consequently should not reflect radiations polarized perpendicularly to the plane of incidence at a certain incidence. This is what has been observed, and it has been decided that the plane of polarization is the plane of the magnetic disturbance. They next tried reflection from sheets of glass, and obtained no results; but, as Mr. Joly suggested, the experimenters were practically observing the black spot in Newton's rings, for the sheet of glass was much thinner than a wave-length, which is about 30 centimetres. Some rough observations at various incidences from the wall seem to show interference at some and not at other incidences due to the same cause as Newton's rings.

THE German Government have granted the sum of £27,500 to repair the building of the University of Berlin, and to erect new lecture-rooms, staircases, and corridors, and for the heating and lighting apparatus. The Government have also given £36,500 to the Natural History Museum, besides £2500 for books. A further sum of £1000 is to be devoted to the purchase of physical apparatus and an anatomical cabinet.

AT the Epidemiological Society, on February 13, Mr. Victor Horsley will read a paper, illustrated by lantern photographs and micro-photographs, on "Rabies, its Treatment by M. Pasteur, and its Detection in Suspected Cases."

A TECHNICAL LABORATORY for special instruction in dyeing and bleaching has just been opened in connection with University College, Dundee. This technical portion of the chemical department consists of a completely fitted dye-house, a laboratory, and a museum for technical samples, more especially connected with the textile industries of the district. Practical instruction in the dye-house was begun by Prof. Percy Frankland last week.

THE *Kew Bulletin* for February consists of a list of such hardy herbaceous annual and perennial plants as have matured seeds under cultivation in the Royal Gardens, Kew, during the year 1888. These seeds are available for exchange with colonial, Indian, and foreign botanic gardens, as well as with regular correspondents of Kew. The seeds are for the most part available only in moderate quantity, and are not sold to the general public. The compiler points out that, as compared with the list previously published (*Kew Bulletin*, February 1887), the number of names inserted in this list is far fewer. This, he says, has arisen on account of the unfavourable conditions experienced during the summer of 1888, when, owing to prolonged rains and absence of sunlight, many plants did not mature seed.

WE learn from *Petermann's Mitteilungen* for January that a Central Meteorological Institute was established on April 7, 1888, at San José, Costa Rica, under the Ministry of Instruction, with Señor Pittier as Director.

AN Intercolonial Meteorological Conference was held at the Melbourne Observatory from September 11–15 last, under the presidency of Mr. R. J. Ellery, all the Australian colonies, New Zealand, and Tasmania, being represented. The Chairman stated that the chief object of calling the Conference together was "with a view of improving the intercolonial weather system, and for the advancement of Australian meteorological science generally." The following are among the principal resolutions adopted: (1) that the amount of information sent by telegraph should be reduced as far as possible, by reducing the number of stations; (2) that, with the telegrams, a forecast be sent from each colony for that colony; (3) that no meteorological forecast or prediction made in one colony and having reference to any other colony shall be communicated by telegraph to any other person or destination than the meteorologist of the colony to which such prediction refers. This motion was carried with one dissentient, Mr. Wragge. A long discussion ensued as to the best mode of thermometer exposure. Mr. Todd stated that he had fully tested the Stevenson stand; he thought it was quite impossible for anyone to say positively what was the best form of exposure. He was going to adopt the Stevenson screen for his out-stations, but was not necessarily going to put it only 4 feet from the ground. The Conference generally agreed that they should all work towards uniformity in the matter as far as possible. On the question of the supply of self-registering instruments to certain stations, Mr. Russell said that he had found the most diverse results from Richard's instruments; some gave satisfactory results, and others were perfectly useless. Sir James Hector said he had been fortunate with the instrument; as an assistant to reading the weather, it was most efficient. On the question of cloud nomenclature the forms given by Mr. Abercromby were approved of; the Chairman urged the importance of having them lithographed in colours, and he undertook to get copies of Mr. Abercromby's photographs so prepared, and sent round for approval to the members of the Conference. Various other questions were discussed, including the connection of climatological observations with hygiene, and the reduction of barometer observations to sea-level.

FRENCH students of ethnography are much interested in the group of Lapps who are at present being exhibited at the Jardin d'Acclimatation, Paris. The other day the group was increased by one, a daughter having been born. The new-comer is called "Parisienne."

THE Geographical Society of Paris has just opened an interesting exhibition of photographs, dresses, weapons, boats, and other objects brought a short time ago from Greenland by M. Charles Rabot.

FOR many years the Kazan Society of Naturalists has devoted a good deal of attention to its collection of skulls, which is now one of the richest collections of the kind in Russia. Dr. Malieff gives, in the Memoirs of the Society (vol. xix. 2) a catalogue of the collection, with the chief measurements and indexes of each skull separately. The Slavonian and Russian skulls—partly from the seventeenth and eighteenth centuries, and partly more recent—are the most numerous; they number about three hundred. The old Bulgarian skulls, represented by thirty-seven examples, come next. The Permians, the Votyaks, the Tchuvashes, and the Tcheremisses are well represented. The like may be said of the Mordovian and the old Finnish skulls derived from the grave-mounds (*kurgans*). The Tartarian skulls are represented both by samples found in *kurgans*, and by modern specimens. Eighteen Kazan skulls found at Astrakhan are especially worthy of note.

RUSSIAN botanists are busily exploring the floras of the various divisions of the Empire, and the number of floras of separate provinces is rapidly increasing. At the same time, they are devoting closer attention to the delimitation of the various floras of European Russia, their chief efforts being directed towards the establishment of the separation lines between the flora of the black-earth or steppe region, and the flora of the forest region. M. Korzchinsky's new work on the northern limits of the former in the Government of Kazan, accompanied by a map which illustrates the conclusions of the author, is a valuable contribution to the subject (Memoirs of the Kazan Society of Naturalists, vol. xviii. 5). Full lists of the species characteristic of separate districts are given, together with a review of the literature dealing with the phenomena. Contrary to views formerly maintained, the author holds that in Eastern Russia there is no such separate flora as might be considered intermediate between the forest and the steppe

floras, and that the latter penetrates within the forest region in the shape of isolated and well-defined oases; while a mixed vegetation, containing species characteristic of the steppes, intermingled with representatives of the meadows of the forest region, is met with only sporadically on the banks of some rivers, on the southern slopes of some hills, or on the outskirts of the forests. He distinguishes, on the contrary, a vegetation which has its own special characters over very wide tracts—from Astrakhan to Yaroslav—and is met with on the banks of the Volga, Kama, and Vyatka, as well as on the banks of the lakes which formerly were connected with the rivers and their old beds.

THE *Annuaire du Bureau des Longitudes* for 1889 contains the usual astronomical and physical tables, and much useful information relating to meteorology and other subjects. There is an admirable list of variable stars, with their positions corrected for 1889, and the dates of maxima and minima. The particulars of cometary orbits are brought up to Olbers's comet of 1887. With the exception of the memoirs at the end, however, there is little novelty. M. Tisserand contributes a very useful paper on the measurements of the masses of celestial bodies, including planets, asteroids, satellites, comets, and binary systems; a better account of the application of the laws of gravitation to this purpose would be difficult to find. Perhaps the most interesting paper is that contributed by M. Janssen, on his memorable expedition to Mont Blanc for the purpose of deciding whether certain lines in the solar spectrum are due to oxygen in our air or in the solar atmosphere. The results of the observations made on Mont Blanc showed that these lines were due to our own atmosphere, as they were weaker there than at lower levels.

WE have received the *Annuaire de l'Académie Royale de Belgique* for 1889, this being the fifty-fifth year of publication. Besides the academical calendar for the year, it contains a general history of the organization and all particulars relating to each department. It also gives accounts of the Commissions delegated to superintend the publication of national biography and history. Details of the prizes and medals at the disposal of the Academy, and the recipients of them from the dates of their institution, are also given. About 340 pages are devoted to biographical notices of deceased members, which are accompanied by admirable portraits, and full particulars of the works of each. It is interesting and gratifying to note the frequent occurrence of "Leopold II., Roi de Belgique," in connection with the work of the Academy.

ANOTHER important paper is contributed by Prof. Emil Fischer and Dr. Tafel to the number of the *Berichte* just received, upon the syntheses of glucose and mannite. Not only has the method of synthesizing glucose been perfected, and large yields of it obtained, but it has also been shown to ferment with yeast like natural glucose, and also like glucose to yield, on reduction with sodium amalgam, the hexhydric alcohol mannite. The first process by which the synthesis was effected, and which was fully described in NATURE, vol. xxxvii. p. 7, consisted in treating acrolein dibromide with baryta-water, the sugar left in solution being afterwards precipitated by phenyl hydrazine in the form of a peculiar compound with the latter substance of the composition $C_{18}H_{22}N_4O_4$. This phenyl hydrazine compound was then reduced with zinc dust and acetic acid, the product being a base which, on treatment with nitrous acid, parted with its nitrogen, leaving a solution from which glucose was extracted by means of absolute alcohol. This method of obtaining glucose from the phenyl hydrazine compound was both exceptionally difficult in manipulation, and gave a very small yield of the sugar. The Würzburg chemists have recently discovered a far better process. The finely-powdered phenyl hydrazine compound is warmed with concentrated hydrochloric acid, when it dissolves to a clear dark red liquid. On cooling, phenyl hydrazine hydrochloride crystallizes out and is filtered off. The diluted filtrate is neutralized with hydrated lead carbonate, decolorized with animal charcoal, again filtered, and the solution made slightly alkaline with baryta-water. A syrupy substance of the constitution $CH_2OH \,.\, (CHOH)_3 \,.\, CO \,.\, COH$, which differs from glucose in possessing two atoms of hydrogen less, is at once precipitated in combination with lead. The precipitate is next treated with sulphuric acid and again neutralized with barium carbonate. The filtered solution, at last obtained almost pure, is evaporated *in vacuo* upon a water-bath, and the syrup extracted with absolute alcohol; on evaporation of the alcohol, the syrup is left behind in the pure state, and solidifies on cooling to a hard amorphous mass. It is only necessary now to reduce the aqueous solution of this syrup with zinc-dust and acetic acid, when the two additional hydrogen atoms are taken up and glucose formed. The zinc is precipitated from the filtered liquid by sulphuretted hydrogen, and the filtrate evaporated *in vacuo* upon the water-bath. On extraction of the syrup with absolute alcohol, and subsequent addition of ether, the sugar is precipitated in colourless flocculæ, which rapidly coalesce into a sweet-tasting syrup of pure glucose. By this method so large a yield has been obtained that fermentation experiments have been possible; and with beer-yeast this artificial glucose is found to rapidly ferment, evolving abundance of carbonic anhydride at the ordinary temperature. It reduces Fehling's solution, and only differs from natural dextrose and lævulose in being optically inactive, consisting, as it probably does, of a mixture of equal molecules of the right- and left-handed varieties. Further, by action of sodium amalgam, it is readily reduced to a compound of the formula $C_6H_{14}O_6$, which crystallizes in fine plates and melts at 165°; in fact, possesses all the properties of the hexhydric alcohol, $C_6H_8(OH)_6$, mannite.

THE *Board of Trade Journal* publishes a memorandum which has been drawn up in the Fisheries Department of the Board of Trade relative to the Sea Fisheries Regulation Act, 1888. The memorandum says that the Board of Trade may on the application of any county or borough Council create a sea fisheries district, and define its limits, and provide for the constitution of the local committee, which body is to have power to make by-laws regulating sea-fishing and oyster-fishing, to impose fines and forfeitures for the breach of such by-laws, and to appoint fishery officers for enforcing the observance of the by-laws within the district. Fishery officers will be empowered to search any vessel or vehicle used in fishing or in conveying fish.

THE *Zoological Record* for 1887 has just been issued. The editor is Mr. Frank E. Beddard. He explains that the only alteration of importance in the present volume is that authors' names have been printed throughout in capitals. It will be found that this renders clearer the references in the systematic part of the several records.

WE have received the first number of *Art and Literature*, published by Messrs. Maclure, Macdonald, and Co., Glasgow. It is well printed and illustrated, and the only fault we have to find with the new venture is that the word "Science" is not included in the title.

THE fourth part of Cassell's excellent "New Popular Educator" has been issued. This part, which contains contributions to the study of geography, physical geography, physiology, astronomy, and other subjects, is accompanied by a map of England, and is well illustrated.

A VALUABLE bibliography of Indian geology has been compiled by Mr. R. D. Oldham, Deputy Superintendent of the Geological Survey of India. It contains a list, as nearly complete as possible, of books and papers relating to the geology of British India and adjoining countries, published previous to the end of the year 1887.

ARNOLD GUYOT'S "Earth and Man" has been recently published for the first time in French. The French edition is not a rendering from the English; it is the original from which the English edition was translated.

AT the monthly meeting of the Royal Institution of Great Britain, on February 4, the special thanks of the members were returned to Mr. William Anderson for his present of a portrait of Prof. Mendelejeff.

IT is reported from North Central Norway and Sweden that wolves are very numerous this winter. They have reappeared in districts where they have been unknown for many years.

THE beaver is getting very scarce in Sweden, but recently a colony has been discovered near the mountain Middagsfjeldet, in the province of Jemtland, in the heart of Sweden.

IT is reported from the districts around the Christiania Fjord that sparrows have almost completely disappeared from those parts this winter.

SOME French students in Paris are distinguishing themselves by wearing a peculiar cap, the *bérêt* of the Pays Basque, to which is joined a small badge, varying in colour according to the Faculty or School (Scientific, Literary, Law, Medical, &c.) the possessor belongs to. The students of Montpellier have been better inspired in reviving the cap worn in the old school at the time of Rabelais.

WE have received the Calendar for the current academical year of the Imperial University of Japan. The record of events for the past year notes that in June the Tokio Observatory was founded. It is formed by the amalgamation of the University Observatory, the Astronomical Section of the Home Department, and the Astronomical Observatory of the Imperial Navy; the whole being placed under the control of the University, which is now intrusted with the duty of publishing the Astronomical Almanac. By a new arrangement, also, the income of the University from tuition fees and other minor sources is for the present to be accumulated year by year with the object of forming a capital fund for future use. The same is to be done with the fees of other educational institutions under the Education Department. At the time when the Calendar was issued, 276 students were attached to the Faculty of Law, 246 to that of Medicine, 91 to Engineering, 45 to Literature, and 36 to Science. The total number of graduates was 954.

THE additions to the Zoological Society's Gardens during the past week include a Golden Eagle (*Aquila chrysaëtus*), European, presented by Mr. Thos. Barclay; an Alligator (*Alligator mississippiensis*) from Florida, presented by Mrs. G. Peacock; two Himalayan Monauls (*Lophophorus impeyanus*) from the Himalayan Mountains, deposited; an Aard Wolf (*Proteles cristatus* juv. ♂) from South Africa, purchased.

OUR ASTRONOMICAL COLUMN.

THE COLOURS OF VARIABLE STARS.—In his new Catalogue of Variable Stars, noticed in NATURE, vol. xxxviii. p. 554, Mr. S. C. Chandler gave to each star a number indicative of the depth of the red tinge in its light, and in a more recent paper he has explained how these numbers were obtained. Two independent methods were followed: the first, the one proposed by Klein, and adopted by Schmidt and Dunér, in which the stars were arranged according to a scale on which 0 corresponded to pure white light, 1 to the slightest perceptible admixture of yellow with the white, and so on with 4 for full orange, and 10 for the purest red light known to us amongst the stars, and as seen in such examples as R Leporis. In spite of the vagueness of the definition of this scale, Mr. Chandler found by experience that the process of thus referring the impressions of colour to these imaginary standards could be effected with greater precision than he had supposed, or would naturally be inferred by an observer previous to trial. His second method seems, however, to promise more precision, and is both simple and ingenious. It consisted in estimating the relative change in brightness effected in two stars by the interposition first of a blue, and then of a red, shade-glass. Thus, supposing a red and white star appeared of the same brightness when viewed without any shade-glass, the white star would seem decidedly the brighter when the blue glass was used, but the fainter when the red glass was interposed, and these differences could be very precisely estimated by Argelander's method, and thus afford definite measures of the differences in colour of the two stars; of course, on an arbitrary scale depending upon the shade-glasses employed. In all, 665 estimates upon 108 telescopic variables were made by the first method, the "decimal scale" method; and 287 "relative diminution estimates," as Mr. Chandler terms his second method, were made upon 77 of the same stars. The mean of the two methods, equal weight being given to each separate observation, was given as the value of the redness of the star in the Catalogue.

Two somewhat important results appear from these observations: first, that the observations are evidently not affected by any serious systematic error depending on the magnitude, for on the average the same colour is given both at maximum and minimum, the recorded differences being small in amount and of varying sign. It would appear, therefore, that the change in the magnitude of a variable does not usually involve a change in its colour. This is an important point, as the more general opinion hitherto has been that such a change does generally take place. The second result is the intimate connection that exists in a variable between length of period and depth of colour. The Algol type stars are strikingly white; the very short-period stars are colourless, or nearly so; and those of longer period show a deeper red the greater the duration of their periods.

NEW MINOR PLANETS.—A new minor planet, No. 283, was discovered by M. Charlois, of the Nice Observatory, on January 28. This is M. Charlois's fourth discovery.

COMET 1888 *e* (BARNARD, SEPTEMBER 2).—The following ephemeris for Berlin midnight is in continuation of that given in NATURE for 1888 December 27 (p. 211):—

1889.	R.A. h. m. s.	Decl. ° ′	Log *r*.	Log Δ.	Brightness.
Feb. 9	23 42 28	4 28·0 S.	0·2598	0·4096	2·6
11	23 41 51	4 18·5			
13	23 41 18	4 8·9	0·2608	0·4196	2·5
15	23 40 47	3 59·3			
17	23 40 19	3 49·7	0·2621	0·4284	2·4
19	23 39 54	3 40·1			
21	23 39 31	3 30·5	0·2637	0·4362	2·3
23	23 39 11	3 20·9			
25	23 38 52	3 11·3 S.	0·2656	0·4429	2·2

The brightness at discovery is taken as unity.

HAYNALD OBSERVATORY (HUNGARY).—The results of the observations of solar prominences at this Observatory during the year 1886 have just been published (Kalocsán, 1888). The observations were made with a telescope of 190 millimetres aperture, and a spectroscope consisting of six flint glass prisms. The chief object was to determine the dimensions of metallic prominences, and their relations to sun-spots. Tables showing all the details of the observations, and the daily and monthly means are given. Prominences less than 20″ in height have been neglected. There are also three plates—the first showing the forms of some of the largest prominences observed, and the second indicating the state of the chromosphere for each day of observation between September 1 and October 31. The third plate, showing the relation of the heights of the prominences to latitude, is particularly interesting. The highest prominences in 1886 occurred in latitudes 18° N. and 37° S., whilst there were secondary maxima in 45° N. and 8° S., and tertiary maxima in 80° N. and 75° S. The secondary maxima do not fall far below the principal ones, but the tertiary maxima are not nearly so well marked.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 *FEBRUARY* 10–16.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on February 10

Sun rises, 7h. 24m.; souths, 12h. 14m. 28·9s.; sets, 17h. 4m.: right asc. on meridian, 21h. 37·5m.; decl. 14° 11′ S. Sidereal Time at Sunset, 2h. 28m.

Moon (Full on February 15, 22h.) rises, 12h. 7m.; souths, 20h. 12m.; sets, 4h. 23m.*: right asc. on meridian, 5h. 36·5m.; decl. 21° 1′ N.

GROWTH OF OUR KNOWLEDGE OF THE NEBULÆ.

OUR present knowledge of those celestial bodies which we term nebulæ may be said to date from a paper by Sir William Herschel on nebulous stars, published in 1791 (Phil. Trans., vol. lxxxi. p. 71). It is perfectly true that we have not here the first recorded observations of nebulæ: several observers before Sir William Herschel, and Sir William Herschel himself, had previously referred to them. All observers previous to Sir William Herschel, among whom we may include Kepler, Tycho Brahé, Halley, and others, were of opinion that the nebulæ were composed of something differing entirely in its essence from stars. There was no question whatever of their being simply clusters of stars considerably removed. Tycho Brahé, in the record of his observations of the new star observed by him in Cassiopeia, suggested that it was in some way generated from an ethereal substance, and to him the Milky Way was composed of the same material. This ethereal substance was liable to dissipation by light and heat, and in this way he accounted for the ultimate disappearance of the star. Kepler shared this opinion, and it may be stated that it was generally accepted at the time that Sir William Herschel began his observations of nebulæ about the year 1780. His first important paper, however, did not deal with these objects: it had reference to the motion of the sun in space (Phil. Trans., vol. lxxiii., published in 1783). In this memoir he points out the universal sway of gravitation in the celestial spaces; and the infinite possibilities opened out by such an all-prevailing and pervading cause seem, although he does not state it in terms, to have led him to the conclusion that such ideas as Brahé's and Kepler's were invalid. His first real survey of the nebulæ appears in his paper of 1784 (Phil. Trans., vol. lxxiii.) He began by observing those bodies which had already been recorded in the *Connaissance des Temps* for 1783, and then those further afield; and it is not a little remarkable that in this first paper he describes almost every distinct form of nebulæ which has been observed from that day to the years about 1846, when Lord Rosse brought a still more powerful instrument than Herschel's largest to bear upon these objects. He noticed that in certain parts of the heavens there was a marked absence of stars, and that this was so invariably followed by the appearance of nebulæ on the confines of the empty region that he records in his memoir that after passing over one of them he was in the habit of giving the word to his assistant to "prepare for nebulæ." This strengthened his view as to the power of gravitation, and as to nebulæ being masses of stars produced by it.

In another paper published in the next year (Phil. Trans., vol. lxxv.) he shows evidently that to him the nebulæ of all orders which he had discovered were simple agglomerations of stars, and he refers to the action of gravity in bringing about such condensations. In the next year (Phil. Trans., vol. lxxvi.) he published the first catalogue of a thousand nebulæ, and gives his first classification, one based upon brightness (p. 466). In 1789, that is three years later (Phil. Trans., vol. lxxix.), he published his second catalogue, and it is clear from the text that he still considered nebulæ to be all distinct star clusters. It required another interval of three years before the possibility of their nature being in any way distinct was brought fairly before his mind. In 1791 (Phil. Trans., vol. lxxxi.) he published his remarkable paper on "Nebulous Stars properly so-called." In this paper it will be seen how convincing was the line of argument which Herschel followed to bring him ultimately to the conclusion that in the bodies which he observed there was either a central body which is not a star, or a star involved in a shining fluid of a nature totally unknown to us (p. 83).

This conclusion seems to have made a profound impression upon Herschel's mind, and we had to wait for ten years before he returned to the subject. He did so in 1801 (Phil. Trans., vol. ci.), in a paper detailing "Astronomical Observations relating to the Construction of the Heavens, arranged for the purpose of a critical examination, the result of which appears to throw some new light upon the organization of the celestial bodies." In this paper he classifies all the different kinds of nebulæ which were then known to him, and specimens of which, as has been before stated, he really seems to have glimpsed in his paper of 1784. He points out that, in the classification which he proceeds to give, the bodies under consideration are treated in such a manner that each shall assist us to understand the nature and construction of the others; and he endeavours to attain this end by assorting them into as many classes as are required to produce the most gradual affinity between the individuals contained in any one class and those contained in that which precedes and that which follows it (p. 271). He remarks: "This consideration will be a sufficient apology for the great number of assortments into which I have thrown the bodies under consideration."

His classification may be stated as follows:—

1. *Extensive diffused nebulosity.*—Under this title he includes faint nebulosities stretching and branching over various portions of the sky, which he was the first to discover by means of the enormously increased optical power which he brought to bear. He states that "they can only be seen when the air is perfectly clear, and when the observer has been in the dark long enough for the eye to recover from having been in the light" (p. 274). He gives fifty-two of these diffused nebulosities, which he had observed in the nineteen years from 1783 to 1802. He remarks that "extensive diffused nebulosity is very great indeed; for the amount of it, as given in the tables, is 151·7 square degrees; but this, it must be remembered, gives us by no means the real limits of it;" and he finally adds, "it will be evident that the abundance of nebulous matter diffused through such an expansion of the heavens must exceed all imagination."

2. *Nebulosities joined to nebulæ.*—He refers to fourteen

objects in which real nebulæ are distinctly associated with the above diffused nebulosity.

3. *Detached nebulosities.*—He next mentions six cases in which, instead of the extensive diffusion referred to under the first head, the nebulosity is found detached.

4. *Milky nebulæ.*—He here remarks that when detached nebulosities are small we are used to call them nebulæ, and he shows that the nebulosities and the nebulæ, whatever may be their appearance, as well as those expressly called by him "milky," partake of the same general nature.

5. *Milky nebulæ with condensations.*—He refers to the brightest portions of the nebula in Orion as an indication of what he means by condensation; then to another in which the greatest brightness lies towards the middle; and then he adds:—"By attending to the circumstances of the size and figures of this nebula we find that we can account for its greater brightness towards the middle in the most simple manner by supposing the nebulous matter of which it is composed to fill an irregular kind of solid space, and that it is either a little deeper in the brightest place, or that the nebulosity is perhaps a little more compressed. It is not necessary for us to determine at present to which of these causes the increase of brightness may be owing; at all events it cannot be probable that the nebulous matter should have different powers of shining, such as would be required independent of depth or compression" (p. 282).

6. *Nebulæ which are brighter in more than one place.*—He associates the general swelling of the nebulous matter about the places which appear like nuclei with the unequally bright places in the diffused nebulosities, and further on he refers to universal gravitation "as a cause of every condensation, agglomeration, compression, and concentration of nebulous matter."

7. *Double nebulæ with joining nebulosity.*—He points out that "in fifteen objects two nuclei or centres of attraction have been observed, and that if the active principle of condensation carries on its operation a diffusion of their at present united nebulosities must in the end be the consequence" (p. 285).

8. *Double nebulæ not more than 2′ from each other.*—He points out that there are twenty-three of this class.

9. *Double nebulæ at a greater distance than 2′ from each other.*—Of these he gives a hundred examples, pointing out that "there are not more than five or six which differ so much in brightness from one another that we can suppose them to be at any very considerably different distance from us" (p. 288), and he further adds that "equal brightness or faintness runs through them all in general."

10. *Treble, quadruple, and sextuple nebulæ.*—He refers to twenty treble, five quadruple, and one sextuple object of each kind.

11. *Very narrow long nebulæ.*

12. *Extended nebulæ.*

13. *Irregular nebulæ.*

14. *Nebulæ that are of an irregular round figure.*

15. *Round nebulæ.*

16. *Nebulæ that are remarkable for some peculiarity of figure or brightness.*—He ascribes this irregularity to the as yet imperfect concentration of the nebulous mass in which the preponderating matter is not in the centre (p. 300).

17. *Nebulæ that are gradually a little brighter in the middle.*

18. *Nebulæ which are gradually brighter in the middle.*

19. *Nebulæ that are gradually much brighter in the middle.*

20. *Nebulæ that are suddenly much brighter in the middle.*

21. *Round nebulæ increasing gradually in brightness up to a nucleus in the middle.*

22. *Nebulæ that have a nucleus.*

23. *Round nebulæ that show a progression of condensation.*

24. *Round nebulæ that are of an almost uniform light.*

25. *Nebulæ that have a cometic appearance.*

26. *Extended nebulæ that show the progress of condensation.*

27. *Nebulæ that draw progressively towards the period of final condensation.*

28. *Planetary nebulæ.*

In addition, Sir William Herschel in his various papers gives drawings illustrating the classification which has been above referred to (Phil. Trans., vol. ci. Plates 4 and 5, and vol. civ. Plate 11). A more elaborate set of plates illustrating the various gradations of the different forms will be found accompanying Sir John Herschel's catalogue (Phil. Trans., vol. cxxiii., 1833, Plates 9, 10, 11, 12, and 13). In these illustrations will be found some forms of great interest not referred to by the elder Herschel. Long parallel nebulæ, for instance, with a dark streak separating them, and elliptic and ring nebulæ. With these exceptions, all the illustrations readily fall into Sir William Herschel's classification.

In the valuable paper of Sir John Herschel, to which reference has been made, there is evidence to show that he gives up the idea of nebulous matter distinct from stars advocated by his father. He says: "If the nebula be anything more than a cluster of discrete stars, as we have every reason to believe, at least in the generality of cases, no pressure can be propagated through it" (Phil. Trans., 1833, vol. cxxiii. p. 502). Coming down to the work of Lord Rosse, we find that as early as 1846 he had convinced himself almost completely that no such thing as so-called nebulous fluid existed. In a letter to Nicol ("Architecture of the Heavens," p. 143) under date March 19, referring to the nebula of Orion, he states that he could "plainly see that all about the trapezium is a mass of stars, the rest of the nebula also abounding with stars and exhibiting the characteristics of resolvability strongly marked."

The magnificent observations of the nebulæ made by Lord Rosse will be found in the Philosophical Transactions (R. S.) for the years 1850 and 1861, the latter giving an account of the work done by the 6-foot, and in the Scientific Transactions of the Royal Dublin Society for 1880. In the volume for 1861, p. 702, Lord Rosse seems rather inclined to withdraw the very definite letter which has been previously quoted, and states that, "When the letter R, meaning that the nebula is resolvable, has been used, he does not attach much importance to the expression of opinion it conveys, because the question of resolvability can only be successfully investigated when the air is steady and the speculum is in fine order."

This state of uncertainty, however, did not last long, for in 1864 Dr. Huggins and Dr. Miller demonstrated that the spectrum of several planetary and other nebulæ which they examined, instead of giving spectra like those of the stars, gave one of bright lines, one of the lines being due, as they asserted at the time, to hydrogen; the other, as it lay very near a line of nitrogen, was supposed by them to represent "a form of matter more elementary than nitrogen, and which our analysis has not yet enabled us to detect" (Phil. Trans., 1864, p. 444). Then they wrote:—"It is obvious that the nebulæ (that they had examined) can no longer be regarded as agglomerations of suns after the order to which our sun and the fixed stars belong. We have in these bodies to do no longer with a special modification only of our own type of suns, but find ourselves in the presence of bodies possessing a distinct and separate plan of structure."

THE INSTITUTION OF MECHANICAL ENGINEERS.

THE forty-second annual general meeting of the Institution of Mechanical Engineers took place at 25 Great George Street, Westminster, by permission of the Council of the Institution of Civil Engineers, on January 30 and 31, and February 1, the President, Mr. Charles Cochrane, in the chair.

The three papers down for reading and discussion were: supplementary paper on the use of petroleum refuse as fuel in locomotive engines, by Mr. Thomas Urquhart, Locomotive Superintendent, Grazi and Tsaritsin Railway, South-East Russia; on compound locomotives, by Mr. R. Herbert Lapage, of London; on the latest development of roller flour milling, by Mr. Henry Simon, of Manchester.

The author of the first paper states that his object is to bring before the Institution the more recent results of his experience in the use of petroleum refuse as a locomotive fuel, now being used on an unprecedented scale on the Grazi and Tsaritsin Railway. Since the publication of the original paper in 1884, nothing new in principle has been discovered, and the same appliances have been used, having undergone very slight modifications, dictated by experience and constant observation. The whole of the 143 locomotives under the author's superintendence, as well as various stationary boilers of various types, have been fired with petroleum refuse, to the complete exclusion of all solid fuel, as well as in all the heating furnaces at the Company's Central Works at Boriooglebsk. The petroleum refuse is burnt in the form of a spray, being blown into the furnace against a brick structure, serving the double purpose of a reservoir for the heat, and against which the spray is broken up. Many experiments were made with a variety of forms of

brickwork inside the furnace or fire-box, which are duly described by the author. The spray-injector is of course illustrated. On this depends the efficient working of the furnace. The oil is blown into the furnace by means of a steam jet. Experiments have been made on the use of compressed air instead of steam; and, from what could be observed during a two months' trial, the complication and cost of the extra gear would not be recouped by a sufficient economy in fuel consumption. The effect of petroleum fuel on the boilers, after five years' experience, appears to be less destructive than when firing with anthracite, which is particularly destructive to the fire-boxes and tube-ends. The author states that the petroleum flame produces in reality no more detrimental effect on the fire-box and tubes than a wood flame, owing to the protection afforded to the more important parts by the fire-brick lining; moreover, petroleum refuse contains no sulphur, which is so prevalent in all coals, and so injurious to the metal of the fire-box and tubes. The evaporative value of petroleum refuse appears to be very high. With an effective steam pressure of 125 pounds per square inch, the highest evaporative duty of the fuel in the author's locomotives has been 14 pounds of water per pound of fuel, in comparison with the theoretical evaporative value of 17·1 pounds. The actual efficiency of the fuel is therefore nearly 82 per cent., the tables giving an evaporation, under the same conditions, for good English coal, of 12·16 pounds of water.

Mr. Urquhart's paper will be read with great interest by those following his example in using various oils and tar as a fuel for locomotives and stationary boilers. Provided a cheap source of fuel in the form of petroleum refuse or oil can be relied upon, the many reasons for raising steam in this way are obvious, to say nothing of the possibility of the machinery being kept free from all the dirt necessitated by the use of coal on a locomotive.

The object of the paper on compound locomotives, by Mr. R. Herbert Lapage, is to furnish an account of some recent practice in designing and working two-cylinder compound locomotives. The advantages of compounding—that is, expanding the steam in more than one cylinder—is due to the difference of temperature between the boiler steam and the exhaust being distributed over two cylinders, with the important result that there is not so much difference as in the ordinary locomotive between the temperature at the beginning and that at the end of the stroke in each cylinder; consequently there is less initial condensation and less re-evaporation of condensed steam, and a more uniform pressure on the pistons throughout the stroke; and owing to the more constant and even pressure on the pistons, the turning moments about the driving axle are more uniform, giving less sudden strains to the machinery generally, thereby increasing the life of the machine. The fact that so little attention has until recently been paid to the compounding of locomotives appears to be owing to there having hitherto been considerable complication of parts, in connection both with obtaining a simple device for starting the engine and of equalizing the power developed in the high and low pressure cylinders. These objections have now been thoroughly overcome in what is known as the Worsdell and Von Borries system, in which the two-cylinder compound locomotive has been brought to a high pitch of efficiency. The author of the paper describes a six-wheel-coupled goods engine which was sent out in 1886 to the Entre-Rios Government Railway, having been built by Messrs. Dubs and Co., Glasgow. This engine was built on the compound principle, after investigating the excellent results obtained by the Worsdell and Von Borries system. The dimensions of the cylinders are—high pressure, 16 inches diameter; low pressure, 23 inches; both cylinders having a stroke of 24 inches; the working pressure being 175 pounds per square inch; diameter of driving wheels 3 feet 9 inches. The total weight in working order is 37 tons, probably having about 30 tons useful weight for adhesion; the cut-off of the valves in ordinary running being in the high pressure cylinder 40 per cent., and in the low pressure 50 per cent. Various trial trips were made with this compound on the Caledonian Railway, the work done without doubt showing the power and efficiency of the engine. In the locality where this engine is working coal costs at least £2 a ton; presuming an ordinary engine runs 30,000 miles a year at 25 pounds of coal per mile, it will have burnt 335 tons, which, at £2 per ton, costs £670. The compound, effecting a saving of about 20 per cent., will accordingly save £134 in a year. It is found that a compound locomotive of less weight can haul as heavy a train at the same speed as an ordinary engine, provided the adhesion is sufficient, with the economy of from 14½ to 20 per cent., and as the cost of the compound is no greater than such an engine, the 20 per cent. or £134 per year saved is a net saving to the engine. Compound express locomotives working the heaviest service, which run about 3000 miles per month, are found to do some 15 per cent. more mileage between shop repairs than the ordinary engines of the same size and class.

The fact that two important papers should have been read before the Institutions of Civil and Mechanical Engineers respectively points to the conclusion that the compound locomotive has out-grown the experimental stage. Mr. Lapage says nothing in his paper about the "Webb" system, and probably this is a sign of the "survival of the fittest." The Worsdell engine requires little, if any, alteration in the primary parts of an ordinary engine. The number of working parts is not increased, and the strains set up in the engine are more uniform and less intense than in the ordinary engine, less steam is used, and therefore the boiler is not worked so hard—in fact, everything in connection with the working of these engines points to less general wear and tear of parts, and therefore longer life to the machine.

The last paper on the list, on the latest development of roller flour milling, by Mr. Henry Simon, deals with the extraordinary revolution which, during the last ten years, has been in progress in the manufacture of flour by the substitution of the roller system for the ancient method of grinding by stones; and the object of the present paper is to give further information about the subsequent development of roller flour-milling as carried out by the author. The completeness of the revolution that has taken place is exemplified by the fact that practically, in less than ten years, the machinery and methods of corn milling have been radically and entirely altered at the cost of an immense amount of capital. The millstone, dating from prehistoric times, has been almost entirely discarded, and the miller has been constrained to unlearn the old methods, and take up one entirely new, based upon very different principles. The first complete roller-mill, without the use of stones, in England, was built by the author in 1878 for Mr. Arthur McDougall, of Manchester, and in Ireland for Messrs. E. Shackleton and Sons in 1879; the first automatic roller flour-mill in England in 1881 for Messrs. F. A. Frost and Sons, Chester. The total number of complete mills, or important reconstructions of old mills, executed by the author since 1878 amounts to considerably more than 200, varying in cost for machinery, exclusive of motive power, buildings, &c., from £1000 to £40,000 for each mill.

As it is nearly impossible to give our readers an adequate description of this class of machinery without diagrams, we do not attempt the task, but recommend Mr. Simon's very interesting paper to the careful perusal of all practical millers.

NOTE ON THE ACTION OF ACIDS UPON ULTRAMARINE.

At the Birmingham meeting of the British Association in September 1886, I read a short paper "On the Fading of Water-colours." This was published in the *Chemical News*, vol. liv.

Observation and experiments had led me to the conclusion that water-colour drawings in which ultramarine was mixed with reds for the representation of purple and gray tints such as are seen when viewing distant mountains, the shadows of clouds, and other luminous shadows, the colours are liable to suffer from the action of acids such as might be found in the drawing-paper, or in the damp atmosphere of towns where much coal is burnt. The general opinion of artists is one which I believe does not coincide with this view. The same series of experiments had shown that under ordinary circumstances indigo was a colour of great stability compared with many other pigments, and this again was in conflict with the experience of artists. It is not impossible to explain how we have arrived at such different views, and though it would be inconvenient to enter into an explanation in full, it may be considered as within the scope of this paper to record the fact that the colours were washed upon the best drawing-paper, dried in a subdued light, and not exposed to the conjoint action of damp and sunlight.

The matter in hand is the question of the stability of ultramarine in presence of acids. In an old work by M. Constant de Massoul, translated into English in 1812, entitled "A Treatise on the Art of Painting and the Composition of Colours," a short

account of ultramarine is given as follows:—"The basis of this colour is *Lapis Lazuli.* This, added to the long and tedious operation of extracting the Blue, makes this colour very dear. In order to prove the goodness of *Lapis Lazuli*, make it red hot upon a plate of iron; and then throw it immediately into strong white Vinegar. If it loses its colour, it is of an inferior quality. You may likewise form a judgement by its weight, the real Ultramarine being much heavier than the false."

It is stated that the stone comes from Asia, where it is found on the frontiers of Tartary, China, and also from America. Having drawn my conclusions as to the behaviour of ultramarine with acids, from the preparations sold for this pigment, it seemed desirable that the behaviour of the mineral should be studied by itself, and likewise that of the artificial preparation. This latter, I am aware, is variable; some of it is more easily decomposed by acids than other samples, the difference being occasioned by the greater amount of silica in the latter.

I applied to Mr. Gregory, of 88 Charlotte Street, Fitzroy Square, for as many different specimens of *lapis lazuli* and minerals resembling it as were at his disposal. They consisted of a specimen from Chili, two from Persia of magnificent colour, three from Siberia, Trans-Baikal, and a specimen of a blue mineral often mistaken for *lapis lazuli* called *glaucolite.* This also occurs in the Trans-Baikal district.

These specimens were chipped, where fragments of a fine blue colour were to be seen, and the pieces were ground in an agate mortar to an impalpable powder.

A specimen of each was placed in the hollow of a white earthenware colour palette, and moistened with sulphurous acid. All the specimens of *lapis lazuli* were attacked, and in nearly every case completely decolorized. Where the blue colour was not quite destroyed, the powder was examined with a powerful lens, and it was seen that blue particles remained which had not been sufficiently finely powdered. Several minute lumps of the colour were noticed to be etched by the acid, showing white spots here and there. Hence the fineness of the powder has much influence on the facility with which the mineral is attacked. This is usual with all mineral substances.

It was next considered of interest to ascertain whether *lapis lazuli* will stand the test applied to it by Constant de Massoul, and therefore some of the powdered mineral was made red-hot and thrown into dilute acetic acid; after waiting for five minutes, the blue colour was not appreciably diminished, and it is to be presumed that its nature would thus be satisfactorily demonstrated. Under these circumstances, however, the colour is in considerable quantity, and though some of it may be acted on, yet it is not all destroyed, neither is the tint altered. But in the previous experiments, the powder was much finer and in a thin layer, and though there was a slight action immediately, yet it was about an hour before the colour was completely destroyed. The specimens did not all behave exactly in the same way: some were destroyed more readily than others, especially those from Chili and from Persia.

It does not appear, therefore, that my statement concerning the use of ultramarine as a pigment upon drawing-paper requires modification. A wash of bluish-gray, obtained by mixing light red with ultramarine, was handed round at the Birmingham meeting, one-half of which was shown to be of a foxy red tint after treatment with sulphurous acid. This is, of course, beside the question as to whether ultramarine is largely used for gray tints in the form of water-colour by artists.

Touching the mineral glaucolite, its composition, according to the analysis of G. von Rath, quoted in Dana's "Mineralogy," is the following: silica 47·49, alumina 27·57, ferric oxide 1·54, magnesia 0·47, lime 17·16, soda 4·71, potash 0·58, and water 0·48 per cent. It is quite unacted upon by the acids which decompose *lapis lazuli.* It is highly improbable that it has ever been used as a pigment, because in the form of powder its colour is poor.

W. N. HARTLEY.

LONDON ANCIENT AND MODERN, FROM A SANITARY POINT OF VIEW.[1]

DR. POORE began by reminding his hearers that the mere age of London was one of the reasons why it became unwholesome. Roman London was buried deeply amongst rubbish of all kinds, much of which was putrescible, and, therefore, a source of danger in the soil.

[1] Abstract of a Lecture delivered by Dr. G. V. Poore at the Sanitary Institute on Thursday, January 24.

Ancient London was well placed and magnificently supplied with water, for in addition to the Thames there were many streams, such as Westbourne, Tybourne, the Fleet River, Walbrook, and Langbourne, which originally were sources of pure water. All these brooks, however, had become disgracefully fouled, and for very shame had been covered over. One great drawback to the site of London was the proximity of marshy land on every side except the north-west, and formerly from this cause malarial fever and dysentery were great causes of the high death-rate.

In mediæval London, and even down to the eighteenth century, the houses were not so closely packed as they are now. Reference to Aggas's map (time of Elizabeth) would show that there was a great deal of garden ground within the City, and on comparing this map with Newcourt's map (Charles II.) it was evident that just before the Plague and the Fire the crowding of houses had become very much greater than it was in the time of the Tudor monarchs, who discouraged building near or in London.

Parker's map (1720) would also show that after the Fire the houses were not so closely packed as in the days of the Stuarts, for in this map a surprising amount of garden ground is visible within the walls. At this time also Moorfields was not built upon, and remained as a playground and air space as it had done for centuries previously. That mediæval London was very unhealthy, a perfect fever den, there could be no doubt. The Black Death in 1349, and the Sweating Sickness two centuries later, were times of great mortality which struck the popular mind, but it was not till 1593, when bills of mortality were first introduced, that we began to have any certain knowledge of the amount or the kind of disease prevalent. There was reason to think, however, that in the eighteenth century (after the Fire and the Great Plague) the deaths exceeded the births by about 600,000 in the hundred years.

The fatal diseases were mainly fevers—malarial fever, small-pox, typhus, measles, and (latterly) whooping-cough. The causes of the enormous mortality of mediæval London were due—(1) To the marshy undrained soil, fouled with refuse of every kind. (2) The filthy state of the unpaved city, and a perfectly swinish condition of the houses of the lower orders. (3) The ill-nourished and drunken condition of the masses, among whom a taint of scurvy was very common. (4) The condition of superstition and brutality (as evidenced by the punishments and the pastimes) which made any measures of public health impracticable. (5) The management of epidemics was bad, with a total neglect to separate the sick from the sound; and, finally, the medical faculty were scarcely less ignorant and superstitious than their patients.

Turning to modern London, the lecturer said there had been a great and manifest improvement; but when we looked at the low figure which is called the London death-rate, several things must be taken into consideration, *e.g.* (1) The London of the Registrar-General included large districts such as Lewisham, Wandsworth, Fulham, &c., which, in great part, were scarcely urban in character; and these being occupied largely by well-to-do persons, lowered the average death-rate for the whole city. (2) London being a city in which wealthy people abounded, its death-rate must not, in fairness, be compared to a city packed with undiluted operatives. (3) The mobility of the population was so great that this fact must vitiate our statistics, and it was to be remembered that nothing quickened the departure of an individual from London more than ill-health. (4) The age distribution in London was very abnormal. It was largely recruited by selected adults from the country, and there was a great deficit in the extreme ages among which (the very young and very old) death-rate is always highest. (5) Again, the diminishing birth-rate (that for 1887 was 2·8 below the average of the previous ten years) very greatly diminished the death-rate in a city where 158 children out of every 1000 born die before they are one year old.

It was difficult to believe that Londers were very robust when more than 25 per cent. of them had recourse to the public hospitals in the course of the year.

The cause of the diminished death-rate (which was very considerably reduced after every allowance had been made) was due —(1) To the increase of knowledge, not only among doctors, but amongst the people generally, for we must remember that "self-preservation is the first law of Nature." (2) Vaccination, and the modern plan of treating infectious diseases by the prompt separation of the patients, had done a great deal; the total absence

of small-pox and typhus were mainly due to these causes. (3) The cheapness of food, clothing, and fuel had, of course, diminished the tendency to disease, and the ease with which fresh fruit and vegetables were to be got had abolished the taint of scurvy which was so fatal to our ancestors. (4) The water-supply had been improved, and the intake of the water companies was now removed to a portion of the river less tainted with sewage than that formerly in use. (5) Although the system of sewage disposal was an undoubted evil, and had given us three or four epidemics of cholera, and was the foster-mother of typhoid, still it was probable that so far the balance for good was in its favour, because it had removed a good deal of filth from dwellings.

The outlook in the future was dashed by three considerations:—(1) Our system of sewerage and water-supply had increased overcrowding by enabling us to build houses of any height without inconvenience to the occupant, and without any curtilage whatever, and since all sanitarians recognized that overcrowding was the greatest of all sanitary evils, it was impossible to shut one's eyes to this danger.

(2) There was an expensive and menacing "loose end" to our sanitation in the shape of 150,000,000 gallons of sewage pouring into the Thames every day. The only proper destination of organic refuse was the soil, and it was not possible to see the end of the gigantic blunder we had committed in throwing it into the water.

(3) The rapid increase of population along the Valley of the Thames where sewage disposal is on the same lines as in London, must make us apprehensive for our water-supply, because the various tricks played with sewage in the shape of precipitations, &c., were not probably of a kind to make the effluent a desirable or a wholesome beverage. If the evil effects of free trade are to be counteracted, it will be by returning the refuse of our towns free of cost to the impoverished agriculturist. "If we go on as we are going," said the lecturer, in conclusion, "and if our brethren in the colonies follow our bad example, as they appear to be doing, it will be a Chinaman rather than a visitor from New Zealand who will sit in contemplation on the ruins of London Bridge."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Among the scientific lectures this term, we may note the following:—

Prof. Clifton, Acoustics and Magnetism; Mr. Selby, Theory of Electrical Measurements.

Prof. Odling, Four-carbon Compounds; Mr. Veley, Physical Chemistry; Mr. Vernon-Harcourt, Quantitative Analysis.

On the Biological side, the Linacre Deputy-Professor, Mr. Hatchett Jackson, lectures on the Morphology of the Invertebrata, Mr. P. C. Mitchell on the Morphology of the Cell, and Mr. Barclay Thompson on the Osteology of the Sauropsida. Prof. Burdon-Sanderson's subject is the Nervous System. Prof. Green is giving two courses of lectures on Geology, and Prof. Gilbert lectures on the Rotation of Crops and the Feeding of Animals.

On the Mathematical Lecture List we find that Prof. Sylvester is treating of Surfaces of the Second Order (illustrated by models), Prof. Price of Hydromechanics, and Prof. Pritchard of the Elements of the Planetary Theory.

SCIENTIFIC SERIALS.

THE *Quarterly Journal of Microscopical Science* for December 1888 contains the following:—Note on a new organ, and on the structure of the hypodermis, in *Periplaneta orientalis*, by Edward A. Minchin (plate xxii.). The new organ consists of two pouch-like invaginations of the cuticle lying close on each side of the middle line, between the fifth and sixth terga of the dorsal surface of the abdomen. They are covered by the fifth tergum; when exposed they are seen to open by two slit-shaped openings, which open backwards. They are lined by a continuation of the chitinous cuticle, which forms within the pouches numerous stiff, branched, finely-pointed hairs, below which are numerous glandular epithelial cells. As to their function, it is suggested that they are stink glands.—On certain points in the structure of Urochæta, E.P., and of Dichogaster, nov. gen., with further remarks on the nephridia of earthworms, by Frank E. Beddard (plates xxiii. and xxiv.). The important facts recorded about the anatomical structure of the species of these two genera, and on the nephridia in earthworms, do not admit of being further condensed. *Dichogaster damonis*, nov. gen. et sp., is described from Fiji.—On the development of *Peripatus novæ-zelandiæ*, by Lilian Sheldon (plates xxv. and xxvi.). A further supply of living specimens was obtained in January 1888. Twenty-seven out of forty-nine were females. The uteri of all but nine of these were filled with embryos. The stages of development did not allow of all the gaps left in Miss Sheldon's previous paper being filled up, but this paper is a welcome addition to our knowledge. A useful summary of the author's investigations is appended.—Note on the development of Amphibians, chiefly concerning the central nervous system; with additional observations on the hypophysis, mouth, and the appendages and skeleton of the head, by Dr. Henry Orr, (plates xxvii. to xxix.).—Studies on the comparative anatomy of Sponges, ii. on the anatomy and histology of *Stelospongus flabelliformis*, Carter; with notes on its development, by Arthur Dendy (plates xxx. to xxxiii.). This interesting paper may be regarded as the first-fruits of Mr. Dendy's researches into the anatomy and embryology of recent Australian Sponges, and we hope to be long favoured with such. The embryos, "each as large as a small pea," of *S. flabelliformis*, Carter, were found in abundance. Though varying in diameter from about 3 to almost 5 mm., they exhibited nearly the same stage of development. Doubtless we may expect at some future time the whole story of their evolution. The membrane connecting the fringes of the "choanocytes," which have been so clearly demonstrated by Sollas in the Tetractinellida, and the occurrence of which in *Leuconia aspera* has been described by George Bidder, also occurs in this Sponge, and has been called by Mr. Dendy "Sollas's membrane."—On some points in the natural history of Fungia, by J. J. Lister.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, January 24.—"On the Influence of Carbonic Anhydride and other Gases on the Development of Micro-organisms." By Percy F. Frankland, Ph.D., B.Sc. (Lond.), F.C.S., F.I.C., Assoc. Roy. Sch. of Mines, Professor of Chemistry in University College, Dundee.

Carbonic anhydride, hydrogen, carbonic oxide, and nitrous oxide, were the gases employed in a series of experiments for observing what action was exerted by them on pure cultivations of Koch's comma Spirillum, Finkler's comma Spirillum, and the *Bacillus pyocyaneus*. It was found that hydrogen had the least, and carbonic anhydride the most, prejudicial influence upon these micro-organisms. There is, therefore, no longer any doubt that in the anaërobic culture of organisms hydrogen is by far the most suitable medium for the expulsion of air, whilst carbonic anhydride is not only ill-suited owing to its markedly deleterious action upon many forms of Bacteria, but in many cases is quite unfit for such a purpose.

With carbonic oxide and nitrous oxide it was found that although the development of the *B. pyocyaneus* was checked, yet on removing the cultivations to an *air*-chamber almost the same number appeared as were developed on the original air-control plates. This was not, however, the case with Koch's comma Spirillum and Finkler's comma Spirillum, only a comparatively small number of the organisms surviving the exposure to these gases. Similar experiments made with nitric oxide, sulphuretted hydrogen, and sulphurous anhydride resulted in the complete destruction of the above organisms.

January 31.—"Auto-Infection in Cardiac Disease." By L. C. Wooldridge, M.D., Assistant-Physician, Guy's Hospital.

The author had previously described the fact that the lymph and chyle produce a poisonous influence when injected into the blood. The symptoms so produced have been described by the author as "fibrinogen intoxication." The chief symptoms of this condition already described are intravascular clotting, delay in clotting of the shed blood, great tendency to hæmorrhages, occasionally marked fever. In the present paper the author shows experimentally the following:—

(1) To affect the blood a certain quantity of the fluid of lymph, or the fibrinogen solution, must reach the blood in a given time or no poisoning is produced. A small quantity of the fluid, injected rapidly, will cause instant death. The same quantity, diluted and injected during three or four minutes, instead of suddenly, has no effect at all. The author regards

this as an explanation of the fact that normally the flow of the lymph from the thoracic duct into the blood produces no poisonous effect.

(2) It has long been known that mere mechanical disturbance to the circulation, unless it be of a most extreme character, will not produce dropsy. The ligature of the femoral vein in the dog produces no dropsy. But if previous to the ligature, some of the lymph fluid or fibrinogen solution be injected into the blood, the most severe œdema of the leg is produced, or this accompanied by hæmorrhage.

(3) In cardiac disease and disturbance of the circulation through the lungs there is no reason to suppose that a sudden increase in the flow of lymph ever takes place. But it is certain that the circulation of the blood in the neighbourhood of the thoracic duct is materially slowed in these conditions. This slowing of the circulation acts in the same way as a more rapid injection of lymph, and hence in cardiac disease the conditions for fibrinogen intoxication—auto-infection from the lymph—prevail.

(4) The dropsy, which is so common a symptom of cardiac disease, is commonly explained as being due to the mechanical disturbance of the circulation. This explanation does not harmonize with experimental observations. The fact that even very slight fibrinogen intoxication produces a pronounced tendency to dropsy renders it extremely probable that the dropsy and other symptoms of cardiac disease depend on fibrinogen intoxication.

Physical Society, January 26.—Prof. Fuller, F.R.S., in the chair.—The thanks of the Society were tendered to Mr. Freeman, for presenting to the library a rare and interesting work, "Réflexions sur la Puissance Motrice du Feu, et sur les Machines propres à développer cette Puissance," par S. Carnot, ancien élève de l'École Polytechnique.—Dr. S. P. Thompson read three notes on polarized light, entitled respectively: "The Structure of Natural Diffraction Gratings of Quartz," "Ahrens's Modification of Delezenne's Polarizer," and "The Use of Two Quarter-Wave Plates in Combination with a Stationary Polarizer." Two microscope slides of iridiscent quartz (prepared by the late Mr. Darker), which have recently come into the possession of the author, exhibit remarkable peculiarities. Both act like diffraction gratings, one as if the rulings were about 12,000, and the other about 26,000, to the inch. On examining the specimens by the microscope, it was found that the parts which exhibited the grating effect showed a spindle-like structure, and by micrometer measurements the dimensions of the spindle-shaped bodies were determined to be from 1/1000 to 1/3000 of an inch in diameter, and 1/100 to 1/300 of an inch long. These were much too large to cause the effects noticed, but on closer examination it was found that the bodies were crossed at right angles by fine markings, the distances between which are in close accordance with those deduced from the spectra produced. As a probable cause of the phenomenon, the author mentioned a recent paper by Prof. Judd, "On the Production of a Lamellar Structure in Quartz by Pressure," and suggested the possibility of making diffraction gratings by such means. Ahrens's modification of Delezenne's polarizer consists of a total-reflection prism combined with glass plates and black glass mirror, arranged so that the polarized beam is parallel to the original one. The combination of plates and mirror is adopted so as to give enough light and still keep the polarization sufficiently good. One or two plates laid over the mirror are found to give the best results The fact that a beam polarized by reflection is not coinciden with the original beam, renders it inconvenient, if not impossible to rotate the polarizer, and to overcome this defect, the author has arranged two quarter-wave plates, one of which may be rotated. The first plate circularly polarizes the plane-polarized beam, and the second (or rotating one) re-plane-polarizes it in any desired plane. Objects were shown on the screen to illustrate the degree of perfection attainable by using the new polarizer in combination with the two quarter-wave plates.—A note on a relation between magnetization and speed in a dynamo machine was read by the same author. In a note presented to the Society in June last, it was shown that $\Sigma\rho \,.\, \Sigma R = 4\pi n CS$; where $\Sigma\rho$, and ΣR are the magnetic and electric resistances respectively, n = speed, and C and S the numbers of armature and field windings. By writing the equation in the form—

$$\frac{4\pi CS}{\Sigma R} = \frac{\Sigma\rho}{n},$$

it is seen that, *when the electric resistance is maintained constant, the magnetic resistance is proportional to speed.*—Prof. Herroun read selections from a paper on the divergence of electromotive forces from thermo-chemical data. The fact that the electromotive forces of voltaic cells do not always coincide with calculated values has not hitherto received a satisfactory explanation, and this paper describes an experimental research bearing on the question. Several suggested explanations are given. In some cells the anticipated chemical change does not occur, and some metals become coated with oxide or subsalts; others are affected by dissolved gases, and the hydration or solution of the salts formed may supplement or diminish the E.M.F. of a cell, as well as the absorption or evolution of sensible heat. The question of absorption and evolution of heat is the one chiefly dealt with. If such actions do take place, the total heat evolved by passing a definite current through the cell must depend on the direction of the current, and by inclosing the cell in a calorimeter the difference should be detected. The total heat developed by a current C in t seconds is—

$$\frac{C^2rt \mp eCt}{J};$$

where r is the resistance of the cell, and e the divergence of the observed from the calculated E.M.F., the − or + sign depending on the direction of the current. In the case of mercury cells, which are usually said to give about half a volt excess E.M.F., the heat was found to be independent of the direction of the current. The heats of formation of mercury salts were then re-investigated, and the results showed that Julius Thomsen's numbers (the ones usually accepted) were greatly in excess o the true values. This accounts for the difference between the observed E.M.F.'s and those calculated from Thomsen's numbers. A copper, silver, nitrate cell was tested in the calorimeter, and the reversible heat effect agreed closely with that deduced from the "thermo-voltaic constant," or divergence of observed from calculated E.M.F. Other experiments on tin, lead, nickel, iron, and calcium cells are described, and the chief conclusions arrived at are: (1) the primary factor in determing the E.M.F. of a voltaic cell is the relative heat of formation of the anhydrous salts of the two metals employed; (2) that this E.M.F. may set up chemical changes of a different direction and character from those predicable from the heat of formation of the dissolved salts; (3) that the E.M.F. set up by (1) may be, and usually is, supplemented by the energy due to the hydration or solution of the solid salts, and may have values which accord with the heat of formation of the dissolved salts. The absorption or evolution of sensible heat depends primarily on the attraction between the salts and water, combined with the heat of solution. Finally, the author states that the E.M.F. of a cell gives a more accurate measurement of chemical affinity than that derived from calorimetric observations.

Chemical Society, January 17.—Mr. W. Crookes, F.R.S., in the chair.—The following papers were read:—A cubical form of bismuthous oxide, by Messrs. M. M. P. Muir and A. Hutchinson. When the puce-coloured precipitate produced by adding an excess of potassium cyanide to a boiling solution of bismuth nitrate in dilute nitric acid is repeatedly treated with boiling concentrated potash solution, a residue is left, consisting of tetrahedral crystals of bismuthous oxide, which have a density of 8·838.—Cupric iodide, and the interaction of iodides with cupric salts, by Mr. D. J. Carnegie. By digesting cuprous iodide with iodine and water in a tightly-closed bottle at 80° for a few minutes, the author has obtained solutions of cupric iodide containing as much as 0·82 gramme per 100 cubic centimetres, but has been unable to obtain cupric iodide in the solid state, either from such solutions or by other means. A well-defined basic periodide, $CuI_2, 2CuO, 4H_2O$, was obtained by digesting copper with barium iodide.—Periodates, part 2, by Mr. C. W. Kimmins. The periodates of lead, iron, copper, nickel, cadmium, and silver were described.—Compounds of arsenious oxide with sulphuric anhydride, by Mr. R. H. Adie. A series of compounds, of the formula $As_2O_3 \,.\, xSO_3$, where x = 1, 2, 4, or 8, can be prepared by the interaction of arsenious oxide and either sulphuric acid or sulphuric anhydride.—A compound of boric acid with sulphuric anhydride, by Mr. R. F. d'Arcy.—Notes of experiments with butter fat, by Messrs. A. W. Blyth and G. H. Robertson. The main result of the experiments is to show that butter fat is composed of about 54·5 per cent. of solid crystalline fats, and about 45·5 per cent. of an oil. The authors consider that butter is mainly made up of compound and not simple triglycerides, and have separated a crystalline glyceride, to which they ascribe the formula $(C_4H_7O_2) \,.\, C_3H_5 \left\{ \begin{array}{l} C_{18}H_{31}O_2 \\ C_{18}H_{34}O_2 \end{array} \right.$

—Gawalowski's method for the volumetric estimation of sulphuric acid, by Mr. B. North.—Note on the 1 : 3 homo- and the isomeric hetero-α-β-dichloronaphthalenes melting at nearly the same temperature, by Prof. H. E. Armstrong, F.R.S., and Mr. W. P. Wynne. In their last note on the isomeric dichloronaphthalenes (Proc. Chem. Soc., 1888, 104), the authors brought forward evidence proving that the dichloronaphthalene melting at 61°·5, and characterized by yielding a sulphochloride melting at 148°, is the meta- or 1 : 3-derivative, and pointed out that the dichloronaphthalene melting at 64°, and characterized by yielding a sulphochloride melting at 118°, is the hetero-α-β-dichloronaphthalene. Erdmann and Kirchhoff recently effected the synthesis of a heteronucleal α-β-dichloronaphthalene from parachlorobenzaldehyde, which had a melting of 61°·5 (*Annalen*, ccxlvii. 366). The description of the compound was, however, insufficient to determine its identity, so the authors have prepared it by Erdmann and Kirchhoff's method, and find that it forms a sulphochloride melting at 117°, which, on hydrolysis, yields the pure dichloronaphthalene melting at 63°·5. The authors' conclusions have also received additional confirmation by the synthesis of the 1 : 3 dichloronaphthalene from the 1 : 3 dichlorobenzaldehyde (Erdmann, *Ber.* xxi. 3446). The remainder of the note is devoted to a reply to Erdmann, who, among other matters which are dealt with in the note, calls attention to the existence of two dichloronaphthalenes melting at about the same temperature as if it were an original observation, whereas the fact was first brought under notice by one of the authors at the Manchester meeting of the British Association (B.A. Report, 1887, 231).—The constitution of β-naphthol-α-sulphonic acid (Bayer's acid), by Prof. H. E. Armstrong. The author points out that Witt (*Ber.* xxi. 3489) altogether misrepresents his views on the constitution of β-naphthol-α-sulphonic acid, and quotes passages from his Report to the Manchester meeting of the British Association (B.A. Report, 1887, 231), showing that in his opinion Bayer's acid is a heteronucleal compound, a view, moreover, which has recently found experimental confirmation, inasmuch as the amido-acid corresponding in constitution with Bayer's β-naphthol-α-sulphonic acid has been shown to yield a heteronucleal α-β-dichloronaphthalene (Armstrong and Wynne, Proc. Chem. Soc., 1888, 104).—The sulphonation of naphthalene-β-sulphonic acid, by the same. The so-called new naphthalenedisulphonic acid, for the preparation of which a patent has been taken out by Ewer and Pick, is identical with that obtained by sulphonating potassium naphthalene-β sulphonate with chlorosulphonic acid (Armstrong and Wynne, Proc. Chem. Soc., 1886, 230).

Royal Microscopical Society, January 9.—Dr. C. T. Hudson, President, in the chair.—Mr. T. F. Smith called attention to his further researches on the structure of *Pleurosigma formosum*. He had found not more than three layers, the first consisting of a grating with square meshes, the second had them of diagonal pattern, and the third was composed of alternate rings and squares. He also described *P. angulatum* as giving appearance of a fine grating showing image in each alternate square.—Mr. Crisp exhibited a form of spirit-lamp sent from America, the reservoir of which was facetted instead of globular, so that it could not be upset and might be used in various positions; also Mawson and Swan's camera arrangement for fixing on the front of an ordinary camera; also the binocular arrangement of Messrs. Bausch and Lomb, which, although described in the Journal in 1884, had not until the present time been seen in this country; also another arrangement for rotating a number of objects so as to bring them in succession under the objective of a microscope.—Mr. A. D. Michael gave an interesting *résumé* of his paper on the internal anatomy of *Uropoda krameri*. He finds that, although the anatomy is essentially of the Gamasid type, yet the external resemblance of *Uropoda* to the *Oribatidæ*, which deceived Hermann, is accompanied by many internal similarities, while many organs differ considerably from those of *Uropoda obscura*, lately described by Winkler. He describes a curious organ which he calls the "vestibule," forming the outer chamber of the female genital system, and which it is suggested may serve to remove the thin egg-shell at the moment of deposition, producing ovo-viviparous reproduction. The female genital organs form a ring with two oviducts, the tracheæ are unbranched; the alimentary canal, excretory system, and male genital system of the œsophageal ganglion are also described.—Dr. F. H. Bowman's paper on the frustule of *Surirella gemma* was read.—Count Abbé F. Castracane's paper on the reproduction and multiplication of Diatoms, was also read.

PARIS.

Academy of Sciences, January 28.—M. Des Cloizeaux, President, in the chair.—Reaction of oxygenated water on chromic acid, by M. Berthelot. The remarkable character of the reactions of oxygenated water has induced the author to undertake further researches on the phenomena which it manifests in the presence of chromic acid. These studies show that the chemical mechanism of the so-called actions in presence is characterized by three fundamental conditions; (1) the unlimited nature of the decomposition under certain circumstances, here determined, without permanent alteration of the chromic acid; (2) the formation of an intermediate compound forming the "pivot" of the decomposition: (3) the exothermic properties of the oxygenated water and of the total transformation.—True and mixed butylic ethers (continued), by M. E. Reboul. The study of these compounds is here completed with the description of di-isobutylic ether, $[(CH_3)_2CH{-}CH_2]_2O$; and secondary isobutylic ether,

$$\begin{array}{l} (CH_3)_2CH{-}CH_2 \\ \qquad\qquad\qquad\qquad \searrow O. \\ \quad CH_3 \searrow \quad \nearrow \\ \qquad\qquad CH \\ CH_3{-}CH_2 \nearrow \end{array}$$

It is further shown that the ethers (7), (8), (9), (10), anticipated by theory, are not produced by the method generally employed. No. 7 (di-secondary ether) has been obtained by Fresnel by a different process.—On M. Marignac's gadolinium, by M. Lecoq de Boisbaudran. The elementary nature of the earth Yα, discovered by M. de Marignac, and since named gadolinium, has been denied by Mr. W. Crookes, who holds that this substance consists of samaria with the greenish blue of yttria, and some of the other yttria bands added to it. M. de Marignac has consequently subjected gadolinium to a fresh analysis with the results here described. M. de Marignac's researches having been interrupted by the state of his health, his papers have been placed in the hands of M. de Boisbaudran, who considers that, although the impurities are not yet entirely eliminated, gadolinium may still be regarded as a new element. He also thinks Mr. Crookes may in this case have exaggerated the difficulties and tedious nature of the preliminary work of fractionation, which, instead of occupying a space of time compared with which "the life of man is all too brief," might perhaps be accomplished in a few weeks. However, he does not deny the extreme difficulty of separating the residuums, which have so far resisted fractionations sufficient to get rid of nearly the whole of Yt and Zα.—On a chromatic circle, an æsthetic recorder and triple decimeter, by M. Charles Henry. These instruments embody a practical application of a theory, the principle of which was communicated to the *Comptes rendus* of January 7, and the chief results of which are here detailed. The chromatic circle has for its object the rational determination of the complements and harmonies of colours; the two other apparatus are intended to facilitate the æsthetic study and improvement of forms.—On the relation between solubility and the point of fusion, by M. A. Etard. The object of the present note, and of the diagram accompanying it, is to show that solubility increases steadily with the temperature, and that it becomes unlimited at or close to the point of fusion of the salt entering into the solution; a given quantity of water may then always dissolve a quantity of any salt. It has been supposed that normally the solubility of salt increases up to a certain point and then decreases. But the facts here verified lead to quite a different conclusion.—New solvents of prussic blue, by M. Ch. Er. Guignet. Experimenting with ordinary prussic blue and with Turnbull blue thoroughly purified, M. Guignet has discovered an easy process for preparing ordinary soluble blue and pure prussic blue soluble in water.—On the quantitative analysis of organic nitrogen by Kjeldahl's method, by M. C. Viollette. The author has subjected this new method to certain tests which yield results somewhat different from those recently communicated to the Academy by M. L'Hôte. He finds that, if applied under the conditions here described, it may prove quite as efficient as the processes of M. Dumas and of sodaic lime, although not more expeditious than either.—On the lime present in the ground in combination with other substances, by M. Paul de Mondesir. Nearly all soils, even the most acid, contain a considerable quantity of lime, not as a carbonate, but in combination with the other elements of the earth. It is here shown that this lime may be eliminated at a low temperature by means of diluted acids.—On the precursors of the Canidæ, by M. Marcellin Boule. The

researches which the author is now prosecuting on the Pliocene faunas of the central plateau of France, have afforded an opportunity of studying remains of the canine group older than those of the Quaternary (Pleistocene) epoch, and tending to throw some light on the origin of existing species. During the Middle and Upper Pliocene there existed a considerable number of species, not only closely related to the present Canidæ, but also anticipating the various living forms of dog, fox, jackal, and wolf. These discoveries tend to overthrow the generally accepted opinion that the present domestic varieties of the dog are all merely artificial modifications of living or Quaternary wolf and jackal types.—Papers were contributed by M. Lerch, on the serial development of certain arithmetical functions; by M. Sauvage, on the regular solutions of a system of linear differential equations; by M. W. Lœwenthal, on the virulence of the cultivated Bacillus of cholera, and on the action of salol on this virulence; and by M. C. Pagès, on the locomotion of quadrupeds.

Astronomical Society, January 9.—M. Flammarion, President, in the chair.—Among the communications were the following:—M. de Meissas sent an observation of M. de Boë's second companion to Polaris.—H.R.H. the Prince of Monaco gave an account of the scientific investigations made on board *l'Hirondelle* during the past four years with a view of studying the general physics of our globe.—M. Moussette described an eye-piece for measuring the size of sun-spots and of lunar objects.—M. Mailhat read a paper on a new mercury-bath for artificial horizons, which had been successfully tried at the Paris Observatory.

BERLIN.

Meteorological Society, January 8.—Dr. Vettin, President, in the chair.—Dr. Sprung spoke on some new apparatus for the registration of rainfall and wind.—Dr. Vettin presented a number of curves representing his measurements of the velocity of the wind, by which he confirmed the results of his earlier observations as to the existence of a maximum velocity at midday in the summer, and at midnight in the winter. The measurements were made with Dr. Vettin's feather manometer. On the discussion which ensued, it was pointed out that the records yielded by this anemometer do not confirm the above results.

Physical Society, January 11.—Prof. von Helmholtz, President, in the chair.—The President opened the first meeting of the current year by a memorial address on Clausius, in which he briefly touched upon his most important works and their significance in connection with the whole range of chemistry and physics.—Prof. Kundt gave a short *résumé* of the researches which he had been carrying on of late years on the behaviour of metals to light. He took as his starting-point Kern's discovery that light which is reflected from magnets undergoes a rotation of the plane of polarization, and fully confirmed this as well as all subsequent observations of the English experimenter. In order to avoid any objections which might be raised against the accuracy of the observed phenomenon, he investigated the rotation produced by extremely thin films of metal, whose production was found, after several preliminary experiments, to be most easily attained by pulverizing the kathode *in vacuo*. The light which was transmitted showed signs of rotation, and as a result of a full experimental investigation all metals were found to exert a dextro-rotatory action on light. This law of the positive rotation of the plane of polarized light could be extended to all simple bodies. The thin metallic films further exhibited a doubly-refractive action which led him to determine the refractive index of the metals, after he had succeeded by means of electrolysis in preparing transparent metallic prisms. The speaker described the methods which he employed in these experiments and exhibited the apparatus which he had used. The result of the experiments is already known. The metals possess a varying refractive power, some exhibiting normal, others abnormal, dispersion. The velocity of light in the several metals followed exactly the same serial order as that of their respective conducting powers for electricity and heat. Since it was possible that the deviation of the rays while passing through the metals did not depend upon a true refraction, the speaker had recently examined the behaviour of the refractive indices of the metals at different temperatures. Metals whose refractive index is large showed an increase of the angle of deviation of light as the temperature rises, and thus all doubt as to the fact that he was here dealing with a true refraction was set aside. A further outcome of these experiments was to show that the velocity of light in metals is dependent on changes of temperature in a way exactly similar to that in which their electrical conductivity is dependent. In order to determine accurately the relationship of the velocity of light to their conductivity, these two values must be measured on one and the same piece of metal. When determining the electrical conductivity in films of metal as thin as those he was using for his optical researches, he found that the greatest difficulty was presented by the measurement of the thickness of the film. In his earlier researches, local thicknesses of 0·11 to 0·14 millionths of a millimetre were measured, values which approximate to the diameter of a molecule. These measurements, the preparation of transparent metallic prisms, and a number of other questions which have become prominent in the course of the above researches, partly carried out by pupils of the speaker, he intends to pursue further.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

ALPINE PHYSIOGRAPHY.

Die Gletscher der Ostalpen. Von Dr. Eduard Richter. Mit sieben Karten, zwei Ansichten, und vierundvierzig Profilen im Text. (Stuttgart: J. Engelhorn, 1888.)

The Alps. By Prof. F. Umlauft, Ph.D. Translated by Louisa Brough. With 110 Illustrations. (London: Kegan Paul, Trench, and Co., 1889.)

THE first of these two works—an elaborate memoir of 306 pages—forms the third volume of the "Handbücher zur Deutschen Landes- und Volkskunde," issued by the Centralkommission für wissenschaftliche Landeskunde von Deutschland. About one-sixth of the whole is occupied by some preliminary remarks, and a discussion of the snow-line and the methods of estimating it. As the author points out, this expression is a rather vague one, and in a later part of the book he indicates that it may be or has been used in four different senses: (1) the lower limit of the patches of *firn* or *névé*, which chiefly depends on the steepness and ruggedness of the mountains; (2) the lower limit of the connected permanent fields of snow and ice, excluding the glaciers which descend from them, which may be called the practical snow-line,—this depends mainly on the nature of a declivity and its aspect; (3) the "climatic" snow-line, a theoretical estimate of the snow-line arrived at by considering climatic factors only; (4) the normal snow-covering, estimated by the line up to which the snow melts away from the mountains. In proportion as the mountains become regular in form, the first, second, and fourth approach one another, and tend to coincide with the third, and all must be considered in arriving at a general estimation of the snow-line for any mountain group.

The author then passes in review the various districts of the Eastern Alps, and enters into details as to the distribution, arrangement, levels, and limits of the snow-fields and glaciers. In this section of the work a large amount of statistical information is collected, which, together with the references to the literature, cannot fail to be of much value to anyone engaged upon questions relating to climate, and especially investigations bearing upon glacial geology.

In the concluding part of the work the author gives a summary of the conclusions which follow from the foregoing collection of facts. These are rendered more readily intelligible by means of a map. A short description of this will perhaps be the simplest way of indicating the general results at which the author has arrived. As its scale is comparatively small, details of mountain topography are omitted for the sake of distinctness; but the chief river courses are clearly shown, and the boundary between the mountain and lowland regions, north and south, is indicated by a thin dotted line. But all the ground above the 2600 metres contour-line (a very rough mean for the snow-line of the whole region) is shaded. Thus treated, we may remark in passing, the map gives an excellent idea of what would be the structure of a group of islands produced by the submergence of a mountain region, and a comparison of it with a map of the Lofoten Islands, or indeed with many parts of the Scandinavian and even North British coasts, is not without interest. The "isochional" levels, as perhaps they might be called, are indicated by a series of dotted lines, these being graduated in hundreds of metres, the zones included between them having the snow-line at heights differing by this amount. Obviously, this is only a rough representation of the facts, because, as the author carefully points out, there are numerous minor variations, even in one and the same district, due to the form or composition of the mountains, the aspect of the slope, and the like.

In the zone of 2500 metres, only a small portion of the Eastern Alps is included, viz. the higher summits of the northern limestone zone, such as the Zugspitz and the Dachstein. The southern limit of this district trends slightly north of east. The line limiting the zone of 2600 metres on the western side runs a little south of Landeck and Innsbruck, and so does not include any important summit; but east of the Brenner it has a rather southerly trend, and practically passes along the crest of the Höhe Tauern. The limit of the zone of 2700 metres runs roughly parallel with the last, till at the Glockner group it turns sharply to the south, and then, bending back, it passes to the south of the Adamello group. Thus the Brenta Alta group, the Marmolata and other peaks of the South Tyrol Dolomites, are in the 2700 metres zone, though a few summits of the Julian Alps, at the extreme east of the map, are marked 2600 metres. There is yet one other contour-line—that including the region where the snow-line is at 2900 metres or even more. This is rudely elliptical in shape, and includes the greater part of the Bernina, Ortler, and Oetzthal groups, together with many of the peaks on the left bank of the Upper Innthal. It is thus obvious that the snow-line is not wholly dependent on mountain form, or disposition, or on general temperature. The Adamello stands well to the south of the Oetzthal, yet its snow-line is full 100 metres lower. The northern part of the Oetzthal is only a very little south of the Glockner, yet the snow-line in the one district is 200 metres higher than in the other. But the configuration of the Oetzthal group is, if anything, more favourable to the accumulation of snow, and one would have expected, at first sight, to find the difference incline in the other direction. It is, then, evident that other climatic factors are of great importance, not the least of these being the amount of precipitation during the winter months. On this subject some interesting evidence is adduced.

The book is in clear good type, and the maps and sections at the end are printed with a blank space, equal to a page, on the inner side, so that they can be kept in sight when the book is read—a very convenient arrangement too often neglected. Most of the illustrations in the text are only diagrammatic sections, but the two "views" of the Gaisberg Glacier and of the Marmolata Glacier are excellent of their kind. The former is really no more than a "pen-and-ink sketch," yet it gives a very good idea of an Alpine view, and is far better than the wretched caricatures of mountain scenery which too often do duty in English scientific text-books. It may be commended to our publishers.

The second volume before us is one larger in size, characterized in parts by the same laborious minuteness

but with little scientific value. It is the work of a geographer "pure and simple," and of one, as we suspect from internal evidence, who knows the Alps better from books than from personal experience. The larger half is devoted to Alpine topography, but this is often hardly more intelligible or interesting than a catalogue of names and altitudes. In our opinion Prof. Umlauft's plan of work is defective. At the outset, instead of impressing on the reader the relation of the Alps to the mountain ranges with which they are connected, he obscures it by an elaborate disquisition on their boundaries. The dominant physical features of the chain and its component ranges should have been at once sketched in bold outline, after which a more detailed description of the several districts might have been given. The reader would then have been furnished with a frame-work on which he could arrange the subordinate facts: now, unless previously familiar with the Alps, he will wander bewildered among a labyrinth of names and statistics. In short, Prof. Umlauft appears to be a geographer of the old school. If he has any scientific knowledge, whether as geologist or naturalist, this book affords not only no evidence in favour, but also not a little to the contrary.

For instance, in any notice of the geology of the Alps his statements are commonly unsatisfactory, and sometimes absurd. For the latter, perhaps, the translator is partly responsible, for occasionally a sentence occurs which is devoid of meaning, such as this, "Many of the lofty peaks are composed of Triassic limestones up to the metamorphic dachstein, which, inclosed in cardita, forms the peak." The paragraphs treating of valleys, lake basins, ice-caves, glaciers, erosion, and weathering, are all inadequate and unsatisfactory: all show traces of the unskilled compiler's hand. For example, in the chapter devoted to the last-named subject, the author, in speaking of "giants' caldrons," omits to state that the most remarkable examples, those, indeed, to which this name is commonly applied, and we think usually restricted, have been made by the action of streams which once plunged down the *moulins* of glaciers. It is quite true that these are not excluded by the author's words, but no hint of their occurrence is given, and no mention is made of the remarkable instance at the "glacier garden" near the Lion monument at Lucerne. It is difficult, without long quotations accompanied by a running commentary, to give an idea of the number of small defects or inaccuracies which abound in the book. We may, however, select, without actual quotation, the pages 127–36, which deal with the orography of the St. Gothard district. Here the Rhone glacier is said to be "over twenty miles long,"—probably fifteen would be nearer the mark. The "granite" of the table-land of the St. Gothard is "famed for its great crystals of feldspar." True, these crystals are fairly large, but not remarkable—much less than those occurring on the Lukmanier, which are often quite 3 inches long. Not the granite but the schist is famed "for the great number of minerals found in it." Among these minerals are enumerated various "zoolites" (zeolites), but neither albite, for which the St. Gothard is a rather noted locality, nor garnets, nor tremolite, nor actinolite, which are so abundant near the Val Tremola. One or two more slight inaccuracies, on which it is needless to dwell, may be noted in these pages.

Perhaps one of the most conspicuous instances will be found on p. 49, in a table of the eleven Alpine peaks which surpass 14,800 feet in height. First comes "Mont Blanc, highest point 15,779"; then, "*id.*, Mont Maudit, 15,651"; and third, "*id.*, Cour Mayeur (*sic*), 15,602." This is misleading. It is quite true that the actual summit of Mont Blanc lies a little north of a slight prominence which from Courmayeur appears to be the summit. The latter, however, is not a separate peak in any respect comparable with the Mont Maudit. It is a case very similar to the "Wengern Jungfrau" and the true summit, and on this principle separate peaks might be manufactured to any extent in the Alps. Further down is a more serious error. We find "Mischabelhörner, Täschhorn, 14,972 feet"; and a little lower in the list, "Mischabelhörner, Grabhorn, 14,949 feet." But the latter, more usually called the Grabenhorn or Dom, is the higher peak, as is correctly stated elsewhere in the volume, though there the altitudes given are not the same. There is yet another error. The author enumerates three of the actual peaks of Monte Rosa; then at the end of the list he places "Monte Rosa, Lyskamm, 14,887 feet," and "*id.*, Weisshorn, 14,804 feet." But the Lyskamm is always regarded as a separate mountain, and the depression between the two, crossed by the well-known Lysjock, though it is only 800 or 900 feet lower, is so wide and well marked as to justify the separation. But to rank the Weisshorn as a peak of Monte Rosa is hopelessly indefensible. The mountains are more than ten miles apart as the crow flies, and separated by the deep trench of the Vispthal.

One rather short chapter is devoted to the fauna and flora of the Alps, and the information there given is extremely scanty, and not seldom inaccurate. For example, the rhododendrons only appear under the vague and misleading trivial name of the "Alpine rose," and it is not even hinted that there is a true *Rosa alpina*. Heaths, again, are hardly to be enumerated among the higher Alpine plants, and azaleas are only represented by the abundant but very inconspicuous *Azalea procumbens*. The account of the fauna is equally unsatisfactory. The chamois receives only a passing mention, and is not enumerated among the animals frequently found above the snow-line. The steinbock (*Capra ibex*) is briefly alluded to under the name of the "wild goat." The birds are vaguely enumerated, and, while undue prominence is given to some, others, which as a rule especially attract the traveller's notice, are passed over in silence. The insects are almost wholly neglected; yet, without entering into many scientific details, it might have been possible to give some idea of the crowds of little blue butterflies (*Polyommatus*) that flutter about the puddles on the pathways, of the coppers (*Lycæna*), ringlets (*Hipparchia*), fritillaries (*Argynnis* and *Melitæa*), clouded-yellows (*Colias*), and Apollos (*Parnassius*), which impress the traveller accustomed only to the European lowlands, when first he rambles among the true Alpine regions. It would be easy to name more than one similar work, by no means of recent date, which in this respect is far superior to Prof. Umlauft's.

The illustrations are numerous, but rather unequal in quality. Some are fairly good, but frequently, while accurate in general effect, having probably been engraved

from photographs, they are defective in character. A glance at the representation of the gorge of the Tamina on p. 48, or that of Monte Cristallo from the Dürrensee (facing p. 86), will indicate the nature of our objection. The rocks might be moulded from plaster or canvas. There is, however, a very clearly printed geological map of the Alps, which appears to us generally accurate, though we doubt the correctness of placing a considerable patch of Silurian and Devonian about the upper part of the Brenner Pass.

T. G. BONNEY.

THE PLANTING AND AGRICULTURAL INDUSTRIES OF CEYLON.

Review of the Planting and Agricultural Industries of Ceylon, and Statistics of the Planting Enterprises in India and the Colonies. By J. Ferguson. Pp. 168. (Colombo: A. M. and J. Ferguson, 1888.)

THIS is a reprint, in the form of a small octavo volume, of information contained in Ferguson's "Ceylon Hand-book and Directory," specially relating to the tropical cultures of Ceylon. It affords much authentic information in a handy and accessible form, and is a valuable summary of the results attained in the cultivation of most economic plants suited to a tropical country. Ceylon itself is a singularly interesting island. It is usually described as the largest, most populous, and most important of the Crown Colonies of Great Britain. It has in recent years become the seat of planting industries which have in one or two instances almost monopolized the markets of the world. It is six times the size of Jamaica, and about five-sixths the size of Ireland. Of its sixteen million acres, at present only about three millions are under cultivation, and these support a population of exactly the same number. The value of the imports and exports amounts to about ten millions sterling. The total number of European residents in Ceylon is under five thousand, while the mixed or coloured population called Eurasians or Burghers amounted to about nineteen thousand. The bulk of the population, amounting to nearly two million souls, is composed of Sinhalese—a remarkably tractable and inoffensive people—while the remainder is made up of Tamils, Moormen, Malays, and Veddahs. The latter are an aboriginal race, comparatively few in number, inhabiting the forests of the north-east.

Although the number of the Sinhalese is relatively so large, they contribute very little to the labour supply of the European plantations. Plantation labour is furnished by Tamil coolies from Southern India. According to a Report published by the Government of Madras, out of a population of thirty-five millions of human beings in that Presidency there are sixteen millions whose annual earnings do not average more than £3 12*s*., or a little over 2½*d*. per day. Thus it is that the plantations of Ceylon, paying about 6*d*. or 9*d*. per day, are abundantly supplied with cheap free labour.

The purely European enterprises consist of tea, coffee —both Arabian and Liberian—cacao, cardamoms, rubber, annatto, vanilla, pepper, fibres, nutmeg, cloves, dye-plants. In these is invested English capital to the amount of about eight millions sterling. The native industries are associated with the cultivation of the cocoa-nut palm—yielding oil, coir, and copra—rice, cinnamon, palmyra palm, kitul or jaggery palm, areca palm citronella and lemon grass, tobacco, cotton, sugar-cane, dry grains such as kollu, millet, kurakkan, maize, and numerous vegetables and fruits. It is estimated that there are nearly fifty million cocoa-nut palms in Ceylon, and the yearly yield cannot be less than about 500 million nuts. Next to the cocoa-nut palm, the palmyra palm (*Borassus flabelliformis*) is regarded as one of the richest plants known. According to a Tamil proverb, "It lives for a lac of years after planting, and lasts for a lac of years when felled." Jaggery sugar is made from the sap, and in the dry, arid regions of the north-east of Ceylon more than seventy million nuts are annually produced. The young sprouting nuts are used as a vegetable. The kitul (*Caryota urens*) is another sugar-palm, which, in addition, yields a coarse black fibre used in broom-making. Cinnamon is essentially a native industry. The island has been famous for this spice "from the dawn of historical records." There is a Sinhalese caste of cinnamon peelers, and these, the Chaliyas, hold practically a monopoly in preparing the bark for the market. The dry grain cultivation is associated with that baneful *chena* practice of recklessly cutting down and burning virgin forests—now, we are glad to notice, in course of being kept within proper bounds. The natives of Ceylon have imitated the Europeans in many industries, but by far the greater number are content to follow in the footsteps of their ancestors, and cultivate only such plants as cocoa-nuts, rice, fruits, and vegetables, necessary to supply their daily wants.

For many years the chief European industry was that of coffee. From 1825, when Sir Edward Baines started the first upland coffee plantation near Kandy, to 1875, when Ceylon exported nearly a million hundredweights, "coffee was king." In 1869, a microscopic fungus (*Hemeleis vastatrix*) made its appearance on the leaves of the coffee-plant. This spread with such rapidity, and with such destructive effect, that within a few years the Ceylon coffee plantations were doomed. The disease extended also to Southern India, to Sumatra, and Java; it invaded Mauritius, Madagascar, and Natal, and reached even the young and promising plantations of Fiji. After twenty years' experience of this pest, the Ceylon coffee plantations have so dwindled that the present exports are only one-tenth of what they once were. Fortunately the decline of coffee was accompanied by the extension of cultivation of cinchona, cardamoms, cacao, and tea Ceylon cinchona has been produced in such quantities that the markets have been completely glutted. In consequence the price of bark has fallen so low that the cultivation is unremunerative. The attention of Ceylon planters is now being concentrated, with their accustomed energy, on the cultivation of tea. Coffee, cinchona, and everything not immediately remunerative are being uprooted to give place to the new staple. Although the industry is not more than ten or twelve years old, Ceylon tea is already being exported to the value of £600,000. Tea therefore bids fair to take the place of coffee, and thus the cloud which has overshadowed the prosperity of the island during the last few years is gradually passing away. Ceylon cacao is excellent, but the industry is small and apparently stationary. It is doubtful whether the island possesses

any really large extent of land suitable for the growth of the cacao-plant. The rubber industry in Ceylon, as elsewhere, is mysteriously unproductive, while the cultivation of vanilla, pepper, and fibres, is only in the experimental stage. The total areas under the various cultivations at present are: tea, 183,000 acres; coffee (Arabian), 77,000 acres; coffee (Liberian), 916 acres; cinchona, 36,000,000 trees over two years old; cacao, 12,000 acres; cardamoms, 5000 acres; rubber-trees, 386 acres; croton, castor-oil, aloes, cinnamon, vanilla, pepper, cloves, plantains, and citronella grass, 7400 acres; gum-trees, fruit-trees, sapan, sapu, cocoa-nuts, areca-nuts, nutmegs, 4600 acres.

Such are a few of the gleanings from this useful account of the planting and agricultural industries of Ceylon. Mr. Ferguson is favourably known as a successful journalist, and as the author or joint-author of numerous publications connected with the island in which he has spent the greater part of his life. Indeed, it would not be too much to say that Mr. Ferguson and his uncle have contributed by their writings in no small degree to promote the various industries upon which the prosperity of Ceylon depends. To those whose interest or whose business is connected with tropical cultures this summary will prove most useful. It covers a wide field, but, so far as Ceylon is concerned, it contains information available in no other way. The historical and statistical facts, no less than the points respecting the treatment of tropical plants, are collected from trustworthy sources, and are of interest wherever such plants are cultivated, and we may add scarcely a single tropical product is passed unnoticed. D. M.

PALÆONTOLOGY.

Die Stämme des Thierreiches. Von M. Neumayr. "Wirbellose Thiere." Erster Band. (Wien und Prag: Tempsky, 1889.)

THE palæontologist has been defined as a variety of naturalist who poses among geologists as one learned in zoology, and among zoologists as one learned in geology, whilst in reality his skill in both sciences is diminutive. The division of zoology into palæontology and neontology is one which is, no doubt, logically defensible, and so would be a division of the subject-matter of zoology into as many branches as there are periods recognized by geologists—cambriontologists, siluriontologists, anthrakontologists, &c. On the other hand, it must be admitted that such divisions seem unlikely to tend to the furtherance of our knowledge of animal life in the past. The fragmentary remains of extinct animals can only be interpreted by the application to them of a very thorough knowledge of the form and structure of living animals, and accordingly it would seem desirable that, as is more usually the case in regard to the study of plant remains than in regard to that of animal remains, the study of palæontology should be relegated to those who also occupy themselves with neontology. The botanists, with few exceptions, pursue this plan; but curiously enough, a special class of palæontological zoologists exists and flourishes. A further advantage to be derived from the suppression of palæontologists seems to be this—that there would be a better chance for the cultivation of true geology, which now, to some extent, has its professorial positions, its museums, and its publications invaded by these specialists. Whatever may be said in favour of the palæcntologist, he cannot be allowed to claim geology as his own; nor should the capable geologist, as is unfortunately and so frequently the case, venture beyond his last, and discourse on zoology in the disguise of a palæontologist, for the disguise cannot effectually conceal his incompetency to deal with zoological problems.

Whilst believing that it is increasingly desirable that the truth of the above propositions should be recognized and acted upon, we are yet prepared to admit that, as a practical division of labour in the great field of zoological science, palæontology must be recognized. Human knowledge does not develop according to abstract conceptions of the relations of one branch of study to another, but on a much more homely basis, open to philosophical objections of the most severe character. The way in which things have presented themselves to the hands and minds of students in consequence of practical demands or special opportunities of study is that which has determined the existence of the various divisions of natural history and the consequent groups of naturalists devoted to one or another unphilosophically limited pursuit. The collecting of "fossils," the hammering out of the fragments of a past world from their stony graves, the cultivation of the faculty of recognizing the significance of minute and detailed portions of fossilized shells and bones, is a definite hobby, which has excited the enthusiasm and stimulated the ingenuity of a long list of remarkable men, such as Woodward, Mantel, Barrande, and a host of less-known collectors. It seems not improbable that, were the remains of extinct animals in our great public and educational collections classified and placed with those of recent forms, an injustice, not to say an injury, would be done to the special phase of scientific activity which has produced these collections, and the important knowledge of the history of life on the earth which they represent. The morphologist, dealing with the complete structure of recent forms, is liable to neglect all but the more perfect remains brought to light by the collector of fossils; whilst, on the other hand, the palæontologist interprets the most obscure fragments, and speculates, it may be audaciously, but not unwisely, upon the significance of all that comes to his hand.

The volume which has led to these remarks is the first part of a treatise which is improperly named. It is not a treatise upon the pedigree of the animal kingdom, but an account of extinct animals treated in zoological order—in fact, a manual of palæontology. As an introduction, there is an extensive essay on Darwinism, and a discussion of Lamarckism and the causes of variation, which are becoming more and more the absorbing topics of the day. Dr. Neumayr does not appear to make any contribution of general importance to the discussion; but he makes the doctrine of descent and the Darwinian theory of natural selection the guiding principles of his treatise. The neontologist, if we may venture to call anyone by that name, will find in Dr. Neumayr's pages many facts of great value in the elucidation of biological problems, and a number of excellent woodcuts. The work promises to be one of considerable size, since this first volume consists of six hundred pages royal

octavo. It is written from the point of view of the author's nationality, and naturally such new matter as it contains is chiefly in reference to the palæontology of the Austrian Empire. E. R. L.

OUR BOOK SHELF.

Text-book of Physiography. By Edward Hull, M.A., LL.D., F.R.S. (London: Deacon and Co., 1888.)

FROM the Director of the Irish Geological Survey we should naturally expect a text-book of exceptional merit, but we must confess at the outset that he has disappointed us. In the first place, he does not seem to have a clear conception as to the scope of his subject. Physiography is essentially an introduction to the study of natural forces and their effects, and consequently not only comprises the various movements and physical features of the earth, but also includes a study of the various forms of energy and the properties of matter. Of the latter, Prof. Hull has written nothing. Again, it is difficult to see for what class of students the book has been written. It is evidently not for beginners, being avowedly addressed to those who have access to the Transactions of the learned Societies; and the treatment is far too superficial for advanced students.

The first part of the book is designated "Astronomical and Introductory," the earth being considered in relation to the other planets. The questions of latitude and longitude, and a chapter on the moon, fall under this head. This part of the subject is treated so briefly that very careful reading will be necessary on the part of those who are not previously acquainted with it.

Part II. deals with "Terrestrial Physics and Dynamics," and discusses the form and structure of the earth, volcanoes, and earthquakes. The theory of a viscous stratum beneath the earth's crust is put forward as confidently as if it were the law of superposition of strata, and all reference to the objections which have been urged against it is omitted. It would be hard to compress more debatable matter into a page than has been effected in the diagram which illustrates this theory (p. 55).

The physical features of the globe, such as surface forms, oceans, coral islands, tides, air currents, and the functions of rivers and glaciers, are treated in Part III. Terrestrial magnetism also falls under this head, and this is really an excellent outline of the subject, as far as results go; but practically nothing is said about the instruments which are employed. As a compromise between the views of Darwin and Murray regarding coral reefs, Prof. Hull suggests (p. 110) that "the volcanic islands and banks of organic materials are themselves planted on a floor formed by the surface of a continent, which once occupied the region of the Central and Western Pacific." We will leave the opposing parties to form their own opinions as to the value of this suggestion.

The geographical distribution of plants and animals forms the subject of Part IV., and here there is little to complain of.

The book is illustrated with thirteen coloured plates and maps, and eleven diagrams. Some of these, as, for example, the map showing the lines of equal magnetic variation and declination for the British Isles, are excellent. The whole book bears traces of having been written hastily, and we cannot but regret that the author of "The Coal-fields of Great Britain" should have added one more to the already too large number of text-books that seem to present physiography as a subject in which no originality is possible.

The Clyde, from its Sources to the Sea. By W. J. Millar, C.E. (London: Blackie and Sons, 1888.)

MR. MILLAR has succeeded in writing an interesting book about the Clyde, and about Glasgow in particular. The subject is worthy of the care devoted to it by the author, for what river or city in the United Kingdom has more varied industries to boast of, and where are the applications of science more numerous?

Probably no river owes its improvements more to the engineer than the Clyde. We are told how eminent engineers were called in, and surveys made, in order to deepen the river and make it more navigable; Smeaton and James Watt each had their turn, and afterwards many well-known men in their time reported on the same subject. The result is that the Clyde of to-day is able to float the largest ocean steamers in its harbour, a state of things of which the people of Glasgow are justly proud.

The growth of the steam-ship, of course, occupies much space, since it was on the Clyde the first successful attempts at steam navigation were made. These are duly described, and the boats illustrated. On recent Clyde-built ships our author has much to say, and, among other things, he gives an account of some experiments conducted by the late Mr. William Denny to investigate the relation existing between speed and resistance of ships. Messrs. Denny, at their ship-building yard at Dumbarton, have constructed an experimental tank with all the requisite machinery for the purpose, thus carrying on the investigations initiated by the late Dr. Froude.

This volume gives one a good insight into the varying industries carried on in Glasgow and its neighbourhood, and contains much general information about the district. The book is well written, nicely printed and illustrated, and should find a place in the libraries of the citizens of St. Mungo, and others interested in the progress of the district.

A Playtime Naturalist. By Dr. J. E. Taylor, F.L.S. (London: Chatto and Windus, 1889.)

DR. TAYLOR explains that he has a liking for intelligent English lads, "just as some people have for blue china and etchings"; and he "ventures to think the former are even more interesting objects." Accordingly he has written this little book for the instruction and entertainment of his "human hobbies." The work contains abundant evidence of the author's knowledge and enthusiasm, and any boy who may read it carefully is sure to find something to attract him in the chapters on birds, Lepidoptera, land shells, toads, frogs, newts, invisible life, microscopic plants, and other subjects. The style is clear and lively, and there are many good illustrations.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Climate of Siberia in the Mammoth Age.

PROF. A. NEWTON, in his remarks on my letter, says that the similarity of the birds of Japan and of Europe has been long known. Of course it has. It is an elementary postulate in geographical zoology; but this is not the fact to which I called special attention, and from which I drew my inference. That fact is that, while the birds of Japan and England are in certain species undistinguishable, the corresponding birds of Siberia are sufficiently different to be classed as separate species. This could not be known, in the sense of being proved, until the avifauna of Siberia had been worked out from end to end, resulting in the formation of such a continuous series of skins as that in the possession of my friend Mr. Seebohm.

Prof. Newton goes on to argue that the remarkable fact here referred to is to be explained by the hypothesis that the birds of

Japan and Europe live in insular climates, while those of Siberia occupy an area with a continental climate. I do not think many biologists can accept this explanation. England and Japan are 3700 miles apart. That a single bird whose normal type is found in Siberia should vary from that type in two areas thus remote from one another in precisely the same way is perhaps possible. That a whole string of birds (and I only mentioned a sample) should do the same is, it seems to me, when tested by the doctrine of chances and the infinite variability of bird structure and colour, an impossibility.

Apart from this *a priori* argument, we have the fact—which is, of course, known to Prof. Newton—that Blakiston's line separating Yesso and the southern island of Japan also separates two avifaunas, and that the species on each side of the narrow strait of Yesso are in many cases different, although they live in insular areas close to one another, and subject to virtually the same insular climate, while those of England and Japan, whose climate is not so like, are undistinguishable. I cannot, therefore, for a moment accept Prof. Newton's theory as in any way meeting the facts which are admirably met at every point by the theory which I have propounded, and which is not based on the variation of the birds alone, but upon a whole *catena* of converging evidence from many sides, the evidence of the birds being only a subsidiary support.

I am sorry that I had overlooked Prof. Newton's article in the "Encyclopædia," and am glad that my suggestion about the red grouse, which I can assure him was quite independently made, had already occurred to and been countenanced by so distinguished an ornithologist, against whom I hear continual complaints, which ought to be very flattering, that he writes too little.

Reverting to the main issue, it is a great pleasure to me to have Prof. James Geikie's permission to publish an extract from a letter which he has sent to me, in which he is completely at one with me in the conclusion that, when the mammoth lived, the climate of Siberia was temperate, and that it lived where its remains are found. This is particularly gratifying to me, not only because Prof. J. Geikie is the most learned and voluminous writer upon the so-called Pleistocene age, his stout volumes being marked as much by their extraordinary profusion of references and of facts as by their lucid arrangement, but because upon some of the main conclusions I have arrived at he takes a very different view. Prof. J. Geikie says:—

"I do not need to be converted to the view that Siberia formerly enjoyed a temperate climate. If you will consult the first edition of my 'Great Ice Age' (p. 494), you will see that my belief for the last fifteen years has been that the mammalian remains of North Siberia are the relics of a fauna that lived and died in those now dreary regions. Indeed, I had that notion when I first began to read what had been written upon the subject some five-and-twenty years ago! I was willing, however, to admit the possibility of some of the remains having been drifted north by rivers. But it has always seemed to me inconceivable that this drifting would account for the presence of such great ossiferous accumulations as travellers have described. I likewise long ago discarded the notion of seasonal migrations, such as Dawkins and others have maintained (see *Geol. Mag.*, 1872, p. 164; 1873, p. 49)."

I shall not labour the argument further, nor shall I enlarge upon what I deem to be an inevitable corollary from it—viz. that if the climate of Siberia was temperate when the mammoth lived, and if it lived where its remains occur, on the now bare and almost perpetually frozen *tundra*, it follows that its extinction there must have been followed by a most rapid, if not a sudden, change of climate. The existence of its *undecayed carcasses* in all parts of Siberia, from the Obi to the Indigirka, is consistent only with this conclusion. If the change of climate had been gradual, the flesh of the great beasts could not have been preserved intact, but would have putrefied and decayed. This was long ago seen and emphasized by Cuvier, and even Lyell was constrained to write:—"It is certain that, from the moment when the carcasses both of the rhinoceros and the elephant above described were buried in Siberia, in lat. 64° and 70° N., the soil has remained frozen, and the atmosphere as cold as at this day." Again, he says:—"One thing is clear, that the ice or congealed mud in which the bodies of such quadrupeds were enveloped has never once been melted since the day when they perished, so as to allow the percolation of water through the matrix, for, had this been the case, the soft parts of the animals could not have remained undecomposed." It was to avoid the necessarily awkward inference from this conclusion, for one who preached uniformity so continuously, that Lyell was forced to invoke his theory of river portage, which is no longer tenable, and, so far as I know, is no longer held by any serious student.

HENRY H. HOWORTH.

Bentcliffe, Eccles, February 3.

Peripatus in Victoria.

IT may interest some of the readers of your journal to know that last week, while collecting in a fern-tree gully at Warburton, on the Upper Yarra, Victoria, I had the good fortune to discover two specimens of *Peripatus*, belonging, as I think, to a new and certainly to a very beautiful species.

I hope to publish a full description, with figures, of the species as soon as possible, but I am now preparing for a visit to Tasmania, and some time must necessarily elapse before I can complete the work. I should therefore be greatly obliged if you could find space for this letter in NATURE.

In his "Monograph on the Species and Distribution of the Genus *Peripatus*," recently published in the *Quarterly Journal of Microscopical Science*, Prof. Sedgwick makes no mention of the occurrence of the genus in Victoria; though he describes in detail the Queensland and New Zealand species. In a note in the Proceedings of the Linnean Society of New South Wales (vol. ii. Part 1, 1887), however, Mr. Fletcher has recorded the discovery of the genus in Victoria. He says, "The specimen which I exhibit this evening was given to me a fortnight ago by my friend Mr. R. T. Baker, of Newington College, who had obtained it a few days previously either in or under a rotten log at Warragul, Gippsland, Victoria. It has fifteen pairs of claw-bearing appendages, and has nearly the same dimensions as are given in the abstract referred to; it is therefore in all probability an example of *P. leuckartii*, Sänger."

From Mr. Fletcher's account I am not able to say definitely whether the specimens obtained by me belong to the same species as the single specimen which he mentions; but after carefully studying Prof. Sedgwick's full description of *P. leuckartii*, I am fairly certain that they do not belong to that species, but to a new one which I for the present refrain from naming.

Both of my specimens were captured under fallen logs, where they were lying quite still. The first appeared to be dead soon after it was caught, and was therefore placed at once in alcohol. The second was found under a damp, rotten log, probably of *Eucalyptus*, in the same gully. It was taken home alive and put to crawl about on a newspaper, when it appeared very active. It elongated considerably when crawling, so that the legs came to be much further apart than when the animal was at rest, and when crawling it measured about 39 millimetres in length, excluding the antennæ. When irritated at the head end it ejected a surprisingly large quantity of an intensely sticky fluid, of a whitish colour, from the oral papillæ.

The species has, as in the two already described Australasian forms, fifteen pairs of claw-bearing legs, but it differs very strikingly indeed both from *P. leuckartii* and from *P. novæ-zealandiæ* in the colour and markings of the body. The general tint is brownish red, with only traces in one specimen of the bluish colour so characteristic of the two above-mentioned species. The markings on the body are singularly distinct and well defined, and identical in the two specimens. All down the dorsal surface there runs a median broad reddish-brown or chestnut-coloured band, divided into a series of diamond-shaped patches by regular lateral indentations, one diamond corresponding to each pair of legs. In the middle of this band there is a thin, median, whitish line. On either side the chestnut-coloured band is edged by a narrow black line, which follows the indentations of its margin, and outside this comes a broad band of darker brown, and then, at the edge of the dorsal surface, a narrow band of light brown. The ventral surface is light yellowish-brown, speckled with spots of very dark pigment, especially abundant at the base of each leg. In the mid-ventral line there is a row of white spots, one between the two legs of each pair except the first (?) and the last (where, of course, the genital opening is situated). The antennæ are light brown, closely ringed all the way up with very dark brown or black.

This species, though small, is to my mind even more beautiful than any of those figured by Prof. Sedgwick, and I think there can be little doubt as to its distinctness. The anatomical features I hope to describe at a later date, and perhaps they will throw further light upon its relations to previously described forms.

ARTHUR DENDY.

University of Melbourne, December 18, 1888.

Mass and Inertia.

PROF. WORTHINGTON is perfectly right in saying that in my little book on mechanics I did not carefully and solely use the term inertia in the precise sense I suggested for it in my last letter. The fact that m is really only the coefficient of inertia had not been seized by me when I wrote that book. The idea of calling mass-acceleration inertia simply, was suggested, I believe, by a discussion on Newton's third law of motion in the pages of the *Engineer* some few years back. It is a suggestion which has gradually commended itself to me, and I am calling the attention of the British Association Committee on Mechanical Units and Nomenclature to it.

With regard to the other matter referred to by Prof. Worthington, it scarcely strikes one as a satisfactory plan to have one system of units for teaching and another for actual use. Is it not better to get students to tackle difficulties rather than evade them? OLIVER J. LODGE.

The Crystallization of Lake Ice.

THE percussion figures that Mr. Holland has discovered both are interesting in themselves and seem to be a very handy means of marking off one crystal from another in thin lake ice. Their symmetry about a vertical axis is evidence that the optic axes of the crystals were vertical. The small amount of snow here this winter has afforded unusual opportunities for examining the ice on the Davos lake, and I have found crystals, not indeed equal to those on the Welsh lakes, but still very large. A striking feature in the ice, about a week after it was strong enough to bear skaters, was the presence of a number of hexagonal disks, of all sizes up to a quarter of an inch diameter, with their planes apparently horizontal. Some were regular hexagons, but generally the sides were unequal, though the angles were always 120°. I concluded that within a single crystal all the hexagons would be similarly oriented, and that an interface of two crystals could be distinguished by a sudden twist in the direction of the sides. Judged by this test some of the crystals were at least a foot broad, and in depth no doubt equal to the thickness of the ice, at that time about a foot. To verify this conclusion Mr. Kidd hacked out a piece with the axe, and we prepared a rough plate six inches long and three thick, which we examined in the polariscope. The rings and cross were easily seen, and the plate proved to be all one crystal with the optic axis vertical *in situ*.

These hexagons are not identical with the figures observed by Prof. Tyndall in the path of a sunbeam through ice (described in "Forms of Water"), for at the time I saw them the ice was so cold that water froze rapidly in any hole that was made. A friend describes them as looking more like bits of cover-slip glass than anything else. They were formed, I was told, on a day when the warm Föhn wind was blowing, and the ice, no doubt, was at a thawing temperature. But the puzzle is, why they did not vanish when the temperature fell. They reflected light strongly, far more than Tyndall figures, and in some cases showed the colours of thin plates. I noticed that those that gleamed with reflected sunlight often lay considerably to right or left of the vertical plane through the sun. This showed that their planes were (allowing for refraction) inclined sometimes as much as 10° or 15° to the horizontal, and inferentially that the optic axes of the crystals were tilted an equal amount from the vertical. I hunted about all over the lake for signs of the columnar structure that I described in my article on "The Plasticity of Ice," but only succeeded in detecting it in one place close to the shore. We cut out a piece there and verified the existence of the columns with the polariscope. There were no hexagons in that part of the ice.

Of the St. Moritz lake last winter I can only give a very imperfect account. For at the time I began observations the great depth of snow had sunk the ice, and water had oozed into the snow and there frozen, so that the clear ice was covered with some eighteen inches of hard snow ice. The only part easy of access was where a supply of ice was being cut for the hotels. The process adopted was, after clearing the ice from a certain space, to leave that for a week or two, till the new ice had reached the thickness of a foot, and then cut it again. Both the new ice and the old ice in its neighbourhood was columnar. In one place, however, at some distance from the shore, where we got out a lump of clear ice, we found crystals with the optic axis vertical, and one, at least, three or four inches across.

Davos Platz, January 29. JAMES C. MCCONNEL.

Falls of Rock at Niagara.

THE following passages, which will interest geologists, I copy from the *Montreal Daily Star* of the dates given :—

"Niagara Falls, Ontario, January 7.—Last Friday evening, about 9 o'clock, a large mass of rock fell from the precipice of the Horse-shoe or Canadian Falls, and on Saturday night, at 10 o'clock, another mass broke away. In both cases the noise made alarmed the residents in the vicinity. In the Table Rock House, a stone building, doors were thrown open, and the occupants jumped out of bed greatly excited by the unusual noise and vibration, resembling severe shocks of an earthquake. The same sensation was experienced at the residence of the gate-keeper on Cedar Island, and also half a mile up the river. The effect of these falls on the contour of the cataract is quite marked, the change being from that of an angle at the vertex to the original horse-shoe shape."

"Niagara Falls, Ontario, January 15.—Another piece of rock broke away from the crest of the Horse-shoe on Sunday night. Although the jar was comparatively slight, the shock was distinctly felt at the Table Rock House. The cataract now presents the extraordinary shape of a double horse-shoe, the smaller one caused by the recent displacement being in advance and to the right of the great horse-shoe. Visitors familiar with the shape of the Canadian Falls during recent years will be able to appreciate the change at a glance.

"Thousands of people visited the Falls yesterday and to-day to view the relics of the bridge torn down by the late gale,—this is the upper suspension bridge, close to the Falls, destroyed by the storm of last week,—and also to enjoy the magnificent scenery which Niagara always presents when arrayed in her winter apparel. The contract for a new bridge to replace the one destroyed has already been let, and the work will be completed in ninety days."

Additional facts are here furnished in favour of the opinion that the recession of the great cataract is going on at a rate much more rapid than some have maintained, and more rapid than was estimated by Sir C. Lyell in 1842. Indeed, the rate given by Mr. Bakewell in his work on geology seems to have been nearer to the truth, 3 feet per annum instead of the 1 foot assumed by the author of the "Principles of Geology."

Akron, Ohio. E. W. CLAYPOLE.

Origin of the Radiolarian Earth of Barbados.

THE Barbados infusorial earth is well known for the beautiful specimens of Polycystina which it contains, but concerning the rock itself, its geological position, and probable mode of formation, little has been written.

Schomburgk, in his history of Barbados, gave a general description of it and indicated some of the localities where it had been found, but he did not separate it geologically from the group which he designated the "Scotland formation." One of us having resided in the island for some years has had opportunities of studying the lie of the deposit, and has found that it always overlies the rest of the Scotland beds, and that it generally, although not invariably, intervenes between them and the raised coral reefs which form the surface of the greater portion of the island. It has been found below the coral in certain borings recently made by the Barbados Water-supply Company, and there can be little doubt that it originally formed a sheet of considerable thickness extending beyond the present limits of the island.

The rock itself varies much in composition: in some places it is almost purely siliceous, consisting mainly of Radiolaria and Diatomaceæ, whilst in others it is largely calcareous (one sample having yielded as much as 79·9 per cent. of calcium carbonate), containing in places many Foraminifera. The more siliceous specimens agree closely with the descriptions given of those deep-sea oozes which contain Radiolaria and are more or less destitute of Foraminifera. We intend to pursue our investigation of the deposit, and to compare it, if possible, with samples of modern Radiolarian ooze, but the facts already known to us render it highly probable that the deposit is part of a raised ocean bed. If this conclusion be confirmed, it will correct the prevalent belieef that oceanic deposits are not to be found amongst the rocks which form continents and continental islands, and will at the same time form a strong and well-nigh invincible argument against the theory of the permanence of oceans, a theory which has recently been discussed and rejected by one of us. J. B. HARRISON.

A. J. JUKES BROWNE.

Natural History in the Field.

WILL you allow me to draw the attention of students of field botany, field naturalists, and those interested in encouraging natural history in the field, especially schoolmasters who may be initiating classes for the study of our native plants, to the high probability of the present year being quite an exceptionally prolific year for all our sun-loving vegetable flora.

The want of sunshine last year kept all our wild flowers back. Nothing had its full development: flowers were late, foliage was thin, colours were dull and undefined, fruit small and without flavour, seeds unripe.

But one season's loss is the next season's gain; in all probability the plants this year will be exceptionally fine, and many plants that are usually small and poor will flourish with unusual vigour, while, not improbably, many plants which seldom show themselves here will this year blossom and become visible.

On this account it might be well to advise the starting of classes for the study this year of field natural history, for students, particularly young students, are encouraged to go on with a pursuit that has been very successful at its commencement.

Chigwell. W. LINTON WILSON.

Detonating Meteor.

ACCORDING to the Jamaica Weather Report for November 1888, a very brilliant meteor was seen at Kingston, Jamaica, on the evening of November 10, at 8h. 52m. local mean time.

It appeared about 30° above the south-west horizon, crossed the heavens, and disappeared about 30° above the north-north-east horizon; and as Kingston is in lat. 18° N., we have for the point of appearance the celestial co-ordinates R.A. 21h. 24m., N.P.D. 113°, and for the point of disappearance, R.A. 3h. 45m., N.P.D. 25°.

Mr. R. Johnstone writes:—"It was by far the brightest meteor I have ever seen, and it so lit up the sky as to cause consternation among many of the negro population. Exactly four minutes afterwards I heard a sound as of a distant explosion, which was not quite so loud as the 9 o'clock gun at Port Royal, heard in due time about four minutes later. The sound was heard by other people in Kingston."

As Kingston is 5h. 7m. W. of Greenwich, the meteor appeared November 11, 1h. 59m. a.m. Greenwich civil time; and therefore the meteor falls within the period November 11–15, which is one of the large-meteor periods, according to the useful summary given in Whitaker's Almanac.

The interval of four minutes between the appearance of the meteor and the sound of its explosion corresponds to a distance of forty-eight miles. I am sorry that the details are at present incomplete in many respects, but inquiry will be made.

MAXWELL HALL.

12 Hartington Road, Ealing, February 2.

MEMORIAL TO G. S. OHM.

A MEETING was held on Thursday afternoon, January 31, in the meeting-room of the Royal Society, the Right Hon. Lord Rayleigh, Sec.R.S., in the chair, for the purpose of promoting the co-operation of English men of science and others in a project, set afoot in the first instance by some of the Professors and other leading men in Munich, of erecting in that city a statue of George Simon Ohm—a man who, although he discovered no new phenomena of very striking importance, yet by the accuracy of his thought, and the clearness of his insight into the true bearings of physical facts, was able to lay one of the principal and firmest parts of the foundation of the noble edifice of modern physics.

The occasion for the proposal at this particular time to erect a memorial to Ohm is the near approach of the hundredth anniversary of his birth, on March 16, 1789. There are, moreover, reasons why this proposal should be, and no doubt will be, taken up warmly in this country. English physicists may recall with satisfaction that the award of the Copley Medal by the Royal Society on November 30, 1841, was the first public or official recognition that Ohm received of the value of his work upon the laws of the electric circuit, and that this award contributed in a very great degree to obtain for his researches the attention and appreciation they deserved. It may not be without interest at the present time to refer to the words in which the Chairman, Sir J. W. Lubbock, Bart, V.P. and Treas., announced the award. The following is from the report of the proceedings at the anniversary meeting of 1841:—

"The Council has awarded the Copley Medal for the present year to Dr. G. S. Ohm, of Nuremberg, for his researches into the laws of electric currents, contained in various memoirs published in *Schweigger's Journal*, *Poggendorff's Annalen*, and also in a separate work, entitled 'Die galvanische Kette mathematisch bearbeitet,' published at Berlin in the year 1827. In these works, Dr. Ohm has established, for the first time, the laws of the electric circuit; a subject of vast importance, and hitherto involved in the greatest uncertainty. He has shown that the usual vague distinctions of intensity and quantity have no foundation, and that all the explanations derived from these considerations are utterly erroneous. He has demonstrated, both theoretically and experimentally, that the action of a circuit is equal to the sum of the electromotive forces divided by the sum of the resistances; and that whatever be the nature of the current, whether voltaic or thermo-electric, if this quotient be equal, the effect is the same. He has also shown the means of determining with accuracy the values of the separate resistances and electromotive forces in the circuit. The light which these investigations have thrown on the theory of current electricity is very considerable; and although the labours of Ohm were for more than ten years neglected (Fechner being the only author who, within that time, admitted and confirmed his views), within the last five years, Gauss, Lenz, Jacobi, Poggendorff, Henry, and many other eminent philosophers, have acknowledged the great value of his researches, and their obligations to him in conducting their own investigations. Had the works of Ohm been earlier known, and their value recognized, the industry of experimentalists would have been better rewarded. In this country those who have had most experience in researches in which voltaic agency is concerned, have borne the strongest testimony to the assistance they have derived from this source, and to the invariable accuracy with which the observed phenomena have corresponded with the theory of Ohm. This accordance it may be observed is altogether independent of the particular hypothesis which may be adopted as to the origin of electromotive force; and obtains equally, whether that force is regarded as being derived from the contact of dissimilar metals, or as referable to chemical agency."

Ohm's book, "Die galvanische Kette," referred to in the above extract, was translated into English by Dr. William Francis, and published in 1841, in the second volume of "Taylor's Scientific Memoirs." The publication of Wheatstone's paper (read to the Royal Society, June 15, 1843), entitled "An Account of several New Instruments and Processes for determining the Constants of a Voltaic Circuit," also contributed in an important degree to attract attention to Ohm's work and to cause its importance to be recognized. We may call to mind also that it was in this country that the necessity of expressing electrical quantities in absolute measure first came to be generally recognized, and that the term "ohmad" or "ohm," suggested by Sir Charles Bright and Mr. Latimer Clark at the meeting of the British Association in Manchester, in 1861, first came into use as the name of a decimal multiple of the absolute unit of resistance convenient for practical purposes. Twenty years later, at the Congress of Electricians in Paris, in 1881, the "ohm" was unanimously adopted as an international standard. The name of the modest German Professor has thus come to be an understood term in the language of every civilized community in connection with the conception which he

was the first to define with perfect clearness, and to show the true bearing of in relation to the connected ideas of electromotive force and strength of current.

At the meeting on January 31, resolutions, moved by the President of the Royal Society and by Sir Frederick Abel, K.C.B., were adopted, expressing the concurrence of those present with the proposal to erect a statue to Ohm, and appointing a Committee to make the scheme known in this country and to collect subscriptions. Dr. Hugo Müller, F.R.S. (who, when a student at the University of Munich, was a pupil of Ohm's), was requested to act as Treasurer of the fund to be collected, and Profs. G. Carey Foster, F.R.S., and John Perry, F.R.S., were appointed Secretaries.

The following memoranda, taken from Lamont's *Denkrede* to the Munich Academy, 1855, may not be without interest at the present time:—Ohm was born in Erlangen, where his family had been settled for several generations. His father, who followed the hereditary trade of lock-smith, was a man of active intellect, and gained a very considerable acquaintance with mathematics and physics. It was in great measure owing to his example and encouragement that his two sons, George Simon and Martin (who afterwards attained great distinction as Professor of Mathematics in the University of Berlin), developed a love for similar studies. In 1805, G. S. Ohm became a student of the University of Erlangen, whither he returned in 1811, after some years spent as a private tutor in Switzerland, and then took his doctor's degree and established himself as *Privatdocent.* For a short time he was a teacher in the *Realschule* at Bamberg, and in 1817 obtained a more important post as teacher of mathematics in the Jesuits' Gymnasium at Cologne. It was while he held this appointment that his ideas as to the laws of the galvanic circuit took definite shape, and that his memorable book, "Die galvanische Kette mathematisch bearbeitet," was written. Soon after the publication of this book in 1827, Ohm presented himself at the Ministry of Education in Berlin, and there met with a reception so little appropriate to the whole-hearted and self-sacrificing devotion to science of which he was conscious, that he felt it impossible to remain any longer in the public service. He was thus driven to spend seven years in the prime of life in a state of deep mental dejection, and with very scanty means of subsistence. The end of this dismal period came in 1833, when he was appointed, by the Bavarian Government, Professor in the Polytechnic School at Nuremberg. The award of the Copley Medal, in 1841, already mentioned, cheered and encouraged him still further, and in grateful acknowledgment he dedicated to the Royal Society his "Molecular Physics." From this time he came to be recognized as one of the leading physicists of Germany, and "Ohm's law" soon found its way into every text-book of physics. In 1849, he was called to Munich as Curator of the Physical Cabinet, and in 1852 he became Professor of Experimental Physics in the University. On July 7, 1854, he died suddenly from apoplexy. For a great part of his life he had a hard fight with outward circumstances; but he seems to have remained throughout singularly simple-minded and unassuming, and at the same time thoroughly honest and conscientious in his work. G. C. F.

THE ROYAL SOCIETY OF EDINBURGH.[1]

At the commencement of the session 1883-84, the Royal Society of Edinburgh entered upon the second century of its existence. Since its foundation it has had among its members men whose fame is national and often world-wide—Joseph Black, Henry Dundas, James Hutton, John Playfair, Adam Smith, Dugald Stewart, Adam Fergusson, James Gregory, Henry Mackenzie, John Leslie, William Wallace, Walter Scott, Maclaurin, Brewster, Forbes, and more recently Clerk Maxwell; and at present it has members whose names will rank as high as these. In the year 1886 the membership of the Society was 507, and was rapidly increasing. The number of papers communicated to it in the period 1883-87 was 317. We shall therefore select for special notice a few of these, which may be taken as typical of the work done by the Society; and it will be seen that its work, if large in quantity, is also high in quality. We agree with the opinion expressed to the Society by the Chairman in his opening address in December 1886, that, "if we include the extra volumes on the Ben Nevis observations, and on the botany of Socotra, . . . the Proceedings and Transactions of the Society during the past three years probably surpass in bulk and importance those of any other Society in the United Kingdom for the same period."

In the department of mathematics, these volumes include valuable contributions to the science of situation, or of those space-relations which are independent of *measure* though not necessarily of *number*, from the Rev. T. P. Kirkman and Prof. Tait. The former writer contributes papers "On the Enumeration, Description, and Construction of Knots of fewer than Ten Crossings," and "On the 364 Unifilar Knots of Ten Crossings;" a note "On the Twists of Listing and Tait," and "Examples upon the reading of a Circle or Circles of a Knot." Prof. Tait gives a "Census of 8-fold and 9-fold Knottiness," and a "Census of 10-fold Knottiness," with a special treatment of amphicheirals. There is also a paper, "Ueber algebraische Knoten," by Prof. Fr. Meyer, of Tübingen.

Dr. Thomas Muir treats of subjects connected with the theory of continued fractions and with the theory of determinants. Dr. Muir constantly aims at the attainment of simplicity through great generalization. An example of this is given in his paper "On the Researches of M. de Jonquières on Periodic Continued Fractions." He points out that many of the theorems given by M. de Jonquières are not new, and that the earlier ones are all special cases of a more general theorem previously published by Dr. Muir himself. He then proceeds to use this general theorem for the purpose of giving unity to M. de Jonquière's work.

Among other papers we note, "The Expansion of Functions in terms of Linear, Cylindric, Spherical, and Allied Functions," by Mr. P. Alexander; a quaternion investigation by Dr. G. Plarr of "The curve on one of the co-ordinate planes which forms the outer limit of the position of the point of contact of an ellipsoid which always touches the three planes of reference;" and a note "On the Hessian," by Prof. Chrystal. M. Hermite contributes a paper "Sur la Réduction des Intégrales Hyperelliptiques," and Prof. L. Cremona gives an "Esempio del metodo di dédurre una superficie da una figura piana."

In a remarkable paper "On the Law of Inertia; the Principle of Chronometry; and the Principle of Absolute Clinural Rest, and of Absolute Rotation," Prof. James Thomson treats of questions on the border-ground between pure mathematics and physics. He discusses "such motions of points in unmarked space, as can have a reference frame relatively to which these motions are rectilinear and are changeless in mutual rate." The problem of finding a reference frame for a known set of such points is worked out in another paper by the same author by a method of mechanical adaptations, and Prof. Tait has given a quaternion solution of it. Prof. Thomson's law of inertia is the equivalent of Newton's first and second laws of motion. The paper is one which merits the perusal of all students of dynamics, and it may be specially recommended for study to certain classes of metaphysicians.

[1] Proceedings, Sessions 1883-87. Transactions, Vol. xxx. Part 4; Vol. xxxii. Parts 2, 3, 4; Vol. xxxiii. Parts 1, 2.

The fact that, in the kinetic theory of gases, Boltzmann's extension of Clerk Maxwell's theorem regarding the distribution of energy in a system of colliding spheres has led to results which are inconsistent with either the observed value of the ratio of the specific heats of a gas, or the complexity of the radiation spectra of gases, has induced Prof. Tait to investigate the question afresh from the very commencement. His results are contained in papers "On the Foundations of the Kinetic Theory of Gases," published in the Transactions. His great aim is the simplification of the mathematical treatment of the subject, and he has "purposely gone into very minute detail in order that no step taken, however slight, might have the chance of escaping criticism, or might have the appearance of an attempt to gloss over a difficulty." Abstracts of the papers have appeared in the *Philosophical Magazine*. The subjects treated in the first two papers are as follows: one set of equal spheres; mean free path among equal spheres; number of collisions per particle per second; Clerk Maxwell's theorem; rate of equalization of average energy per particle in two mixed systems; mean path in a mixture of two systems; pressure in a system of colliding particles; effect of external potential; pressure in a mixture of two sets of spheres; viscosity; thermal conductivity; diffusion. On the suggestion of Prof. Tait, Prof. W. Burnside applied a method used by the former in his first paper to the problem—Given a very great number of smooth elastic spheres, equal and like in all respects, whose centres of figure and centres of inertia do not coincide, and the sum of whose volumes is but a small fraction of the space in which they move, it is required to find the ultimate distribution of energy among the various degrees of freedom when by collisions the system has attained a "special state." Prof. Burnside's result is given in a paper "On the Partition of Energy between the Translatory and Rotational Motions of a Set of Non-Homogeneous Elastic Spheres." The various steps of the investigation are given in detail, and the assumptions are clearly specified. The conclusion is that the average energies of rotation of a sphere about each of the three principal axes are equal, and the whole average energy of rotation of a sphere is twice the average energy of translation.

Sir W. Thomson communicated sixteen papers to the Royal Society during the period under consideration. These include a remarkable series of investigations of various cases of fluid motion. Most of the papers have already appeared in the *Philosophical Magazine* or elsewhere; only four are given in detail in the Proceedings. These are "On a New Form of Portable Spring Balance for the Measurement of Terrestrial Gravity," "On the Front and Rear of a Free Procession of Waves in Deep Water," "On the Equilibrum of a Gas under its own Gravitation only," and "On Stability of Fluid Motion: Rectilinear Motion of Viscous Fluid between two Parallel Planes." From results obtained in the latter paper, Sir William considers it probable "that the steady motion is stable for any viscosity, however small; and that the practical unsteadiness pointed out by Stokes forty years ago, and so admirably investigated experimentally five or six years ago by Osborne Reynolds, is to be explained by limits of stability becoming narrower and narrower the smaller is the viscosity."

The following extract will give an idea of the scope of a paper by Lord Rayleigh, "On the Colours of Thin Plates":—"The theory set forth so completely in our treatises tells us indeed how the composition of the light reflected depends upon the thickness of the plate, but what will be its colour cannot, in most cases, be foretold without information of an entirely different kind, dealing with the chromatic relations of the spectral colours themselves. This part of the subject belongs to physiological optics, as depending upon the special properties of the eye. The first attempt to deal with it is due to Newton, who invented the chromatic diagram, but his representation of the spectrum is arbitrary, and but a rough approximation to the truth. It is to Maxwell that we owe the first systematic examination of the chromatic relations of the spectrum, and his results give the means of predicting the colour of any mixed light of known composition. Almost from the time of first reading Maxwell's splendid memoir, I have had the wish to undertake the task of calculation from his data the entire series of colours of thin plates, and of exhibiting them on Newton's diagram. The results are here presented, and it is hoped may interest many who feel the fascination of the subject, and will be pleased to see a more complete theory of this celebrated series of colours."

A little note by the (then) Astronomer-Royal for Scotland on Brewster's line Y in the infra-red of the solar spectrum is illustrated by an exceedingly instructive plate. The line Y is one of three discovered by Brewster in a portion of the spectrum usually invisible. As the Astronomer-Royal well remarks, "It was Brewster's eye that looked; so no wonder that he saw with it more than any of his predecessors, and most of his successors as well." Prof. Smyth proves that Y is a true solar line, being more distinct with a high than with a low sun. In the Royal (London) Society's publications the opposite had been asserted; and ultimately, though perhaps unintentionally, the line was altogether omitted from the spectrum—or, rather, it was misnamed Z. It is to be hoped that Prof. Smyth's paper will have the effect of removing all the ambiguity, and the consequent confusion, on this point. In this note, short as it is, we have evidence of the unlooked-for rewards which often await the scientific observer. While seeking for direct confirmation of M. Henri Becquerel's discovery that the line Y is due to sodium, Prof. Smyth discovered three new air-lines much farther in the infra-red than any previously discovered.

Prof. Piazzi-Smyth has also a paper on "Micrometrical Measures of Gaseous Spectra under High Dispersion." The paper is accompanied by maps of the spectra investigated on the scale of 40 feet to the visible spectrum. The prism arrangement gave a dispersion of 60° from A to H, and the magnifying powers of the telescope varied from 12 to 36 with a further magnifying power of 5 in the recording apparatus. There was thus in effect a possible dispersion of 9000°. The gases dealt with are CH, CO, H, O, and N. The peculiar arrangement of the leading lines (usually two) and train of linelets in each of the five bands of the CH spectrum is fully shown in the diagram and described in the text. The low-temperature (simple spark) spectrum of hydrogen is given, over 1600 lines being recorded. Prof. Smyth has found that three of the four principal oxygen lines are triple, and he has discovered three other such triplets. The remarkably methodical spacing of the lines in these triplets and of the triplets themselves is noted; but a more striking example of regular spacing is furnished by the lines in the green CO band. The map of this band is given on the scale of 120 feet to the visible spectrum. Prof. A. S. Herschel has made out two series of lines (single and double respectively) following the same law of arithmetical progression. The full interpretation of such "natural writing" may possibly never be obtained until we know the nature of molecules and atoms; but, on the other hand, a further investigation of spectra such as we have here may throw some light on molecular and atomic structure. So magnificent are the maps that accompany Prof. Smyth's paper, that one is rather inclined to speak of his contribution to the Transactions as a series of maps of spectra with explanatory text. But besides explanations the paper contains a full record of the experiments, and also tells a tale of high war—the combatants being the author on the one hand, and the London Royal Society, the London Royal Astronomical Society, *et hoc genus omne*, on the other. Vacuum-tubes containing nominally CO, but also

showing exceptionally strong CH bands, were "by a London maker." Prof. Smyth once admitted (though with great reserve), with "the English spectroscopists," that the CO spectrum might be that of pure carbon; he "begs now to apologize for that error;" and, long after he has come off victorious throughout the whole line, the rumble of distant thunder is heard in his "concluding notes."

Mr. John Aitken's investigations regarding the formation of small clear spaces in dusty air are already known to the scientific public, from the abstract published in NATURE, vol. xxix. p. 322 (January 1884). His paper on dew, a short abstract of which appeared in NATURE, vol. xxxiii. p. 256 (January 1886), is also contained in the Transactions. Some observations in addition to those indicated in NATURE are described. These refer to evaporation from extremely dry soils in Britain and France, and also, on the evidence of travellers, in Australia and South Africa. Additional evidence regarding the formation of the dewdrop is also given.

Mr. A. Crichton Mitchell has repeated Forbes's and Tait's experiments on the thermal conductivity of iron, copper, and German silver. His observations were conducted under improved experimental conditions, and the methods of calculation were different in some respects. These differences are pointed out and explained by Prof. Tait in an introduction to Mr. Mitchell's paper. On the whole, Mr. Mitchell's work confirms that of previous experimenters. One of the most important of his conclusions is that iron forms no exception to the rule that the thermal conductivity of ordinary metals increases with rise of temperature.

Prof. C. G. Knott, of Tokio University, Japan, gives a full experimental investigation of the thermo-electric peculiarities and the electrical resistance of hydrogenized palladium. In another paper he treats of the electrical resistance of nickel at high temperatures, and concludes from his results that "there is a strong presumption that the Thomson effect in metals has a close connection with the mutual relations of resistance and temperature."

From a series of observations made in atmospheric electricity at the top of Dodabetta, the highest hill in the Neilgherries, Prof. C. Michie Smith is led to the conclusion that on the edge of a dissolving mist the potential is lower than the normal, while in a condensing mist it is higher than the normal. He says: "If my results are confirmed by more extended observations, strong support will be given to the theory which looks on the condensation of a number of slightly charged particles into larger drops as the cause of the high potential indicated by disruptive discharges." In connection with this, results obtained by Mr. H. N. Dickson regarding the direction of earth-currents at Ben Nevis are worthy of note. When mist descends on the mountain, or rain (or snow) falls, a down current is observed in the telegraph cable when put to earth at both ends; but when the mist rises from the mountain-top the direction of the earth-current is upwards.

Von Helmholtz contributes an account of galvanic currents passing through a very thin stratum of an electrolyte.

Many of the facts brought out in a series of papers by Dr. H. R. Mill and others on various physical and chemical conditions of tidal estuaries should be of much use because of their evident bearing on the distribution of various forms of animal life, and on questions connected with meteorology.

A number of years ago Prof. Tait undertook the work of determining the pressure-errors of the *Challenger* thermometers. This investigtion gave rise to many others: such as the lowering of the maximum density-point of water by pressure; the variation of the compressibility of water with temperature, pressure, and amount of salt dissolved; and the question of the internal pressure in water. The various results obtained by Prof. Tait are contained in a series of notes scattered throughout the Proceedings.

The complete series of observations made at the Ben Nevis Observatory have been handed over to the Royal Society of Edinburgh for publication; and, from time to time, valuable meteorological information in connection with the Observatory is communicated to the Society and appears in their Proceedings. Dr. Murray remarks that "the refusal of assistance (to the Observatory) by the London Committees may be partly due to the fact that there are many claims on the funds which they administer, but it appears also to be very largely due to a want of proper knowledge of what has been done, and what may be reasonably expected to be done, by the Observatory, there being no Observatory in these islands that can compete with the Ben Nevis Observatory for the accuracy and intrinsic value of the hourly observations; and absolutely no pair of stations anywhere in the world that can be named alongside the Observatory and the station at Fort William as contributing data in furtherance of our knowledge of storms and the science of weather generally."

These volumes contain two or three papers in the department of engineering. Mr. A. C. Elliot gives a new formula for the pressure of earth against a retaining wall, which is an improvement on Rankine's formula. In a paper on "Cases of Instability in Open Structures," Dr. E. Sang discusses a class of theorems of which one previously enunciated by him—to the effect that any symmetric structure built on a rectangular basis, having no redundant parts, and depending on longitudinal strain alone, is necessarily unstable—was a particular example.

In the department of chemistry we note an elaborate paper by Prof. Dittmar and Mr. John McArthur, entitled "Critical Experiments on the Chloro-platinate Method for the Determination of Potassium, Rubidium, and Ammonium; and a Redetermination of the Atomic Weight of Platinum." The paper consists of five parts—two detailing experiments on the composition of chloro-platinate of potassium, a part on Finkener's and Tatlock's methods of potash determination, a part descriptive of experiments on chloro-platinate of rubidium, and another describing experiments on chloro-platinate of ammonium. The authors conclude that the atomic weight of platinum is very nearly 195·5.

Prof. Dittmar also gives, in conjuction with Mr. C. A. Fawsitt, a "Contribution to our Knowledge of the Physical Properties of Methyl-alcohol." The "vapour-tension" (why not *pressure* since it *is* pressure?) is investigated under varying conditions, and the specific gravity of aqueous methyl-alcohol for all the integral percentages is also tabulated at 0° C. and 15°·56 C.

Dr. John Waddell has determined the atomic weight of tungsten by an entirely new method, and has obtained results confirmatory of the commonly accepted value.

Comparatively few papers dealing with botanical questions were communicated to the Society during the period under consideration. A note "On the Structure of the Pitcher in the Seedling of *Nepenthes*, as compared with that in the Adult Plant," in which the late Prof. Alexander Dickson first called attention to the peculiar large marginal glands of *Nepenthes*, is of much interest. The Proceedings contain the fourth part of "Diagnoses Plantarum Novarum Phanerogamarum Socotrensium, &c.," by Prof. Bayley Balfour, and a note "On Degenerated Specimens of *Tulipa sylvestris*, by Mrs. A. B. Griffiths. Mr. John Rattray contributes a note on the marine plant *Ectocarpus*.

The number of papers in zoology and allied sciences is somewhat large.

In the summer of 1868, H.M.S. *Lightning* explored the region of the North Atlantic lying between the Hebrides and the Faroes. In 1869 H.M.S. *Porcupine* made three

cruises, the first off the north-west and the west coasts of Ireland, the second off the south and south-west coasts of Ireland, and the third off the north of Scotland as far as the Faroes. In 1870, the *Porcupine* dredged down the west coasts of France and Spain and in the neighbourhood of Gibraltar Strait, and explored the African coast of the Mediterranean as far east as Sicily. Prof. W. A. Herdman contributes to the Transactions the Report upon the *Tunicata* dredged during the cruises of H.M.SS. *Porcupine* and *Lightning* in the summers of 1868, 1869, and 1870. The Simple Ascidians alone are treated of. The Report on the *Pennatulidæ* dredged by the *Porcupine*, is by Prof. Milnes Marshall and Dr. G. H. Fowler. One new genus and one new variety were obtained. Dr. P. H. Carpenter writes "On the *Crinoidea* of the North Atlantic between Gibraltar and the Faroe Islands," and some notes are added by Prof. L. von Graff on the *Myzostomida*. The Report on the *Ophiuroidea* of the Faroe Channel, mainly collected by H.M.S. *Triton* in 1882, is drawn up by Mr. W. E. Hoyle. Mr. Hoyle also gives the second part (on the *Decapoda*) of a preliminary Report on the Cephalopoda collected by H.M.S. *Challenger*.

Mr. J. T. Cunningham (then of the Scottish Marine Station) writes on the "Eggs and Larvæ of Teleosteans;" on the "Reproductive Organs of *Bdellostoma*, and a Teleostean Ovum from the West Coast of Africa;" on *Stichocotyle nephropis*, a new Trematode, found as a parasite in the Norway lobster; and, along with Mr. Rupert Vallentin, on the "Luminous Organs of *Nyctiphanes norvegica*." Mr. George Brook discusses "The Formation of the Germinal Layers in Teleostei." Mr. Harvey Gibson gives a detailed account of the anatomy of *Patella vulgata*, no systematic account having been previously given, though separate accounts of various organs have appeared. Mr. Frank E. Beddard writes "On the Minute Structure of the Eye in certain *Cymothoidæ*;" "On the Structural Characters of certain new or little known Earthworms," five apparently new species and possibly a new genus being described; and "On the Reproductive Organs of the Genus *Eudrilus*." Mr. J. Arthur Thomson describes the structure of *Suberites domuncula*, a sponge found covering the outside of a sea-snail shell inhabited by a hermit-crab.

In geology some important papers appear. Dr. Traquair contributes the first part of a Report on fossil fishes collected in Eskdale and Liddesdale (*Ganoidei*). Mr. R. Kidston gives the first two parts of an account of the fossil flora of the Radstock series of the Somerset and Bristol coal-field (Upper Coal Measures). A note is appended on the fossil flora of the Farrington, New Rock, and Vobster series, and a table is given comparing the flora of the Radstock series with that of other coal-fields. Mr. Kidston also discusses the fructification of some ferns from the Carboniferous formation. Prof. Geikie writes on the geology and petrology of St. Abb's Head. The final Report of the Boulder Committee of the Society is contained in the Proceedings.

The plates in Vol. xxx. accompanying a paper by Dr. Traquair on fossil fishes are of great artistic merit. Indeed, the illustrations which are contained in the Proceedings and Transactions are probably unsurpassed by those published by any other similar Society.

Observations by Dr. H. B. Guppy, of H.M.S. *Lark*, on coral reefs and calcareous formations of the Solomon Group, appear in both publications. He is led to the conclusions: (1) that these upraised reef-masses, whether atoll, barrier-reef, or fringing-reef, were formed in a region of elevation; (2) that such upraised reefs are of moderate thickness, their virtual measurement not exceeding the limit of the depth of the reef-coral zone; (3) that these upraised reef-masses in the majority of islands rest on a partially consolidated deposit which possesses characters of the "volcanic muds" which were found during the *Challenger* expedition, to be at present forming around volcanic islands; (4) that this deposit envelops anciently submerged volcanic peaks. The bearing of the two latter conclusions on Dr. Murray's theory of the formation of coral islands is important.

We conclude with another quotation from the address already referred to:—"With respect to Scotland, the only grant for scientific purposes in aid of learned Societies is £300 annually to the Royal Society of Edinburgh, which is repaid to a department of the Government in the form of rent. One might well ask what Scotland had done that her learned Societies and scientific men should be treated so niggardly as compared with those in England and Ireland. It cannot be because she does no scientific work. It is sometimes said, indeed, that in literary matters Scotland, and especially Edinburgh, is a mere shadow of her former self; but in science this is not the case, and it is towards scientific matters that the great ploughshare of human thought and activity is, in this age, directed. I question if any country in the world, taking into consideration its size, can show a better record of scientific work, or a more excellent volume of scientific literature than Scotland, during the past ten or twenty years."

TIME.

TIME is one of the very numerous subjects which seem to be perfectly simple until we begin to think about them; then difficulties crop up in all directions, and afford a favourite battle-ground to philosophers.

Newton, avoiding metaphysical difficulties, gave an account of time which suffices for all the purposes of the mathematician and experimentalist. "Absolute, true, and mathematical time of itself and from its own nature flows equably and without regard to anything external, and, by another name, is called duration; relative, apparent, and common time is some sensible and external measure of duration by means of motion."

The word time is here used to express two distinct ideas, for the former of which it would be better to reserve the term duration. This double meaning of the word has caused much controversy between idealists and materialists, which is still far from arriving at any definite result. Thus, Whewell writes ("Hist. Ind. Sci.," 131):—"Time is not a notion obtained by experience." "Time is a necessary condition in the presentation of all occurrences to our minds. We cannot conceive this condition to be taken away. We can conceive time to go on while nothing happens in it, but we cannot conceive anything to happen while time does not go on."

It has always seemed to me that philosophers are rather hard on the intellect of their fellow-mortals in laying down so absolutely, as they are fond of doing, what can and what cannot be conceived by the mind, when they are in reality arguing from a single instance—their own. Many persons would be tempted to say that the idea of the fourth dimension of space is inconceivable, did not men of more powerful intellect assure them that their crude ideas on the subject are quite erroneous. I can myself find no impossibility in the conception of a universe composed of a homogeneous mixture of gases, to which the ordinary conception of time does not apply. If I err, I I at least do so in good company. Lucretius writes (i. 460):—

> "Tempus item per se non est, sed rebus ab ipsis
> Consequitur sensus."

And, in 1690, Locke gave the following luminous exposition of this difficult matter ("Hum. Und.," xiv.):—"A man having, from reflection on the succession and number of his own thoughts, got the notion or idea of duration, he can apply that notion to things which exist while

he does not think; as he that has got the idea of extension from bodies by his sight or touch can apply it to distances where no body is seen or felt." "Thus, a man when he is asleep, or when his mind is entirely occupied by one subject, has no notion of the passage of time." "This consideration of duration, as set out by certain periods and marked by certain measures or epochs, is that, I think, which most properly we call time."

According to Locke, then, duration is measured out, as it were, into time by changes, and as these changes are, so far as we know, due to motion, the ideas of time and motion are closely connected. These views have been further developed by Herbert Spencer ("First Principles," 163, 167, 171):—"The relation of sequence is given in every change of consciousness." "The abstract of all sequences is time. The abstract of all co-existences is space." "The conception of motion, as presented or represented in the developed consciousness, involves the conception of space, of time, of matter—a something that moves; a series of positions occupied in succession; and a group of co-existent positions united in thought with the successive ones." "These modes of cohesion, under which manifestations are invariably presented, and therefore invariably represented, we call, when contemplated apart, space and time; and when contemplated along with the manifestations themselves, matter and motion."

The abstract idea of duration without beginning or end is of the greatest value to the mathematician, but, so far as we know, it has no representative in Nature. It would, of course, be measured out by the equal spaces passed over by a body moving under the action of no forces, but no known body is in such a condition. As possible instruments for the accurate measurement of time, Thomson and Tait suggest a spring vibrating *in vacuo*, and Clerk Maxwell the period of vibration of light-waves of definite length. From this conception of duration or equable flow, Newton deduced his method of fluxions, which, owing to his delay in publishing the method, occasioned the lamentable controversy as to priority with Leibnitz. Though the manuscript of Newton's first paper on fluxions has been found with the date May 20, 1665, it was only communicated in a letter to Collins in 1672, used in some papers on motion read before the Royal Society in 1683, and printed in 1684. The method was first definitely published to the world in the "Principia," in 1687. According to Maclaurin: "In the doctrine of fluxions, magnitudes are conceived to be generated by motion, and the velocity of the generating motion is the fluxion of the magnitude." Suppose a movable point, starting from a fixed point, A, describes a line A B, of length x, Newton represented by $\dot{x}$ the velocity with which the line is described. Again, the velocity itself may not remain constant, but either increase, as when a stone falls, or decrease, as when a shot is fired. This change of velocity, now called acceleration, was expressed by $\ddot{x}$.

The conception of velocity is passing over a certain space in a certain time, as a mile in a minute or 88 feet in a second, and we may conceive both space and time to become infinitesimally small, so that the ratio of the one to the other becomes a fluxion. Acceleration is measured by the number of units of velocity gained or lost in the unit of time; thus, the acceleration due to gravity is a velocity of 32 feet per second gained or lost in a second.

The discussion of the connection between this conception of fluxions and the various methods of conceiving space as made up of infinitesimal portions, which were used more or less imperfectly by various mathematicians, until they were generalized and systematized by Leibnitz into the differential calculus (1675), would occupy too much space. A fluxion or differential, as was clearly pointed out by Newton, depends upon the philosophical conception of a limit, the foundation of so many of the higher branches of mathematics.

Important as are these theoretical questions deduced from the idea of duration, the practical questions of time and the means of measuring it with accuracy are far more so.

Since astronomers have been unable to find any truly equable motion by which to measure equal intervals of time, they make use of a fictitious sun, which apparently moves round the earth in the same period as the real sun does, alternately before and after it, but coinciding with it four times in the year—on April 15, June 14, August 31, and December 24.

The interval between two apparent passages of the fictitious sun over the meridian is a mean solar day, which is divided into 24 hours, 1440 minutes, or 86,400 seconds. The length of the tropical year, or the interval before the return of the sun to the same equinox, is 365·2422 mean solar days.

In the observatory, astronomers use as their unit the sidereal day, or the interval between two appearances of the same star on the meridian; owing to the apparent motion of the sun, there are 366·2422 sidereal days in the tropical year, or a mean solar day is equal to 1·0027379 sidereal days. About March 22 of each year, sidereal 0 hour coincides with mean noon, and for each day from that date the difference increases by 3 minutes 56 seconds. For purposes of calculation, astronomers make use of "the Julian period" of 7980 tropical years, of which 1889 is the 6602nd; and at mean noon on January 1, 2,411,004 mean solar days of the period had elapsed.

The oldest time-measurer, the sun-dial, dates from, at all events, 700 B.C. In its most simple form it consists of a style fixed parallel to the axis of the earth, and a graduated circle upon which the shadow falls. The clepsydra, or water-clock, in which time is measured by the equable flow of water, was introduced into Rome about 150 B.C.; and various methods of indicating the quantity of water which had flowed out by bells, hands, figures, &c., were subsequently added. A simple form of the instrument is still used in physical laboratories for measuring intervals of a few seconds. The replacement of water by sand furnished the hour-glass used by our ancestors for measuring out the eloquence of their preachers, as their more feeble descendants now use the three-minute glass for measuring the boiling of their eggs. A transit-instrument affords a ready means of correcting a clock; and mean-time signals are now sent from Greenwich to many places in England; hence in practice we individually measure only comparatively short intervals of time, correcting our private clocks and watches by public clocks regulated by time-signals.

Of all measures, those of time are most frequently and most accurately made. Public clocks are far more numerous than public standards of length or mass, and in 1880 the value of the clocks and watches imported amounted to £880,000. Few persons carry a foot-rule costing say 1*s*., but many a watch costing more than £2. Even among engineers but little attention is paid to lengths less than 1/64 of an inch; and few common balances indicate a difference of 1/100 of the load. But, according to Mr. Rigg (Cantor Lectures on Watch-making, 1881), a watch that does not vary more than half a second per diem, or 1/172800, is frequently met with, while an accuracy of two or three minutes per week, 3/10000, is attained even by cheap articles. It is no uncommon occurrence to meet with a chronometer which does not vary one-fifth of a second in twenty-four hours, or by about 1/432000 of the time measured out.

Almost all modern instruments for measuring time consist of three essential parts: (1) a motive-power, such as a falling weight, an uncoiling spring, an electric current; (2) a regulator, to render the motion steady, such as a pendulum, a balance-wheel, or a magnet; (3) some means

of indicating the space passed over, such as hands, bells, or marks on paper.

About the eleventh century the motive-power of a stream of water or sand was replaced by a falling weight; and in the early part of the sixteenth century, Peter Hele, of Nürnberg, substituted a coiled-up spring for the weight. As is often noticed when a foreign clock is wound up, the motive-power of such a spring varies very much as it uncoils. This difficulty was overcome in 1525 by the invention of the fusee, the increased leverage of which compensates for the decreased power of the partly uncoiled spring. In modern going-barrel watches reliance is placed on the careful adjustment of the regulating machinery; while in chronometers a very long spring is wound up so frequently that it never uncoils beyond a very small extent. In 1840, Wheatstone proposed a method of conveying the motion of a standard clock to several others by a current of electricity, and the electric current has since been used both as a motive power and as a regulator.

But little is known about the early methods of regulating clocks and watches, but, according to Shakespeare, the result does not seem to have been satisfactory, though some may consider his testimony invalidated by the accompanying libel ("Love's Labour Lost," iii. 1, 191). Biron speaks:

> "What I, I love, I sue, I seek a wife!
> A woman, that is like a German clock,
> Still a-repairing, ever out of frame,
> And never going aright, being a watch,
> But being watched, that it may still go right."

The use of clocks in observatories (1500), and for finding longitudes at sea (1530), caused a demand for better instruments which was only slowly met.

Galileo is said to have discovered the isochronism of the pendulum before about 1590, by observing a lamp swinging in the Cathedral at Pisa, but the discovery, though used by him, was not published until 1639, and it is doubtful if he applied it to clocks. In 1673, Huyghens proved the isochronism of the cycloidal pendulum, and showed that a pendulum could be caused to vibrate in a cycloid by making the upper portion of the suspending arrangement of steel springs or silk fibres, which wrap round cycloidal cheeks. The cycloidal cheeks are not found to answer in practice, but many makers use one or two parallel steel springs, which causes the bob to describe a curve which falls within the circle, and adds a positive and negative accelerating force at the commencement and end of each swing.

The time, t, of one swing of a simple circular pendulum of length l, at a place where the acceleration due to gravity is g, is—

$$t=\pi\left\{1+\left(\frac{1}{2}\right)^2\frac{\text{vers }\theta}{2}+\left(\frac{1\cdot 3}{2\cdot 4}\right)^2\left(\frac{\text{vers }\theta}{2}\right)^2+\&\text{c.}\right\}\sqrt{\frac{l}{g}};$$

where θ is half the angle through which the swing passes. When θ is very small, vers θ vanishes, and the swing is isochronous. If $\theta = 2°$, the error is about 1/13333, or two seconds in three days. If $\theta = 8°$, vers $\theta = 0\cdot 00973$, and the second and third terms become 0·00122 and 0·000003 respectively, or the time of oscillation is about 1/833 longer than it would be if the arc were indefinitely small.

Increase of temperature causes l to become longer, and therefore the clock to go more slowly. This cause of error is minimized by making the rod of some substance, such as varnished pine, which expands but little, or compensated for by some device, such as Graham's mercurial pendulum (1722), Harrison's gridiron pendulum (1725), or Baily's astronomical pendulum, in which expansion away from the axis of suspension is neutralized by an equal expansion towards it, so that the effective length of the pendulum remains unaltered.

The spring balance-wheel, which consists essentially of a heavy horizontal wheel, to which an oscillating motion is given by a long fine hair-spring, was invented by Hooke in 1660, and perfected by Huyghens in 1674. The difficulty of expansion is got over by dividing the wheel into two semicircles, each attached by one end only to the diameter, and made of two strips of metal of different coefficients of expansion, so that each curves inwards to compensate for the expansion of the radius which carries it.

Extremely short intervals of time have to be accurately measured in various scientific and practical researches, such as those connected with the science of astronomy and the art of gunnery. Many forms of the chronograph used for this purpose are extremely complicated, but the principle on which they all act is simple. A cylinder covered with paper is driven round by clockwork, at the rate, say, of a turn per minute, and a point connected with a pendulum beating half-seconds divides the circumference into 120 equal spaces. Suppose that by pressing a key an electric current causes a pen to press against the paper. So long as the key is down a line is traced, and the length of it, measured by the half-second pricks, determines how long the key has been down. Usually the cylinder is also caused to move along its axis, so as to throw the two circles of pricks and lines into spirals. It is said that 1/1000 of a second can be estimated by this method.

The need of accurate measures of time has had great effect upon, if it did not absolutely originate, the science of astronomy, and in many of the most important physical laws time is either directly or indirectly a most important factor. Thus, Sir William Thomson has found that, by a long-continued stress, the elastic resilience of a body may diminish, and has proposed for this curious fact the name of elastic fatigue; Harcourt and Esson and other chemists have investigated the circumstances which cause the rate at which certain chemical changes take place to vary; Berthelot and Dixon have measured the velocity of propagation of explosion waves; the time taken for sensation to pass through nerve-fibre and for other physiological phenomena has been carefully studied.

In 1830, Lyell, following up the work of Smith, Hutton, Murchison, and Sedgwick, showed that the history of the earth is continuous, and was governed by the same laws in the past as it is now, and hence that the rates at which changes are now going on are measures of the rates at which they have gone on in the past. Great doubt was thus thrown on the current view that the world has only existed for about 6000 years. For suppose chalk is now being formed at the bottom of the Atlantic at the rate of one-fifth of an inch per annum, and that the chalk formations in England, which are known to be more than 3500 feet thick, were formed in the same way at about the same rate; the time required for the mere formation of this series of beds would be, not 6000 years, but more nearly 3500 × 12 × 5, or 210,000 years! And we must reckon, in addition, the time required to form all the other beds below and above the chalk and to bring them all into their present positions and conditions.

Advanced geologists, then, convinced by the arguments of Lyell, postulated a world history of many millions of years, but their results were ignored or ridiculed by those who had not taken the trouble to investigate the proofs upon which the theory rested. In 1859, the publication of the "Origin of Species" brought this, among many other questions, prominently before the public. The admirable style and careful manner in which facts and theories, old and original, were shown by Darwin to point to the great law of evolution as opposed to the theory of special creations, threw what were previously the arcana of science open to all, and caused the acrimonious discussion of the duration, not only of each living or extinct type, but of the world itself. The fiercest

conflict raged about the age of man, and evidence was gradually accumulated, which proved that for many thousand years the human type has been practically the same as it now is: the question then forced itself forward, How long would it take a simple cell to develop through various forms to the anthropoid apes and man? The answer was given in figures higher even than those required by the geologist.

On the other hand, the question of the possible age of the world in its present condition has been attacked by Sir William Thomson from the side of mathematical physics, and his results have been recalculated and extended by Profs. Tait and Darwin. Arguments based upon (1) the internal heat of the earth, (2) the retardation of the rotation of the earth due to tidal friction, (3) the temperature of the sun, seem to show that the earth has not continued under present conditions for more than from ten to a hundred millions of years; while the theory of evolution probably requires at least three hundred millions of years for even a comparatively brief portion of geological history. The two results, each supported by strong evidence, are at present in contradiction to each other.

Political economists have for some years past been gradually realizing the immense importance of time in all their theories and calculations. The various causes which accelerate and retard the rate of growth are most important questions, not only for agriculturists, but for the whole population, who are dependent for their subsistence upon the reproduction of plants and animals. As Malthus pointed out in 1798, the population of a civilized country increases in geometrical ratio, while the food-supply can only be increased by importation, by taking inferior land into cultivation, or by improved methods of production. The gradual advance of civilization tends to quicken the rate of increase of population, while it decreases the three palliatives; hence, at some time, a limit must be reached at which population will increase faster than the means of subsistence. The results of this condition of affairs have been most ably discussed by Mill, and will possibly, before long, be exemplified in England.

To an individual, all duration beyond comparatively few years is of no importance, but, to a country or corporation, the difference between a hundred years and perpetuity may be very great. Two instances of this distinction have recently caused some discussion. The services of a general or lawyer may be amply rewarded by the grant of an annuity for a hundred years or for three lives; while the burden of a "perpetual pension" is felt long after the services for which it is granted are forgotten, and too often after all who have any real claim upon, or connection with, the original recipient have passed away.

The old fiction of English law, that all the land of the country belongs to the Government, and that the holders of the land are in reality not owners, but tenants, has recently been brought into prominence by Mr. George and his followers. The tenure of land varies almost infinitely in different countries, and even in diffent parts of the same country, but two simple examples may serve to render the point at issue clear. In the United States the land in the Territories, speaking generally, belongs to the Government, and has been, and to some extent is being, sold to capitalists in large lots at "prairie value."

Suppose 1000 acres worth £1 an acre are sold outright, they would fetch £1000, but the present value of a lease for a hundred years, interest being reckoned at 4 per cent., is £980. So far as the capitalist is concerned, for all practical purposes, the land is as much his own in the second case as in the first, since any change would take place in the time of a descendant whom he has never seen, and a fair compensation might be arranged for any unexhausted improvements. But, from the point of view of the Government, the case is very different: they would receive for the lease only £20 less than the selling price, and at the end of the century the land, with its "unearned increment," would revert to them in the same or better condition than it originally was, with the exception of minerals, for which special arrangements by royalty or otherwise must be made, and the conditions of the tenancy could then be altered to meet any change of circumstances. Where, as is generally the case in England, the land has long ago passed out of the possession of the community, considerations of public faith rightly overpower all considerations of expediency, but even in this case the absolute sale of "Crown lands" or "commons" seems to be suicidal. That things are not perfect is no reason for making them worse.

SYDNEY LUPTON.

NOTES.

WE print to-day an article on the proposal that English men of science and others should co-operate in the movement for the erection of a statue of Ohm in Munich. The Committee appointed by the meeting at the Royal Society to make the scheme known in England, and to collect subscriptions, consists of the following members:—Sir F. Abel, Prof. D. Atkinson, Mr. Vernon Boys, Mr. Conrad Cooke, Profs. Ewing, Fitzgerald, Fleming, G. Carey Foster, Mr. Glazebrook, Prof. D. E. Hughes, Mr. Norman Lockyer, Dr. Hugo Müller, Prof. John Perry, Mr. W. H. Preece, Lord Rayleigh, Profs. Reinold, Rücker, Stokes (President of the Royal Society), Mr. Swinburne, Sir William Thomson, and Prof. S. P. Thompson. Lord Rayleigh was elected President.

THE manuscript of the Royal Society Catalogue of Scientific Papers for the decade 1874–83 is now ready for the press, but Her Majesty's Government have informed the President and Council that it is not their intention to undertake, as in the case of previous decades, the printing and publication of the work.

THOSE who knew Dr. O. J. Broch, either when he was Professor of Mathematics at Christiania, or when he was Minister of the Board of Trade in Norway, or more recently, when he acted as Director of the International Bureau of Weights and Measures at Paris, and all who had any opportunity of intercourse with him either in social or official life, will hear of his death with deep regret. Dr. Broch died at Sèvres on the 5th inst., at the age of seventy-one. It has been the especial duty of the Bureau, over which Dr. Broch presided from its creation after the Metric Convention of 1875, to construct new standards of the metre and kilogramme for the different countries, including Great Britain, which were parties to that Convention. At the time of his death all these standards had been constructed, after much patient investigation, and were only awaiting final approval at Sèvres, before their delivery this year to the several contracting States. Dr. Broch's work remains to us, not only in those standards of exact measurement which, with the assistance of the men of science attached to the Bureau, he so well designed and verified, but also in the various scientific contributions by which he advanced our knowledge, particularly those published annually by the Comité International des Poids et Mesures; and in the mathematical papers issued by the Academy of Sciences at Paris (Elliptic Functions, *Comptes rendus*, 1864, &c.). Dr. Broch was a corresponding member of the Paris Academy; he was also a member of the Academies of Sciences of Berlin and Copenhagen, and a high officer of the Legion of Honour of France, and of the Order of St. Olaf of Norway.

THE death is announced of M. G. Meninghini, who had been Professor of Geology at Pisa from 1849. He died, on January 29, at the age of seventy-eight.

THE monument to be placed over the grave of the late General Prjevalsky on the shores of Lake Issik-kul has received the final approval of the Czar. It was designed by the traveller's companion and friend, M. Bilderling. The *Invalide Russe* gives the following description of it:—"The monument represents a picturesque rock 28 feet high, on the top of which is perched a large eagle, emblem of strength, intrepidity, and intelligence. The eagle grasps in its talons a map of Central Asia, the arena of the scientific exploits of the deceased, and in its beak an olive-branch, symbol of the peaceful scientific conquests which Russia owes to Prjevalsky. On one of the sides of the rock is a large bronze cross, beneath which is the inscription, 'Nicholas Mikhailovitch Prjevalsky, born 29th of March, 1839, died 20th of October, 1888.' In the interior of the rock is cut a spiral staircase crowned with an enlarged copy of the medal struck by the Academy of Sciences in 1887 in honour of Prjevalsky, and showing the original inscription, 'To the first explorer of Nature in Central Asia.'"

AT the last meeting of the Royal Swedish Geographical Society the *Vega* Gold Medal—the highest honour at the disposal of the Society—was conferred upon Dr. Nansen. There are only five other recipients, viz. Nordenskiöld, Palander, Stanley, Prjevalsky, and Junker.

THE eighth annual meeting of the Sanitary Assurance Association was held at 5 Argyll Place, W., on Monday, the President, Sir Joseph Fayrer, F.R.S., in the chair. After the reading of the Report, the following resolution was adopted: "That Dr. R. Farquharson, M.P., be ask to introduce the Sanitary Registration of Buildings Bill on the opening of Parliament, and to take the necessary steps to obtain as early a day as possible for the second reading; that Sir W. Guyer Hunter, M.D., M.P., Sir Henry Roscoe, M.P., F.R.S., and Dr. Cameron, M.P., be asked to again join Dr. Farquharson in introducing the Bill; and that as soon as the Bill is printed and in the hands of the members of the House of Commons, the President of the Local Government Board be asked to receive a deputation in support of the Bill."

THE Sanitary Institute has made arrangements for a series of lectures and demonstrations for sanitary officers, specially adapted for candidates preparing for the Institute's examination for Inspectors of Nuisances. The lectures will be delivered on Tuesdays and Fridays at 8 p.m., beginning with a lecture on the general history, principles, and methods of hygiene, to be given by Dr. Benjamin Ward Richardson, F.R.S., on March 5.

A MASTERLY paper on the scientific work of the German poet Adelbert von Chamisso was read by Emil du Bois-Reymond before the Berlin Academy of Sciences on June 28, 1888. This paper has now been issued separately. A most interesting account is given of Chamisso's voyage round the world in the *Rurik*—a voyage which in some respects resembled that of Darwin in the *Beagle*, fifteen years later. Among the many subjects which attracted Chamisso's attention during the voyage was the construction of coral islands. In connection with this question, curiously enough, he often receives credit for an observation with which he had in reality nothing to do. Darwin, for instance, was under the impression that it was Chamisso who had noticed that "the larger kinds of coral, which form rocks measuring several fathoms in thickness, prefer the most violent surf." M. du Bois-Reymond shows clearly that this observation was made, not by Chamisso, but by his companion in the *Rurik*, Dr. Eschscholtz.

AMONGST the memoirs recently published by the Société Philomathique of Paris in celebration of the hundredth anniversary of its foundation, is one by M. A. Milne-Edwards, describing a very singular new species of marsupial mammal of the genus *Dactylopsila* from New Guinea. *Dactylopsila palpator*, as it is proposed that this species shall be named, is remarkable for the enormous length of the fourth digit of the fore-limb, which surpasses in its proportions even that of the celebrated third finger of the Aye-aye, and is more than an inch longer than the two adjoining fingers. This new marsupial makes a second addition to the accurate catalogue of this order of mammals recently prepared by Mr. Oldfield Thomas, another important species (which will probably turn out to be the type of a new family) being the extraordinary fossorial form from South Australia, of which the discovery was announced in our issue of October 18, 1888 (see NATURE, vol. xxxviii. p. 588).

ON Sunday night, about 10.40, a shock of earthquake was felt in many parts of East Lancashire. At Great Harwood the vibration was so distinct that the occupants of a bedroom saw the wardrobe rocking and feared it would fall. "At Heapey, near Chorley, where there are many geological faults," says the *Times*, "a villa residence seemed to be struck three times, as if an attempt were being made to turn it round, and afterwards it oscillated to east and west five or six times, as if settling down after a violent shaking. But this effect was unique, and in most cases only a slight tremor was observed." At Bolton "there was first a heavy shock, and then for a few seconds a tremor. Doors were banged up; light articles danced in the houses; people were lifted in their beds, and one man in the out districts, who was sitting in front of a fire, was thrown into the grate, burning his hands and face. The electric bells at the fire brigade station were rung, and the central telephone office was besieged with inquiries. It was at first thought there had been a terrible colliery explosion." At Greenhaugh, near Kirkham, the shock was heralded by "a noise travelling in a westerly direction, which was followed by two or three oscillations."

AN earthquake occurred at Klagenfurt, on January 27, at 10.49 p.m., and on the same day a slight shock was felt at Ala, in the South Tyrol. At San José (Costa Rica), the National Capitol, the Cathedral, the President's palace, and many houses, were destroyed by the earthquake on December 29 and 30, 1888; and at Alejuela, several people were killed, and much damage was done.

A MANILA paper gives an account of an eruption of the Mayon volcano, in the Philippine Islands, on December 15, 1888. Vast columns of ashes were seen to ascend from the crater, and in a very short space of time the darkness became so intense that, though it was midday, lights had to be used in every house. The inhabitants of Legaspi, Camalig, Ligao, Libog, and other surrounding districts, were quite panic-stricken. At the time when the mail left, no loss of life had been reported. The lava, in vast streams, was then pouring down the mountain.

IN the Report of the Meteorological Council for the year ending March 31, 1888, recently published, the Council regret the loss they have sustained by the resignation of Prof. Stokes, consequent upon his election to Parliament. His place has been filled by the appointment of Dr. A. Buchan, who is well known by his various researches in meteorology. The work of the Office during the year in question is discussed under—(1) Ocean Meteorology. In this branch active intercourse is kept up with the Royal and Mercantile Navies, and an appendix shows that a large amount of valuable observations is being collected from all parts of the ocean. The investigations into the synchronous weather of the North Atlantic, the barometrical pressure charts for the Atlantic, Pacific, and Indian Oceans, and Part 5 of the contributions to Arctic meteorology have been completed, and noticed severally in our columns. Among the discussions now in hand may be mentioned those for the Red Sea, the Aden cyclone of June 1885, current charts for the principal oceans, and cyclone tracks in the Southern Indian Ocean for the years 1848–86 from materials supplied by Dr. Meldrum. It is intended that the discussion of the weather for the region lying between the

Cape of Good Hope and New Zealand shall also be taken up. (2) Weather Telegraphy. The work in this branch of the Office continues to increase. Forecasts are prepared three times a day, at 11 a.m., 3.30 p.m., and 8.30 p.m. A comparison of the results of the latter during the year shows an average success of 84 per cent. over the whole United Kingdom, being 3 per cent. more than for the previous year. Hay harvest forecasts were also issued, the results showing considerable success. Storm warning notices were issued to 146 coast stations. Under this head may be specially noticed a discussion of the severe storms which visited the British Isles between August 1, 1882, and September 3, 1883. From this investigation Mr. Scott concludes that it is extremely improbable that telegraphic reports from America can assist in the forecasting of the weather on our coasts, and this conclusion is supported by the actual results of the experiment made in dealing with the American reports during the year. (3) Land Meteorology. The records received from the Observatories and stations are classed under five heads; the methods employed are fully explained, and the Report shows that several important researches are being carried on in this branch.

A CORRESPONDENT writes to us from Adelaide:—"I am glad to be able to tell you that the drought, which has been so bad over nearly the whole of Australia during the past year, has at last broken up. We have had splendid rains right across the continent; the north-west monsoon, aided by a barometric trough across the interior, and a low-pressure area on the south coast, penetrating south of the tropics, and bringing a deluge of rain and heavy thunderstorms over the whole of South Australia, Victoria, and New South Wales."

IN consequence of the severity of the weather in Russia, wolves have made their appearance in East Prussia, where they have not been seen during the last six years.

THE hydrate of amidogen, or hydrazine, $N_2H_4 . H_2O$, has been prepared by Drs. Curtius and Jay, of the University of Erlangen. It may be remembered that a brief announcement of the isolation by Dr. Curtius of gaseous amidogen itself, $\begin{matrix} NH_2 \\ | \\ NH_2 \end{matrix}$, was made in NATURE (vol. xxxvi. p. 185) nearly two years ago. The free gas appears, however, to possess such an intense affinity for water, that its isolation in any quantity appears almost impracticable; for in all the reactions yet known in which it is liberated, water is also of necessity a secondary product, and combines with the amidogen at the moment of its liberation, forming this interesting hydrate, which is a liquid, and has been obtained pure in large quantities. Hydrazine hydrochloride, or hydrochloride of amidogen, as it is variously called, $\begin{matrix} NH_2 . HCl \\ | \\ NH_2 . HCl \end{matrix}$, a salt which may be obtained from its aqueous solution in fine regular octahedra, was distilled with caustic lime from a silver retort. The tube of the retort was inclined upwards for some distance and then bent into a U-shape, so as to prevent the possibility of any projection of particles from the contents of the retort. To the end of the silver U-tube was attached a horizontal tube, also of silver, containing fragments of quicklime; this in turn passed into a receiver of glass. The reaction between hydrazine hydrochloride and quicklime is exactly analogous to that so well known in the preparation of ammonia, amidogen water and calcium chloride being formed; but instead of obtaining the free hydride, its compound with water distils over. After the distillation had been in progress a few minutes, the horizontal tube was gently warmed, when liquid drops of the hydrate began to fall into the receiver. Barium oxide behaves just like lime, but by far the largest yield of the liquid is obtained by use of a strong solution of potash. Hydrazine hydrate is a fuming liquid, of very high refractive index, boiling unchanged at 119° C. Although boiling so near the boiling-point of water, it may be almost perfectly separated from that liquid by fractional distillation. It attacks glass energetically, and rapidly destroys cork or caoutchouc. It is strongly alkaline, as expected, tastes somewhat like ammonia, and leaves a burning sensation upon the tongue. It forms well-crystallized salts with most acids, which are found extremely poisonous, being fatal to the lower animals. It is probably the strongest reducing agent known. The most easily reducible metals are precipitated from solutions of their salts in the cold. Silver separates from cold strong solutions in fine compact crystalline masses; from very dilute solutions in the form of perfect mirrors of great beauty. On warming with a neutral solution of platinic chloride, metallic platinum separates, according to the degree of concentration, in silver-white particles or shining mirrors. In acid solutions it quantitatively reduces ferric to ferrous, cupric to cuprous, and platinic to platinous salts, with evolution of nitrogen gas. For instance, $N_2H_4 . 2HCl + 2PtCl_4 = N_2 + 6HCl + 2PtCl_2$. Finally, when dropped upon mercuric oxide, it violently explodes. From these facts it will be seen that hydrazine hydrate is one of the most remarkable liquids yet discovered, and appears likely to be of great use in chemical operations.

THE Haileybury Natural Science Society has published the first part of a list of the "Fauna and Flora of Haileybury." The volume is interleaved, and should be of considerable service to students of natural science in the neighbourhood.

MESSRS. ALLEN AND CO. have just issued a new edition of "Practical Microscopy," by George E. Davis. The work has been enlarged, and, as nearly as possible, brought down to the present time. The author has extended its scope, so as to include an account not only of English instruments, but of the apparatus in general use upon the Continent and in the United States of America.

MESSRS. LONGMANS, GREEN, AND CO. have published "The Student's Atlas," by the late Mr. R. A. Proctor. It consists of twelve circular maps, on a uniform projection and one scale, with two index maps, and is "intended as a *vade-mecum* for the student of history, travel, geography, geology, and political economy."

THE Royal University of Ireland has issued in a separate volume the examination papers of 1888. The volume forms a supplement to the University Calendar for 1889.

WE understand that the Trustees of the Australian Museum, Sydney, have decided to publish the manuscript and drawings relating to the life-histories of Australian Lepidoptera left by the late Alexander Walker Scott, and since acquired by them, and that the work of editing and revising this material has been intrusted to his daughter, Mrs. Edward Forde, and Mr. A. Sidney Olliff.

THE French Government, immediately after the recent outbreak of yellow fever at Jacksonville, despatched Dr. Paul Gibier, a French physician, to study the causes of the outbreak. Dr. Gibier now appeals to the American Government, on the ground that his own Government will not spend any more money on the task. He merely asks for the payment of incidental expenses, and for the moral support of the United States.

AT a recent meeting of the Scientific Society of Christiania, Prof. H. A. Getz exhibited the tusk of a mammoth found in Vaage, in Central Norway. This is the first discovery of remains of this animal in Norway.

THE Woman's Anthropological Society, Washington, has entered upon the fifth year of its existence; and, according to *Science*, it displays "undiminished enthusiasm and vigour." Mrs. Sybil A. Carter (wife of the Hawaiian Minister) and Miss Florence Spofford act respectively as President and Secretary.

We learn from *Science* that Dr. Thomas Featherstonhaugh, a grandson of the famous pioneer geologist, has just returned from a visit to Florida, and has brought back an interesting collection of aboriginal remains. He thoroughly examined a mound of damp sand on the shore of Lake Apopka, about the geographical centre of the State, and farther south than any previous researches of the kind. The mound was 50 feet in diameter and 14 feet high, and was covered with a dense growth of palmetto and other trees. It was found to be full of fragmentary bones and pottery, so numerous that Dr. Featherstonhaugh estimates that there could have been no less than four hundred bodies deposited there. A few Venetian beads near the top indicated intrusive burials, but below 4 feet there were no evidences of any intercourse with whites. Four shapely hatchets were recovered, also a charm-stone, and numerous specimens of decorated pottery. The whole find was presented to Major Powell, and by him turned over to the National Museum.

All hope has now been abandoned of saving Prof. J. Mainwaring Brown, who occupied the Chairs of English Language and Literature and of Political Economy in the University of Otago, New Zealand. He was one of an exploring party, being accompanied by Mr. White and Major Goring, which set out on an expedition to the neighbourhood of Lake Manapouri. One morning, Mr. Brown left his tent for a stroll in the bush, and, shortly after, a terrific storm of snow, wind, and hail burst over the district, and lasted without intermission for three days. His companions made every effort to find him, but without avail. Large search-parties were formed, but no tidings were obtained of the unfortunate gentleman. An enterprising newspaper proprietor in Otago despatched a special search-party at his own cost, and the Government have sent a steamer to Smith Sound, in the hope of obtaining some intelligence.

At the Royal Institution, Dr. Sidney Martin will, on Thursday next (February 21), begin a course of four lectures on the venom of serpents, and allied poisons, including those used in the Middle Ages; and Lord Rayleigh will, on Saturday (February 23), begin a course of eight lectures on experimental optics (polarization, fluorescence, wave-theory, &c.). Mr. Harold Crichton-Browne will give a discourse on Friday evening (February 22), entitled, "In the Heart of the Atlas."

A correspondent writes to point out that the planet Venus is now visible before sunset even in London. A few days ago he saw it at 4.30 p.m., thirty minutes before sunset, and as it was then very distinct he has no doubt that he could have seen it earlier if he had looked for it.

Mr. Harold P. Brown and Mr. George Westinghouse, Jun., have had a public discussion on the respective merits of alternating and continuous electrical currents. Mr. Brown, apparently not having satisfied Mr. Westinghouse, issues the following challenge, which we take from one of the electrical papers:—"I challenge Mr. Westinghouse to meet me in the presence of competent electrical experts, and take through his body the alternating current, while I take through mine a continuous current. The alternating current must not have less than 300 alternations per second (as recommended by the Medico-Legal Society). We will begin with 100 volts, and will gradually increase the pressure 50 volts at a time, I leading with each increase, each contact to be made for five seconds, until either one or the other has cried enough, and publicly admits his error. I will warn Mr. Westinghouse, however, that 160 volts alternating current for five seconds has proved fatal in my experiments, and that several men have been killed by the low-tension Jablochkoff alternating current." In other words, says Mr. Harold Brown, "I invite you to have a current passed through your body which I know (though you do not) will kill you, and I invite competent electrical experts to be present at the death which is sure to ensue." Mr. Brown and his experts will make preparations for what they all know to be an experiment highly dangerous to life, and which some of them believe must be fatal to Mr. Westinghouse, and if the latter is oolish enough to agree to his opponent's idiotic proposition, and the result is what Mr. Brown says is certain, then Mr. Brown and his experts will find themselves lodged in gaol awaiting their trial for murder, and being accessories to murder. If Mr. Brown knew a pistol was loaded which Mr. Westinghouse declared was not, and then induced the latter to fire it into his head to test which was right, Mr. Brown and the gallows would run the risk of being acquainted, while the experts who aided and abetted him would have an opportunity of trying the effects of some years' penal servitude. This fustian "challenge" does not make Mr. Brown any more accurate than he was before, but it must make every man of common-sense pretty certain that he can be an excessively foolish person, and that the chances are, when Mr. Brown is particularly positive about anything, he is wrong.

The additions to the Zoological Society's Gardens during the past week include a Tropical Squirrel (*Sciurus æstuans*) from Bolivia, presented by Mr. Peter Suarez; four Marbled Polecats (*Putorius sarmaticus*) from India, presented by Colonel Sir Oliver B. C. St. John, K.C.S.I., R.E.; eight Indian Gerbilles (*Gerbillus indicus* 2 ♂ 6 ♀) from India, presented by Dr. J. Gilbert; a Jackdaw (*Corvus monedula*), British, presented by Mr. Basil Carter; an Areolated Tortoise (*Homopus areolatus*), seven Tuberculated Tortoises (*Homopus femoralis*), two well-marked Tortoises (*Homopus signatus*), a Robben Island Snake (*Coronella phocarum*), two Infernal Snakes (*Boodon infernalis*), two Aurora Snakes (*Lamprophis aurora*), a Many-spotted Snake (*Coronella multimaculatus*) from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; an Adorned Ceratophrys (*Ceratophrys ornata*) from Buenos Ayres, presented by Captain Hairley.

OUR ASTRONOMICAL COLUMN.

New Minor Planet.—M. Charlois discovered a new minor planet, No. 284, on February 8, at the Nice Observatory. M. Charlois has named No. 277 Elvira.

Observations of Variable Stars.—Mr. Paul Yendall publishes in *Gould's Astronomical Journal* the results of his observations of a few variable stars in 1888. The observations compare as follows with the ephemerides given week by week in Nature:

Star.	Observed.		Calculated.
R Ursæ Majoris...	Oct. 22 *M*	...	Nov. 7 *M*
R Scuti	Aug. 6 *m*	...	Aug. 15 *m*
η Aquilæ	June 12·98 *M*	...	June 12·88 *M*
	July 25·76 *M*	...	July 25·96 *M*
	Sept. 6·50 *M*	...	Sept. 7·00 *M*
S Sagittæ	Sept. 27·9 *m*	...	Sept. 27·9 *m*
	Sept. 30·5 *M*	...	Sept. 30·9 *M*

Winnecke's Periodical Comet.—An exceedingly valuable memoir on the motion of this comet has recently been published by Dr. von Haerdtl, *Privatdocent* for Astronomy in the University of Innspruck. The most interesting point of this memoir, which was communicated to the Imperial Academy of Sciences of Vienna, lies in the evidence it supplies that an increase is necessary in the accepted value for the mass of Jupiter. After referring to the early history of the comet, its probable identity with Comet 1766 II., and with that discovered by Pons on February 6, 1808, and its rediscovery by the same observer on July 18, 1819, Dr. von Haerdtl commences the detailed treatment of the observations made during the four last periods when it was seen—viz. 1858, 1869, 1875, and 1886, discussing the individual observations, some 462 in all, with great thoroughness, and forming normal places and computing the resulting

elements for each of the four periods of observation. Then follow the computations of the perturbations exercised by the different planets from Venus to Uranus, Mercury having no appreciable disturbing effect, for the comet at perihelion does not come far within the orbit of the earth, and remains well without that of Venus, its perihelion distance being 0·831. The perturbations exercised by Jupiter, however, are most important, for the aphelion of the comet does not lie far outside the orbit of that planet, and the two tend to come into proximity every eleven years, their aphelion distances being, respectively, 5·57 and 5·20, and their periods 2076·79 and 4332·59 days, so that the comet was only 0·87 distant from the planet in December 1870, and eleven years later, in November 1881, was only half as far from it. These perturbations were computed for intervals of twenty days through the whole period covered by the observations, including thus five revolutions; and where it seemed desirable, for every ten or even every five days. The reciprocal of the mass assumed for Jupiter was $\frac{1}{m}$ = 1047·54, and with this value, so far from finding an acceleration of the mean motion of the comet, as with Encke's comet, a retardation was displayed—a retardation which, however, disappeared when a somewhat higher value viz. 1047·1752, was substituted. It appears that this latter value satisfies the observations not only of the comet in question, but also those of Faye's and Encke's. The value obtained by Dr. Schur from the four satellites of Jupiter does not greatly differ from that now found by Dr. von Haerdtl, and the latter considers that the simple mean of the two, $\frac{1}{m}$ = 1047·204, may be adopted as the nearest approach to the true mass of Jupiter, *i.e.* of the Jovian system, the satellites being included.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 *FEBRUARY* 17–23.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on February 17

Sun rises, 7h. 11m.; souths, 12h. 14m. 12·0s.; sets, 17h. 17m.: right asc. on meridian, 22h. 4·9m.; decl. 11° 48′ S. Sidereal Time at Sunset, 3h. 8m.

Moon (at Last Quarter on February 23, 0h.) rises, 17h. 59m.*; souths, 1h. 12m.; sets, 8h. 10m.: right asc. on meridian, 11h. 0·9m.; decl. 10° 42′ N.

GEOGRAPHICAL NOTES.

A PAPER of more than usual interest was read at Monday's meeting of the Royal Geographical Society, by the Rev. W. Spotswood Green, on his explorations in the glacier regions of the Selkirk Range, British Columbia, in the summer of 1888. This range is generally included in the Rocky Mountains, although, as Mr. Green showed, it is in many respects distinct from them. After crossing the Rockies by the Canadian Pacific Railway, and plunging into the valley of the Columbia River, the Selkirk Range lies before the traveller. It has been but little explored, and some of its glaciers were probably visited for the first time by Mr. Green. The Selkirk Range is entirely bounded by the great bend of the Columbia and its tributary, the Kootenie, and the drainage of all its glaciers finds its way into the Columbia in some part or other of its course. Under many difficulties, owing to the densely forest-clad nature of the ground, the want of guides and porters, the necessity of opening up new routes, and other causes, Mr. Green visited some of the higher parts of the range, and explored, and in some cases named, its previously unvisited glaciers. After crossing the Rockies proper, curiously ridged prairie hills have to be passed, and all the ranges between these and the Columbia have a smooth rounded outline, forming a strong contrast to the ranges on the other side of the watershed. These latter form a complexity of glacier-clad ranges, many peaks rising quite as high as those on the watershed. Among the higher ranges an immense number of small glaciers lie in the hollows, and two extensive snow-fields are to be found within the limits of Mr. Green's map. One of these, being the source of the best-known glacier in the whole region, on account of its being so clearly visible from the railway, Mr. Green has called the great Illecellewaet firn, after the river of which it is the true source. This ice-field, probably 500 feet thick, to the southward extends down into a valley as the Geikie Glacier, and to the eastward, having been joined by ice-streams coming from the Dawson Range, it pours into Beaver Creek Valley as the Deville Glacier. All these glaciers show evidence of shrinking. An immense moraine exists in the valley below the Illecellewaet Glacier. Some of the blocks of quartzite in the moraine are of huge dimensions, one being 50 feet long, 24 feet thick, and 33 feet high. Mr. Green set up some poles at a little distance from the end of the glacier, and found that after thirteen days the ice had melted a vertical foot over its whole surface, and the centre of the glacier had moved 20 feet. The Geikie Glacier, about 4 miles long and 1000 yards wide, is a much more interesting ice-stream. Sheltered from the sun's rays by high cliffs, it flows along a level valley, so that one can walk across its lower portion in various directions without trouble. As it descends from the firn, it is much broken; then its surface becomes level, but with numerous transverse crevasses. Flowing round a bend, longitudinal fissures are set up, crossing the others, and forming such a multitude of *séracs* that the surface presents an appearance more like some basaltic formation with the columns pulled asunder than anything else I can think of. This beautiful structure gives place to the frozen waves of a *mer de glace*, and the glacier terminates in longitudinal and slightly radiating depressions and crevasses. The level of perpetual snow in these mountains may be put down at 7000 feet, and the upper limit of the forest at 6000 feet. Red snow, caused by the presence of *Protococcus nivalis*, is of frequent occurrence. Like most of the rest of British Columbia, the Selkirks are covered with forests, all the trees attaining huge dimensions. These forests are being devastated by fires, often caused by sparks from the engines on the new railway. Beneath the living trees, thousands of prostrate trunks lie piled in every conceivable position, and in every stage of decay. Exploration and mountaineering under such circumstances are attended with enormous difficulties. Above the forest region, the slopes of the mountains are as profusely covered with flowers as the "Alp" region of the Swiss mountains; the most conspicuous plant being the *Castilleia miniata*. The heaps of boulders above the forest region form a refuge for a great

variety of small animals. With regard to the geology of the Selkirks, earlier than the Glacial formation, no rocks later than the Palæozoic seem to be met with in the central range. In the higher ranges, greenish quartzites and micaceous schists are the commonest rocks. The summit of Mount Bonney and the southern and south-western *arêtes* of Mount Sir Donald consist of a beautiful white, smooth quartzite, speckled in the former case with deep brown spots, "probably iron or manganese oxides." Associated with these harder rocks are a number of remarkable silky-looking schists (*phylites* of Prof. Bonney), the result of great squeezing in the movements which upheaved the ranges. Roughly speaking, then, the configuration of this district, with its complexity of valleys, is due to the disintegration and denudation of the softer schists and the permanence of the harder quartzites in mountain-ridges. With regard to age, the rocks range from true Archæan to late Palæozoic, possibly a little later. The presence of very old schists and gneisses would seem, then, to show that though the range called the Rockies, on the Canadian Pacific Railway route, is the water-parting, the Selkirks are geologically the true continuation of the Rocky Mountains of Montana, and the backbone of the continent.

The Russian Geographical Society has received the following news from Captain Grombchevski, who was sent out to explore the Khanate of Kunjut in the highlands between India and Afghanistan, and for a time was supposed to have been lost. After having left Marghelan in Russian Turkistan, M. Grombchevski crossed the highlands of Alai, and, *viâ* the Pamir lakes, Great Kara-kul, and Rang-kul, he reached the sources of the Amu-daria (the Murghab). Thence he proceeded to the Ak-baital River, and on August 16 he crossed the high ridge on the frontier of Afghanistan. On the southern slope of this ridge the Expedition was overtaken by a violent snow-storm, during which M. Grombchevski's Cossacks succeeded in getting hold of two inhabitants of Turm, from whom they learned that the Expedition was surrounded by Afghan troops, who had been sent out to take them prisoners. In consequence, M. Grombchevski, notwithstanding the snow-storm which was still raging, crossed the mountains again and returned to the Pamir, whence he immediately went across the Hindu-kush through a mountain pass which leads to Kunjut. The journey was so difficult that the Expedition lost one-half of its horses and part of its luggage. Circumstances did not permit M. Grombchevski to stay at Kunjut. He re-crossed the Hindu-kush, and entered East Turkistan at the sources of the Raskem-daria, one of the affluents of the Yarkand River. He followed its course, hoping to reach Karakorum, but was soon compelled to abandon his scheme, and only explored the nephrite mines on the banks of the river. After having surveyed part of the Raskem and Yarkand Rivers, the Expedition returned to Little Kara-kul Lake on the Pamir, and reached Kashgar on November 13. Three weeks later they were at Osh, bringing in a mass of interesting information and numbers of photographic views of the explored region.

The last volume of the *Izvestia* of the Caucasus branch of the Russian Geographical Society contains a variety of interesting short articles and notes. V. Massalsky's sketches of the regions of Kars and Batum are especially valuable to botanists. M. Konshin gives a most interesting geological and geographical sketch of the Transcaspian region; and two obituary articles (with portraits) devoted to Abich and Von Koschkul contain excellent reviews of their work in the Caucasus. The appendix contains a note on the study of the Caucasian languages, and various papers relating to Persia, Asia Minor, and Afghanistan. The most important of the latter is a report on the work done by the Russian Commissioners of the Afghan Boundary Commission, with a map of the region (13 miles to the inch) brought up to date in 1888. A short paper on the economic conditions of the Russian Transcaspian dominions, and a condensed translation from a "Guide to Armenia," by Bishop Srvandziantz, are also worthy of notice.

ELECTRICAL NOTES.

Hallwachs (*Ann. Wied.*, vol. xxxiv. p. 731, 1888) is continuing his researches on the connection between light and electricity. He has found that if the light of an arc lamp falls on clean plates of zinc, brass, and aluminium, they are always charged positively, the zinc to a potential of over 1 volt, the brass to 1 volt, and the aluminium to 0·5 volt. The plates become fatigued by constant illumination.

Sir William Thomson gave the Friday evening lecture on February 8 at the Royal Institution, on "Electrostatic Measurement," and described voltmeters and their functions; but the most interesting part of his discourse was his approving and eulogistic reference to Hertz's work, his own measurement of "v," which brings it very close to 3×10^{10} centimetres per second, and his long-deferred conversion to Maxwell's electromagnetic theory of light, which he thought had sprung from Maxwell's inner consciousness.

Himstedt (*Ann. Wied.*, vol. xxxv. p. 126), using a condenser, has determined the value of v to be $3{\cdot}0093 \times 10^{10}$.

Nahrwold (*Ann. Wied.*, vol. xxxv. p. 107) has shown that platinum rendered incandescent in a closed space is electrified negatively, the air being positive, but the same effect is not to be obtained with hydrogen, or any other pure gas.

E. G. Acheson in New York (*Electrical World*, January 19) has repeated many of Prof. Oliver Lodge's experiments on the "alternative" path in discharging Leyden jars, but has deduced from them different conclusions. He has avoided the errors due to charging which vitiated Prof. Lodge's early experiments. This is done by using one jar instead of two, and separating the charging system entirely from the discharging. He shows that the effects are due entirely to "extra currents" in the alternative wire dependent on the geometrical form of the current, and modified a little by the electro-magnetic inertia of iron. He has photographed the sparks, and obtains clear traces of oscillation when self-induction is present. His results have little or no bearing on the form of lightning protectors.

Wesendonck (*Ann. Wied.* vol. xxxv. p. 450) has made the curious observation that if in a long vacuum tube the distance between the electrodes be increased, the resistance is not affected. This does not agree with Varley's conclusions (Proc. R.S. vol. xix. p. 236, 1871), who showed that after the polarization of the electrodes is overcome gases obey Ohm's law.

Mebius (*Beiblatter der Physik*, vol. xii. p. 678, 1888) has tried to verify the statement that an electric current diminishes the coefficient of elasticity of metals, and he has come to the conclusion that it has no action on elasticity.

ON THE INTENSITY OF EARTHQUAKES, WITH APPROXIMATE CALCULATIONS OF THE ENERGY INVOLVED.[1]

As an exact science, seismology is in its infancy. Although great progress has been made during the past ten years, and especially in the development of instruments and methods for a more precise study of seismic phenomena, the results thus far have served rather to reveal the complicated nature of the problems involved; and while encouraging the seismologist to renewed effort, they warn him that his efforts are not to be light. The recent advances of the science have been, and properly, toward the study of the phenomena at hand, the nature and extent of the motion of the earth particle together with the rate at which the disturbance is propagated, in the expectation and hope that in time the location and character of the original cause may be revealed through these.

In the early growth of an exact science one of the obstacles met with is the absence of an exact nomenclature, and seismology furnishes no exception to this rule. Whenever it becomes desirable or necessary to incorporate the meaning of a word in a mathematical expression, it is imperative that the necessary restrictions be placed upon its use. It has long been customary to speak of the *intensity* of an earthquake without any special effort to give the word an exact meaning. Generally it is applied to the destructiveness of the disturbance on the earth's surface, and sometimes to the magnitude of the subter-

[1] By Prof. T. C. Mendenhall, President of the Rose Polytechnic Institute, Terre Haute, Indiana. (From the Proceedings of the American Association for the Advancement of Science, 1888.)

ranean cause of the same. But modern seismology proposes to measure the intensity of an earthquake and to express its value numerically. It is worth while, therefore, to inquire in what sense the term may be used with precision, and what may be accepted as its mathematical equivalent. Evidently it may mean, and in fact it has been made by different writers to mean, the measure of the surface destruction; the energy per unit area of wave-front of a single earthquake wave; the rate at which energy is transmitted across unit area of a plane parallel to the wave-front; and the total energy expended in the production of the original disturbance. The use of well-constructed seismographs has furnished us, within a few years, a good deal of fairly trustworthy information relating to certain elements of earthquake motion, notably the amplitude and period of vibration and the velocity of transmission, by means of which, and aided by a few not very violent assumptions, some of the above quantities may be calculated. They are not identical, numerically or otherwise, and it is manifestly improper to apply the word *intensity* to all of them.

An earthquake wave is generally assumed to be the result of an harmonic vibration. While this supposition is not strictly correct, it is probably not so far erroneous as to materially vitiate the results which follow.

If then—

a = maximum displacement,
t = periodic time,
v_1 = maximum velocity of particle,
V = velocity of wave transmission,
d = density of material through which transmission occurs,

the following are easily obtained:—

(1) Maximum velocity, $v_1 = \frac{2\pi a}{t}$.

(2) Maximum acceleration, $\frac{v_1^2}{a} = \frac{4\pi^2 a}{t^2}$.

(3) Energy of unit volume with velocity, $v_1 = \frac{1}{2}dv_1^2 = \frac{2\pi^2 a^2 d}{t^2}$.

(4) Energy of wave per unit area of wave-front $= \frac{2\pi^2 a^2 dV}{t^2}$.

(5) Energy per second across unit area of plane parallel to wave-front (rate of transmission) $= \frac{2\pi^2 a^2 dV}{t^2}$.

It is well known that Mallett and others of the earlier seismologists attempted to find a mathematical expression which should represent the so-called "intensity" of the shock, by means of the velocity of projection of loose bodies as determined by their range, and also through the dimensions of bodies which would be overturned by the shock. The maximum velocity of the earth might be ascertained by the first method with fair accuracy; the second method is nearly, if not quite, worthless in practice, and both are decidedly inferior in design and operation to the modern seismograph, which gives the principal elements of the motion directly.

In a paper by Profs. Milne and Gray, *Philosophical Magazine*, November 1881, the following occurs:—"The intensity of a shock is evidently best estimated from the maximum velocity of translation produced in a body during an earthquake. This is evidently the element according to which the destructive power is to be measured, it being proportional to the maximum kinetic energy of the bodies on the earth's surface relative to that surface during the shock." Now this statement is inconsistent with that which immediately follows, and with their mathematical expression, which is $I \propto \frac{A}{T^2}$, equivalent to the second expression given above. This inconsistency was doubtless quickly and first detected by the authors, and in a copy of the paper received from them I find interlinear corrections in the paragraph quoted above in virtue of which the words "rate of change of" are substituted for the word "maximum" where it first occurs, and "acceleration" for the words "kinetic energy," thus bringing it into agreement with the remainder of the discussion, and at the same time unquestionably better representing the opinion of the authors, who in all subsequent publications have used the maximum acceleration to represent the intensity as shown in the overturning, shattering, and projecting power of the shock.

The same expression, $\frac{v_1^2}{a}$, is used as a measure of intensity by Prof. Holden in his paper on "Earthquake Intensities in San Francisco" (*American Journal of Science*, vol. xxv. p. 427) where he defines it as "intensity of shock defined mechanically = destructive effect = the maximum acceleration due to the impulse." He asserts that "the researches of the Japanese seismologists have abundantly shown that the destruction of buildings, &c., is proportional to the acceleration produced by the earthquake shock itself, in a mass connected with the earth's surface." This statement is hardly justifiable, at least up to the present time. In the Report of the British Association for 1885, the Committee appointed by the Association for the purpose of investigating the earthquake phenomena of Japan, consisting of Messrs. Etheridge, Gray, and Milne, describe among other seismic experiments one which consisted in determining the quantity to be calculated from an earthquake diagram which would give a measure of the overturning or shattering power of a disturbance. The result of this investigation seemed to show that the acceleration, which by calculation from the dimensions of the columns was necessary for overturning, was something between the mean acceleration, represented by $\frac{4v_1}{t}$, and the maximum acceleration, $\frac{v_1^2}{a}$.

The actual destruction caused by an earthquake wave is undoubtedly a function of many variables, but it seems tolerably certain that maximum acceleration is the leading factor, and at the present time no better measure can be found. It appears to me, however, that it is unwise to apply the term "intensity" or "intensity of shock" to this quantity, which might be called the "destructiveness" of the wave, or perhaps its "destructivity," as indicating a little more clearly the power to destroy.

Dutton and Hayden, in their "Abstract of the Results of the Investigation of the Charleston Earthquake," presented to the National Academy of Sciences on April 19, 1887, define intensity as the "amount of energy per unit area of wave-front," but, in the subsequent discussion, use it almost continually as a measure of surface destruction. Upon the first definition they have based a very interesting and novel method for determining the depth of the focus; but in the application of the method to the Charleston earthquake they have used the word in its other and very different sense. A reference to the formulæ given above will show that one of these quantities is inversely as the square of the distance from the origin, as assumed by them in the development of their method, while the other, used in its application, is not so proportional, and this must be admitted to be fatal to their deductions.

In the discussion of a somewhat analogous case, Lord Rayleigh says ("Theory of Sound," vol. ii. p. 16), "The rate at which energy is transmitted across unit of area of a plane parallel to the front of a progressive wave may be regarded as the mechanical measure of the intensity of the radiation." The algebraic expression for this quality, as shown above, is, of course, similar to that of the quantity last considered, differing from it only in the power of "t" in the denominator. Both are very important expressions; neither is very closely related to "surface destruction," and the latter is unquestionably a suitable measure of the "intensity of an earthquake" in the most important sense.

It thus appears that at least four measures for earthquake intensities are and have been in use, which are expressed mathematically in terms of amplitude, period, velocity of transmission, and density of medium in formulæ (1) (2) (4) (5) above. To show more forcibly the necessity of placing some restrictions upon the use of the word, I have compared the "intensities" of two earthquakes, using each of the four expressions. The disturbances compared are those of May 6 and May 11, 1884, at Tokio, Japan, the observations being made by Prof. Milne (Trans. Seis. Soc. Japan, vol. x. p. 27). The same instrument, located in the same place, was used in both, and the interval of time between the two is so small as to forbid any important change in the conditions. That of May 6 is called "A," and that of May 11, "B." The results are as follows:—

$\frac{B}{A}$ ...	(1)	(2)	(4)	(5)
	1·1	1·7	0·9	1·3

from which it is evident that much depends on the measure of intensity adopted.

As stated at the beginning of this paper, the more recent

work of seismologists has been in the study of individual disturbances for the purpose of determining the principal elements of motion, amplitude, period, direction, and speed of transmission. In this study much has been learned. From the nature of the case we are almost absolutely restricted to an investigation of surface phenomena, and we are soon forced to admit that what goes on at the surface cannot accurately represent what is going on below. Among other reasons for this conclusion we have, notably, the greatly varying results obtained from the same disturbance at points comparatively very near to each other. The amplitude at one point may be two or three times that at another a few hundred feet away, and not only this, but the periodic times do not agree, and when the maximum acceleration is applied to the disturbance, its so-called intensity or destructiveness will vary greatly within a small area. As a matter of fact, it has long been known that such variations in destructive power do occur in nearly all earthquakes. Not only do the above elements vary, but the speed of transmission, when once the surface is reached, is undoubtedly not constant, although we have no reason to believe that it is not approximately so in the rocks through which it is, in the main, transmitted. Most of these irregularities are doubtless due to the non-elastic character of the materials lying near the surface and to their lack of homogeneity. In spite of their appearance in the phenomena of the surface, it is difficult, if not impossible, to believe that they exist in the rocks below. It is more reasonable to assume that during an earthquake the waves of transmission are, in the main, and until the surface is reached, somewhat regular in their form and approximately constant in certain of their elements. It may also be assumed that in amplitude and periodic time the subterranean wave, although doubtless much less than the surface-wave, cannot differ from it enormously, so that elements of motion obtained by seismometric observations upon the surface may be applied within certain limits to the investigation of the energy involved, the results being considered as rough approximations.

On these assumptions the following calculations have been made:—

Let A be the area of a portion of a wave-front, and l a length measured at right angles to A. Then formula (5) above, which shows the energy per second across unit area, multiplied by $\frac{\mathrm{A}l}{\mathrm{V}}$ will evidently express the energy required to generate the waves existing at any moment in the volume lA. That is

$$\frac{2\pi^2 a^2 d\mathrm{V}}{t^2} \cdot \frac{\mathrm{A}l}{\mathrm{V}}$$

$$= \frac{2\pi^2 a^2 d\mathrm{A}l}{t^2}$$

$$= \frac{2\pi^2 a^2}{t^2} \cdot m \; (m = \text{mass of volume } l\mathrm{A})$$

$$= \tfrac{1}{2} m v_1^2.$$

That is to say, the work consumed in generating waves of harmonic type is the same as would be required to give the maximum velocity to the whole mass through which the waves extend.[1] Sir William Thomson, who was probably the first to apply this principle, in his calculation of the mechanical value of a cubic mile of sunlight, concludes that in the case of a complex radiation this value is more likely to reach twice that of the above expression.

On the assumption that the maximum velocity of the particle is known, we may now apply this formula to the calculation of the energy involved in an earthquake. For this purpose I have selected, first, the Japanese earthquake of January 15, 1887, which disturbed over 30,000 square miles of territory, and the elements of which were well recorded on the Tokio seismographs. Assuming a mass of 150 pounds per cubic foot, and taking a cubic mile as the volume to be considered, I find that to put it in vibration required the expenditure of 2,500,000,000 foot-pounds of energy, and this might be called the "mechanical value of a cubic mile of earthquake." Assuming that an area of 100 miles square, with a mean depth of one mile, was thus in vibration at any one instant of time, which is not improbable considering the known rate of transmission and the long duration of the earthquake, the amount of energy thus represented would be 25×10^{12} foot-pounds. This energy might be generated by the fall, under the action of gravity, of a cube of rock 1000 feet on each edge, the mass of which would be 75,000,009 tons, through a vertical distance of about 166 feet.

[1] Lord Rayleigh, "Theory of Sound," vol. ii. p. 17. Sir William Thomson on "The Possible Density of the Luminous Medium."

It would be interesting to apply this method to the Charleston earthquake of August 31, 1886. Unfortunately no seismographic records were made, and the elements of motion are largely matters of conjecture. Messrs. Dutton and Hayden, in the report already referred to, express the opinion that in some localities the displacement must have been as much as 10 inches or 1 foot. This seems to me improbable, but it may be safe to say that over a considerable area it was as much as 1 inch. Nothing is known with certainty as to the period of the oscillations, but as it generally increases with the magnitude of the disturbance, it would probably not be grossly incorrect to call it two seconds. Assuming these magnitudes, I find the energy of a cubic mile of the Charleston earthquake, taken near enough to the epicentrum to be disturbed as above, to be equal to 24,000,000,000 foot-pounds. The speed of transmission of this disturbance has been pretty well determined, by Newcomb and Dutton, to be approximately three miles per second, so that a cubic mile would be disturbed in one-third of a second. To do this would require 130,000,000 horse-power. Assuming as before that an area about the epicentrum 100 miles square was thus disturbed, the energy involved would be 24×10^{13} foot-pounds, and the rate of its expenditure would be that of 1,300,000,000,000 horse-power.

All of these numbers can only be regarded as gross approximations. They probably indicate the order of magnitudes involved, and may be useful until more trustworthy data are furnished.

THE ROYAL HORTICULTURAL SOCIETY.

THE annual general meeting of the Royal Horticultural Society was held on Tuesday, February 12, at the offices, 117 Victoria Street, S.W. The Society is to be heartily congratulated on the great improvement which has taken place in its affairs since it quitted the Gardens at South Kensington this time last year. From the Report of the Council, and the speech of Sir Trevor Lawrence, Bart., M.P., President, in moving its adoption, we glean the following particulars. During the past year 657 Fellows have joined the Society, 81 have resigned, and 48 died, the total number of Fellows on the books being now 1636. The total income from all sources, independent of the "Donation" account (£1125 5*s.*), was £3617 8*s.* 6*d.*; the total expenditure, £3412 14*s.* 4*d.*, showing a surplus of £204 14*s.* 2*d.* On January 1, 1888, there was a debit balance of £1152, which has been cleared off by the transfer of of £755 7*s.* 6*d.* from the "Donation" account, and £396 12*s.* 6*d.* from current revenue. The total expenditure on the maintenance of the Society's Gardens at Chiswick was £1501 6*s.* 8*d.*, the receipts from the sale of produce, £737 7*s.* 6*d.*, brought up by minor items to £810 4*s.* 3*d.*, making the net cost of the Gardens to the Society £691 2*s.* 5*d.* The income for 1889 is estimated at £3000, and the expenditure at £2950. The President referred to the great value to the Society of the services of Mr. Dyer, F.R.S., Director of the Royal Gardens, Kew, and Mr. H. Veitch, who were retiring from the Council owing to the pressure of other engagements, and of Mr. Wilson, F.R.S., and Dr. Hogg, who were retiring after having served the Society well and faithfully during very many years. He also paid a well-deserved tribute to the energy, ability, judgment, and devotion to their duties, of the Honorary Secretary, the Rev. W. Wilks, and the Treasurer, Mr. D. Morris, Assistant-Director of the Royal Gardens, Kew. During the past year numerous very interesting exhibitions have been held in connection with the fortnightly meetings of the Society in the Drill Hall of the London Scottish Volunteers, James's Street, Buckingham Gate. A magnificent show was held on May 17 and 18, in the Gardens of the Inner Temple, by the permission of the Treasurer and Benchers, in which, for the first time in the history of such displays, attention was drawn to the excellent horticultural work being done by the market growers of the London district. A conference on apples and pears, held at Chiswick from October 16 to 20, attracted great attention, and the papers read and the discussions raised as to the circumstances and conditions requisite for the successful cultivation of these fruits in the British Isles were of great value. The Society propose to hold this year, in addition to a great show in the Temple Gardens on May 30 and 31, and its usual bi-monthly exhibi-

tions, a national rose conference and show on July 2 and 3, a great vegetable conference on September 24, 25, and 26, and a chrysanthemum centenary conference on November 5 and 6, —all at Chiswick. There will be at the bi-monthly meetings a short lecture and discussion on the plants exhibited, such as was in former years very popular under the guidance of Dr. Lindley. The Society will revive the publication of its periodical Journal and Proceedings, and carry on at Chiswick extensive trials of various classes of flowering plants, ferns, vegetables, and artificial manures.

Altogether it is gratifying to find that, the unfortunate and costly connection of the Society with South Kensington having been severed, there is a great revival of vigour and vitality and of interest in a Society which has been in existence for nearly a century, is the parent of a vast progeny of kindred institutions throughout the Empire, and has rendered to horticulture services the value of which it is impossible to over-estimate.

SOCIETIES AND ACADEMIES.

London.

Royal Society, January 31.—"On *Isoëtes lacustris*, Linn." By J. Bretland Farmer, B.A., F.L.S. Communicated by Prof. S. H. Vines, F.R.S.

Many points connected with the development of Isoëtes still remain to be cleared up, and this is especially true of the germination of the macrospore. This structure consists of a mass of protoplasm, which, in perfectly mature spores, is inclosed in a thick envelope, and this envelope is differentiated into six layers, of which the outermost belongs to the episporium, the three within this to the exosporium, and the two innermost to the endosporium. The protoplasm contains very large quantities both of oil and starch, and is provided with a large nucleus, in which are embedded certain bodies which appear yellowish-brown in preparations stained with hæmatoxylin, but as to whose nature it is not at present possible to speak definitely. During germination, hæmatoxylin fails to reveal the presence of a nucleus, and the cytoplasm at this period stains so rapidly and deeply that it is possible that the nuclear substance may be diffused through it. It is when the protoplasm stains thus deeply that the first indication of cell-formation is visible. Its mass is seen to be traversed by "cracks," which divide it into a few large isolated portions, and it is in the direction of these cracks that the cell-walls first appear. The splitting of the protoplasm is doubtless called forth by the methods necessarily used in embedding the spores, but the conclusion that may be drawn from its presence probably is, that the substance destined eventually to form the cell-wall, is present before the appearance of this structure, and is arranged in a plate-like manner, in such a way as to determine the direction of the cracks referred to. The cells thus formed probably owe their existence to a process similar to that obtaining in the endosperm of many plants, except that, at least so far, I have been unable to detect free nuclei in the first stages. Very soon after cell-formation has begun, these bodies are again very easily seen, especially in the upper part of the young prothallium. Division proceeds with great rapidity in this portion, and the rudiments of the archegonia are laid down. Their origin is similar to that in the Marattiaceæ; superficial cells divide at first once, periclinally, and of the two cells thus formed, the upper gives rise to the neck by further division into four stories, each story being divided crosswise in the usual way; the lower cell forms the central series consisting of oosphere, one neck, and one ventral-canal cell.

Division in the lower part of the prothallium takes place with extreme slowness, and here at least the appearance of free nuclei precedes that of the cell-walls. The cells which arise in this region are readily distinguishable, on account of their large size, from those which owe their origin to the primitive cells in the upper portion of the prothallium, but although further cell-division takes place throughout the spore, I am not in a position at present to state exactly how it occurs, or in what relation it stands with regard to the nucleus in these later stages.

Mineralogical Society, January 22.—Mr. R. H. Scott, F.R.S., President, in the chair.—The following papers were read:—On connellite from a new locality, by G. T. Prior.—On pseudomorphs of hæmatite after iron pyrites, by R. H. Solly.—On crystals of percylite, caracolite, and an oxychloride of lead (daviesite), from Sierra Gorda, Bolivia, by L. Fletcher.—On the distribution and origin of the hydro-carbons of Ross and Cromarty, by Hugh Miller.

Edinburgh.

Royal Society, January 21.—Prof. Sir Douglas Maclagan, Vice-President, in the chair.—Mr. J. Arthur Thomson discussed the history and theory of heredity.—Prof. Haycraft communicated a note, written by himself in conjunction with Dr. E. W. Carlier, on the conversion, by means of friction, of ciliated into stratified squamous epithelium. Specimens in illustration were shown under the microscope.—Prof. Tait read a paper on the virial equation, as applied to the kinetic theory of gases, especially as regards the form of isothermals in the neighbourhood of the critical point. The curves obtained from the new formula, with suitable values of the constants, represent with accuracy the isothermals of carbonic acid gas as obtained experimentally by Andrews. But the chief point of interest in the paper is connected with the question, What portion of the whole kinetic energy of a substance is, in each of its molecular states (*i.e.* as gas, vapour, liquid, and solid), to be regarded as proportional to the absolute temperature? Prof. Tait gave reasons for believing that it is incorrect to assume, with Van der Waals and Clausius, that the *whole* kinetic energy determines the absolute temperature. The part which is directly due to inter-molecular forces is at least mainly incommunicable to other bodies, and can thus have little to do with the temperature.—A note, by Mr. R. T. Omond, on a remarkable fog-bow seen from Ben Nevis on December 4, 1888, was communicated.—Mr. George Brook described a new type of dimorphism found in certain *Antipatharia*.—Prof. Crum Brown communicated a paper, by Dr. A. B. Griffiths, on a primitive kidney, or the beginning of a renal system.

Sydney.

Royal Society of New South Wales, October 3, 1888.—Sir Alfred Roberts, President, in the chair.—The following papers were read:—Considerations of photographic expressions and arrangements, by Baron Ferd. von Mueller, K.C.M.G., F.R.S.—Census of the fauna of the older Tertiary of Australia, by Prof. Ralph Tate.—Notes on the storm of September 21, 1888, by H. C. Russell, F.R.S. Mr. Russell pointed out that, although such cyclonic disturbances seldom visited the coast of New South Wales, experience had proved that they were not unknown, and another such storm of greater dimensions would probably cause considerable havoc in the city of Sydney if the unstable class of buildings so much in vogue were adhered to.—Some New South Wales tan substances, Part 5, by J. H. Maiden.

November 7.—Mr. H. C. Russell, F.R.S., Vice-President, in the chair.—The following papers were read:—Results of observations of Comets I. and II. 1888, at Windsor, N.S.W., by John Tebbutt.—Desert sandstone, by the Rev. J. E. Tenison Woods.—On a new self-recording thermometer; and notes on the thunderstorm of October 26, 1888, by H. C. Russell, F.R.S. Three meteorites were exhibited: the first, weighing 35½ pounds, found near Hay, was shown by the Chairman; the second, weighing 137 pounds, found at Thunda, in Queensland, had been received by Prof. Liversidge that afternoon. A preliminary note upon the qualitative analysis of a portion of this meteorite was read before the Society in 1886, which showed that it consists essentially of iron and nickel with a little cobalt, sulphur, and phosphorus. The third was exhibited by Mr. C. S. Wilkinson: it weighed 12½ pounds, and was composed chiefly of iron, of an irregular pear-shape, and was discovered firmly embedded in slate rock on the highest peak of a mountain near the junction of the Burrowa and Lachlan Rivers.

December 5.—Sir Alfred Roberts, President, in the chair.—The Chairman announced that the Council had awarded the Clarke Memorial Medal for 1889 to R. L. J. Ellery, F.R.S., Government Astronomer of Victoria.—The following paper was read:—The Latin verb *jubere*—a linguistic study, by Dr. John Fraser.—Prof. Liversidge exhibited and described a large collection of New South Wales minerals.

Paris.

Academy of Sciences, February 4.—M. Des Cloizeaux, President, in the chair.—On the loss of nitrogen during the decay of organic substances, by M. Th. Schlœsing. The fact that, during decomposition, nitrified organic matter liberates

free nitrogen, was demonstrated for the first time by M. Reiset in 1856, and confirmed by the subsequent experiments of Messrs. Lawes and Gilbert, and others. Here, M. Schlœsing describes the process by which he has endeavoured to determine the quantity of nitrogen dissipated during decomposition under the *natural* conditions of temperature and the general environment. The results of these researches will be communicated in a future paper.—The Buitenzorg Botanic Garden and Laboratory, by Dr. Treub. From this interesting description of the Buitenzorg institution near Batavia, Java, it appears that it comprises three distinct branches: (1) the Botanic Garden, properly so called, where are cultivated from 8000 to 9000 tropical and sub-tropical plants; (2) the Tjibodas Garden, situated at an altitude of 1500 metres in one of the hilliest districts of the Preang residency; (3) the Experimental Garden, in the Tjikeumeuh quarter of Buitenzorg, where are grown all the economic plants of the tropical zone. The first comprises a museum, an herbarium, a large library, a phytochemical laboratory, a photographic *atelier*, and a laboratory for botanic research. This last was established four years ago for the purpose of enabling botanists from Europe to study tropical vegetation on the spot, and is thus somewhat analogous to the Zoological Station at Naples. Buitenzorg is supported by an annual grant of £6000 from the Dutch East Indian Government.—Observations of Barnard's Comet, 1888 *e*, made with the west equatorial of the Paris Observatory, by M. D. Eginitis. These observations, covering the period from December 7 to January 8, give the positions of the comparison stars, and the apparent positions of the comet.—Observations of the new planet discovered on January 28, at the Observatory of Nice, by M. Charlois. The observations were taken on January 28 and 29, when the planet was of the thirteenth magnitude.—On the personal equation in astronomical calculations, by M. J. J. Landerer. The object of this communication is to show that within somewhat wide limits the personal equation depends on an effect of diplopy which may be easily measured.—Euler's problem on the equation $ds^2 = dz^2 + dy^2$, by M. G. Kœnigs. In this note the problem in question is extended to the case of any surface.—On homography in mechanics, by M. Appell. It is shown that the method of transforming figures by central projection, which plays such an important part in geometry, may also be employed in mechanics. These remarks may be extended to the movement of a point in space, and even to the movement of several points, on the condition in the latter case of making a general homographic transformation, which shall simultaneously contain the co-ordinates of all the points.—On the compressibility of mercury and the elasticity of glass, by M. E. H. Amagat. In his communication of October 15, 1888, the author gave the results of his studies on the elasticity of the crystal in the cylindrical piezometers of this substance charged with mercury. By simultaneous inward and outward pressure of these cylinders, he obtains the coefficient of apparent compressibility, and ultimately that of the absolute compressibility of the liquid metal. The whole series of experiments are now repeated, and the results here tabulated, showing for mercury a mean general coefficient of 0·000003918 under pressures not exceding 50 atmospheres. Although slightly higher, this may be regarded as in accordance with the coefficient 0·0000036, obtained by Prof. Tait, who worked up to a pressure of 450 atmospheres, and who considered his result as somewhat too low, even according to the method adopted by him ("Voyage of the *Challenger*," Part 4).—On the heat of formation of the bichromate of aniline, by MM. Ch. Girard and L. L'Hote. In a previous note (*Comptes rendus*, June 13, 1887) the authors showed that the bichromate of aniline might be easily prepared by causing the bichromate of potassa to react on the hydrochlorate of aniline under conditions there specified. In order to complete these researches they here study the thermic conditions of the formation of this salt.—Alcoholic combinations of the glycolalcoholate of soda, by M. de Forcrand. The author finds that the monatomic alcohols combine with the glycolalcoh olate of soda, forming with it crystallized compounds analogous to the alcoholic glycerinates of soda. He has prepared and analyzed the following products:—

$$C_4H_5NaO_4,\ C_2H_4O_2,$$
$$C_4H_5NaO_4,\ C_4H_6O_2,$$
$$C_4H_5NaO_4,\ C_6H_8O_2.$$

—On the quantitative analysis of organic nitrogen by the Kjeldahl method, by MM. E. Aubin and Alla. In reply to M. L'Hôte's objections to this method, experiments are here described showing that it is both trustworthy and accurate, yielding results fully equal, if not superior, to those of MM. Will and Warrentrapp. During the process the organic matter is completely transformed, and in the end all the nitrogen appears under an ammoniacal form; the sulphuric liquids obtained are always limpid and colourless, nor is there any loss of ammonia during the operations.—On the cockroaches of the Carboniferous age, by M. Charles Brongniart. Mr. S. H. Scudder, author of the best monograph on these Palæozoic forms, divides them into the two families of Blattinariæ and Mylacridæ, the former common to both hemispheres, the latter, as he supposed, confined to the United States coal-fields. But it is here shown that this is a mistake, and that the Mylacridæ are as common as the Blattinariæ in the Commentry formations, France.—M. de Malarce contributes a paper on the extension of the metrical system, on the development of uniform monetary systems and of the credit system (cheques, bills, &c.), throughout the civilized world.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

The Scientific Papers of the late Thomas Andrews, M.D., F.R.S., with a Memoir by P. G. Tait and A. Crum Brown (Macmillan).—The Physician as Naturalist: W. T. Gairdner (MacLehose, Glasgow).—Report on the Proceedings of the U.S. Expedition to Lady Franklin Bay, Grinnell Land, vol. i.: A. W. Greely (Washington).—Popular Lectures and Addresses, vol. i., Constitution of Matter: Sir Wm. Thomson (Macmillan).—The Philosophy of Mysticism, 2 vols.: C. du Prel, translated by C. C. Massey (Redway).—Dr. H. G. Bronn's Klassen und Ordnungen des Thier-Reichs, Erster Band, Protozoa, 53, 54, 55, Liefg.: Dr. O. Bütschli (Williams and Norgate).—Bird Life of the Borders: A. Chapman (Gurney and Jackson).—Report on the Cost and Efficiency of the Heating and Ventilation of Schools: T. Carnelley (Dundee).—Yield Tables for the Scotch Pine: W. Weise; converted into English measure and arranged by Dr. W. Schlich (Allen).—Volkaner i det Nordöstlige Island: Th. Thoroddsen (Stockholm).—Journal of the Chemical Society, February (Gurney and Jackson).—Observaciones Magnéticas y Meteorológicas del Real Colegio de Belen en la Habana, 4°. Trim. 1886 (Habana).—Bulletin de l'Académie Royale des Sciences de Belgique, No. 12 (Bruxelles).—Annalen der Physik und Chemie, 1889, No. 2 (Leipzig, Barth).—Beiblätter zu den Physik und Chemie, 1889, No. 1 (Leipzig, Barth).

THE ILLUSTRATED OPTICAL MANUAL.

The Illustrated Optical Manual. By Sir T. Longmore, C.B., F.R.C.S. Fourth Edition. Pp. 239. (London: Longmans, Green, and Co., 1888.)

IN the present edition this manual, which was originally intended for army medical officers, has been considerably enlarged, with a view to its suitability as a text-book for civil as well as for military surgeons. Civil surgeons, however, are abundantly supplied with excellent works on ophthalmology; and for this reason (to say nothing of the fragmentary nature of Sir T. Longmore's Manual) we scarcely think that it will ever enjoy any large vogue amongst that class. The author treats of the detection and correction of refractive errors, and of optical defects generally: surely it would have been better to produce at once a complete manual of ophthalmology than to treat the subject in this piecemeal fashion. For how can any military surgeon be certain of his diagnosis in a case unless he has a thorough knowledge, not only of errors of refraction, but of eye diseases as well?

The opening chapter, on optical principles, is very good; the description of refraction, &c., being well and clearly done. Speaking of the composition of spectacle lenses, the author points out that the only real advantage possessed by quartz lenses ("pebbles") over ordinary crown glass ones is that they are harder, and, therefore, are not so easily scratched. By experiment, he has ascertained, contrary to the common supposition, that there is no difference in weight between pebbles and crown glass lenses of corresponding powers. The tourmaline forceps, for determining whether a pebble lens is, or (as is often the case) is not, cut exactly perpendicular to the axis of the crystal, is figured and explained.

We notice some peculiar statements in the chapters on myopia, hypermetropia, and astigmatism. For example, it is stated that the myopic eye "usually presents some peculiar characters indicative of its condition. It is prominent, or even appears to protrude; the pupil is usually contracted." At times, no doubt, cases of high myopia are seen in which the eyes do appear to be unduly prominent; but it is a sign of no value, and one which is more often absent than present. The pupil, if it shows any change at all, tends, in myopes, not to contraction, but to dilatation. In estimating refraction by the direct method, the examiner is recommended to place himself 18 inches or more from the patient's eye. This is an extraordinary statement, our impression heretofore being that it was impossible to be too close to the patient's eye. In examining the fundus oculi by the direct method of ophthalmoscopic examination, the examiner, it is stated, will have little or no tendency to bring his accommodation into play. This, again, is quite contrary to the experience of most persons; in fact, one of the greatest troubles experienced by tyros is that they almost invariably call their accommodation into play when it should be quiescent, and many adepts are unable, even after years of practice, completely to relax their ciliary muscles. The refraction, as tested by the direct method, is enjoined to be taken at the optic disk. Although this is the usual plan, a caution might well have been given that the refraction at the blind spot (optic disk) and at the yellow spot (the point of the most accurate vision) may differ appreciably. Again, in practising retinoscopy, it is recommended that the patient's eye be turned inwards. By this means, doubtless, a more easily seen reflex is obtainable with a small pupil, but this great drawback attaches to the method, that the refraction of some part of the fundus, other than the yellow spot, is estimated.

Sir Thomas Longmore gives currency to the views of his colleague, Dr. Macdonald, on the subject of normal astigmatism. Briefly, they are as follows. Every eye has a greater curvature in its vertical than in its horizontal meridian, but the difference in curvature is so slight that it does not interfere with visual acuteness. The meridian of greater curvature is not exactly vertical, but intersects the vertical meridian at an angle of about 15°. When a vertical line is held within the near point of an eye it is blurred; but when the left eye alone is used, the left side of the line is less blurred than the right side; when the right eye alone is used, the right side of the line is seen more distinctly than its left side. The effect of this is that a line held within the near point is seen more distinctly when both eyes are used than when either eye by itself is used. Hence, in this view, normal astigmatism becomes an important aid to the perfection of binocular vision of near objects.

The regulations as to the visual examination of recruits are given in detail. The vision of regular army recruits is ascertained by their ability to count test-dots, one-fifth of an inch in diameter, held 10 feet from the eye: this is equivalent to a bull's eye target, 3 feet in diameter, at 600 yards. Sir Thomas remarks that the standard is very low, since an eye with normal vision should be able to count the dots, not at 10 feet, but at 43 feet. At present, therefore, recruits may be accepted who possess less than one-fourth normal vision.

There is no regulation in the English army allowing ametropic soldiers to wear correcting glasses. Sir Thomas Longmore states that the only disadvantage accompanying such permission would be the difficulty of replacing broken lenses when their wearers were on foreign service. The German soldiers, in 1870-71, wore spectacles; and, since then, their use has been sanctioned in the French army. Perhaps when the British mind is emancipated from the thraldom of the red coat, it may give its soldiers fairer play with respect to the use of spectacles. Some day a regimental optician may accompany soldiers on foreign service.

Malingering, or feigned blindness, is stated to be rare in our army, although sufficiently common in the armies of those countries where conscription is in force. If we are to take the two illustrative cases as samples, the British Tommy Atkins does not appear to be so good at deception as he is at fighting. One of the cases is reminiscent of a half-forgotten anecdote. A soldier complained that his sight was very defective. The surgeons were unable to prove that he was shamming. One day he was suddenly ordered by a sergeant to pick up a pin from the floor, where it had been placed at some distance from him; and, taken unawares, he did so. As the text somewhat

naïvely says, "He was sent back to the depot, and made no further complaint of weak sight." The author is not complimentary to his *confrères* when he says that many so-called malingerers are in reality found to be suffering from eye disease which their surgeons have been unable to detect.

The manual is profusely illustrated. Many of the illustrations are excellent, but some are of a fearful and wonderful nature. The frontispiece, representing a section of the anterior hemisphere of the globe of the eye, is, in its way, a masterpiece: the knob-like protuberance on the iris, the wormy ciliary processes, and the aggressively patent posterior aqueous chamber (which is now known to be non-existent as a space) complete a picture which belongs rather to the domain of comedy than to the province of reality.

GENERAL ASTRONOMY.

General Astronomy. By Prof. C. A. Young, Ph.D., LL.D. (Boston, U.S.A., and London: Ginn and Co., 1888.)

PROF. YOUNG is so well known in this country through his researches in solar physics, that he needs no introduction to our readers. The title of his latest work is very comprehensive, but we may at once say that it is not more so than the book itself. Every branch of the subject is touched upon more or less, although no particular branch receives very extended treatment. It is essentially a book for students, "and is meant to supply that amount of information upon the subject which may fairly be expected of every liberally educated person." For an intelligent reading of the book, only the most elementary knowledge of mathematics is necessary, but, as pointed out in the preface, the mental discipline and maturity which usually attend the later years of College life are assumed. The student is warned at the outset that astronomy, notwithstanding its important practical applications, is in the main a subject of intellectual pleasure rather than an economic one.

The general arrangement of subjects is as good as it well can be. Definitions and general considerations come first, then the various instruments are described, and these are followed by the corrections to be applied to instrumental measurements. Succeeding chapters deal with the various phenomena and problems presented by the earth, moon, sun, planets, comets, meteors, nebulæ, and stars. It is not necessary that we should refer in detail to those parts of the book dealing with the "old astronomy." Still, it may be mentioned that the treatment of Kepler's laws and the theory of lunar perturbations is especially good. We may also recommend Art. 253 to the notice of landscape painters who may be in doubt as to the representation of the moon with scientific accuracy. It would be hard to find a better account of this matter than that given by Prof. Young, and it has the great advantage of brevity.

It is in the various departments of astronomical physics that most debatable points arise, and any criticism is naturally directed there. With regard to sun-spots, Secchi's theory, with slight modifications, as previously published in Prof. Young's well-known book on the sun, is regarded as the most probable one. The theory that they are due to falls of cooled materials, however, scarcely receives justice. The objection raised is that it is not in accordance with the distribution of spots in latitude, but Mr. Lockyer has fully explained ("Chemistry of the Sun") how these spot zones may be accounted for by this theory. Obviously, if spots were produced by the fall of meteorites into the sun from any direction whatsoever, and there were no system of regulation, they would be formed all over the surface, and without espect to period. But just such a regulator as is required is to be found in the solar surroundings, and in the system of solar currents, of the existence of which evidence is constantly accumulating. Moreover, by far the greater part of spot-producing material is probably "home-made," consisting of the cool condensed products of the vapours which have been driven out from below. In the face of these explanations, it is difficult to understand why Prof. Young should have dismissed the "downrush" hypothesis with so few words.

Some people find it difficult to believe that a light body like a comet can partake of motion in an orbit just as well as a planet, but these doubters are reminded (p. 407) that a feather falls as freely as a stone in a vacuum, and that this condition holds for space.

The theory that the luminosity of comets is due to collisions between the meteorites of which they are composed appears to find little favour with Prof. Young. He remarks (p. 418) that, "although the *absolute* velocity of the comet is extremely great, the *relative* velocities of its constituent masses, with reference to each other, must be very slight—far too small apparently to account for any considerable rise in temperature or evolution of light in that way." It must not be forgotten, however, that the meteorites must have some relative velocities, owing to the differential attraction of the sun upon the swarm, and that the disturbance thus set up would be increased as the distance from the sun diminished. The number of collisions would therefore vary exactly as the brightness of comets is known to vary, and this argues strongly in favour of the collision theory of luminosity. Prof. Young attempts to get over the difficulty by suggesting (p. 418) that a gas *in the mass* may become sensibly luminous at a much lower temperature than is generally supposed, but this, we fear, is scarcely reconcilable with the kinetic theory of gases.

There is an excellent short account of the zodiacal light on p. 347, but no reference is made to its connection with the aurora, as regards its spectroscopic phenomena and its periodicity. This relation furnishes further important evidence of its meteoritic nature.

Prof. Young has evidently very little sympathy with Mr. Lockyer's new meteoric hypothesis. Only scattered references to it are made, and very little criticism is vouchsafed. The little criticism that there is seems to be based on an imperfect acquaintance with the papers already published. Thus, the collision theory of variable stars is objected to (p. 484) on the ground that it is not consistent with the irregularities in the periods, but Prof. Young is evidently under the impression that this theory limits itself to the case of a single cometic swarm revolving in an orbit round a central swarm, whereas this case was put forward as the simplest possible.

In the chapter on the classification of stars according to their spectra, both Vogel's and Secchi's classifications are given. Now, Prof. Young admits that these are based on the "doubtful assumption" that stars like Sirius and Vega are the hottest, and he further remarks that it is possible for a red star to be younger than a white one. It scarcely seems consistent, therefore, to omit the new classification suggested by Mr. Lockyer, which is the only one that takes into account the probability of there being bodies with increasing as well as with decreasing temperatures. The latter classification is certainly a very new one, but other parts of the book show that Prof. Young must have been acquainted with it.

One remark of Prof. Young's is worth quoting. After stating that there are two Observatories established solely for the study of solar physics (Potsdam and Meudon), he remarks with characteristic straightforwardness that "There ought to be one in this country (America)."

We know of no other book which is so comprehensive and at the same time so well adapted for the use of those who aim at something more than a mere smattering of astronomical knowledge. For the benefit of those whose time may be too limited to take up everything in the book, those parts which may be most conveniently omitted are printed in small type. The language is clear, and to simplify matters there are over two hundred excellent illustrations. Further, as might be expected from the fact that Prof. Young *teaches* astronomy, the book is not diluted with irrelevant matter. A. F.

AN INDEX-CATALOGUE.

The Index-Catalogue to the Library of the Surgeon-General's Office, United States Army. Vol. IX. Medicine (Popular)—Nywelt. Pp. 1054. (Washington: Government Printing Press, 1888.)

THE progress of this *magnum opus* seems irresistible. Year by year the volumes reach us with a regularity that implies strength, and a completeness that indicates a more than mechanical accuracy of work. It still remains, so far as we know, unique among printed catalogues in classifying under subject-headings, such as Mercury, Milk, Neuralgia, &c., not only the books, but also the whole of the signed medical articles in the 3500 periodicals which form the medical press of the world, from Pekin to Paris, from Newfoundland to Uruguay. The newspaper articles are still, as they have always been, collected under the subject-title only, and not under the name of the writer also; for, if the latter cross-cataloguing had been adopted, we should have had more than 300,000 cross-entries, which would have necessitated already two more volumes at least as large as the present; but those articles or essays which the authors have thought it worth while to reprint all come under their names as pamphlets, and this is no inconsiderable number.

This volume includes some names which are embarrassingly popular among medical writers. It needs a clear head to deal with a catalogue of the works of 206 authors of the name of Meyer; but when the librarian comes to Müller, he finds 343 different authors awaiting him with much more voluminous works, and he must be thankful for the great variety of Christian names, and that not more than seven besides the great physiologist contented themselves with the plain Johannes. When we notice that the librarian of the most complete professional library in England has not to do with more than eighteen and thirty-seven authors with these surnames respectively, we can form some rough comparison of their relative completeness; and the student must become aware of what a debt he owes to his Transatlantic *confrère*, who has undertaken and carried through the task of collecting and cataloguing the works of the 494 other medical authors of the same names.

In the first forty-six pages of this volume, the immense collection of facts which had been so well grouped in Vol. VIII. under Medicine, is concluded; and the two longest articles left us are those on the Nervous System, and—perhaps not unnaturally—on New York. That on the Nerves and Nervous System (103 pp.) is one of the most valuable to the student, as such a very large proportion of that rapidly-growing part of medical knowledge is embodied not in books so much as in journalistic and pamphlet literature. The strength of the historic feeling still affecting Mr. John S. Billings and his fellow-workers is shown in the great collection of sixteenth and seventeenth century literature that is to be found under such a heading as Medicine (Popular), and many others. It is very rare nowadays to find in a newly-formed collection, dating from about a quarter of a century ago, any such tendency to accumulate the materials for those great works on the history of disease which we are leaving our successors to write. That is a point towards which the strong modern development of historic research, the earnest inquiry into the origin of species of disease is gradually leading us, but even the great work of Hirsch has left us much to learn and teach, a great field for genius in tracing correctly the broad generalizations in the evolution of the morbid tendencies of men. We are a little surprised to notice the complete absence of the works of Conyers Middleton, which contributed considerably to the understanding of Roman medicine; but we have been much more surprised at the almost unimpeachable way the Index-Catalogue has stood firm in our tests on minute points of very trifling general interest.

Now that these first nine volumes have covered the ground as far as the end of the letter N, it is not unlikely that the work may be finished in five more volumes, and that at Christmas 1893 the enthusiastic student of medicine may be able to possess himself of a work not much smaller than the latest edition of the "Encyclopædia Britannica," containing a catalogue of some 150,000 medical authors, and the titles of about 600,000 of their books, pamphlets, and articles that have been got together in a generation, mainly by the untiring energy of Mr. John S. Billings. A. T. MYERS.

OUR BOOK SHELF.

The Anatomy of Megascolides australis (the Giant Earthworm of Gippsland). By W. B. Spencer. Transactions of the Royal Society of Victoria, Vol. I. Part 1, pp. 1–60, 6 Plates. (Melbourne: Stillwell and Co., 1888.)

THE Royal Society of Victoria, which has hitherto issued only an *octavo* volume of Proceedings each year, will in future publish also Transactions in *quarto*. The present memoir is the first part of this new series; the

style in which it is printed and the excellent plates seem to promise that the Transactions will be quite on a level with any journal published in Europe. The illustrations are, indeed, unnecessarily large; but this cannot be pointed to as a fault—at least by those who are not responsible for the cost.

Prof. Spencer's paper is of considerable interest, particularly that section which refers to the nephridia. *Megascolides*, like *Perichæta* (as was first pointed out by Beddard, not by Perrier, as Prof. Spencer asserts), possesses a ramifying network of nephridial tubes which are continuous from segment to segment, and which open on to the exterior by numerous pores; connected with these there are—in the posterior segments of the body—a pair of large nephridial tubes in each segment, which open internally by a funnel. It is from these latter that the single pair of nephridia per segment of *Lumbricus*, &c., are to be derived; the network of minute tubules, which represents the excretory system of the flatworms, has disappeared in such forms as *Lumbricus*.

Prof. Spencer discusses the much-vexed question of the homologies of the sexual ducts, and concludes that they are not derived from nephridia.

Other points of interest cannot be touched upon in this short notice.

Lectures on Geography, delivered before the University of Cambridge, during the Lent Term, 1888. By Lieut.-General Strachey, R.E., C.S.I., President of the Royal Geographical Society. (London: Macmillan and Co., 1888.)

THESE lectures are published opportunely at a time when it is most desirable that the now almost general effort to further geographical education should be properly directed. They form a short course introductory to the work of the Lectureship on Geography now established in Cambridge, and in them General Strachey describes the aspects of the subject which he considers most suitable for the instruction of students at the University. He thus gives a complete summary of the aims and matter of scientific geography—of geography as a natural science related to other natural sciences, much as mathematics is to physical science. He assumes that students, before going to University, have acquired a general knowledge of geography; and, in passing, he points out that the primary object of the school teaching of geography is to impart an accurate knowledge of the main topographical features of the entire earth, all trivial details being omitted, and suitable instruction being given in the physical, economical, and historical characteristics of important places.

As material for the higher or University teaching of geography, the author practically claims the various branches of science which in recent years have been assembled under the term "physiography"; but he is most successful in showing that the science is not a mere patchwork, but a connected whole; and he sees no reason for abandoning the well-known name "geography." Certainly from many points of view the introduction of the new term has retarded the spread of a knowledge of the science.

An excellent epitome of the growth of our knowledge of the astronomical relations of the earth, and a short account of the methods of projection and orography, prepare the way for the history of geographical discovery. This department is reviewed in a manner at once interesting and philosophical, indicating clearly the close connection between the progress of discovery and the political movements of the world. The influence of the form and movements of the earth on terrestrial phenomena, terrestrial magnetism, our knowledge of the interior of the globe, and the relation of geology to geography, are in turn shortly discussed. The sections on land, sea, and air, and on the history of life and of man, indicate the results of recent investigation, and suggest many points which may well receive much attention from students of geography.

The lectures are written throughout in an agreeable and simple style, and will prove valuable to general readers as an elementary epitome of scientific geography.

F. GRANT OGILVIE.

A Text-book of Elementary Metallurgy for the Use of Students. By Arthur H. Hiorns. (London: Macmillan and Co., 1888.)

WE recently had occasion to notice a useful little work on practical metallurgy by Mr. Hiorns. He has now endeavoured to write a purely elementary treatise on theoretical metallurgy, adapted to the capacity of beginners. The attempt can scarcely be considered successful. In 172 pages printed in large type he deals with the whole of the wide field of metallurgy. This necessitates a very fragmentary treatment. And besides this, errors are so frequent as to render the book quite unsuited for beginners. The following examples may be cited:—The barrel method of amalgamation is stated (p. 90) to be carried on at Freiberg, where it was discontinued twenty-four years ago. One of the seven methods of producing steel is stated (p. 74) to be "by melting raw steel in crucibles." The Coppée coke-oven is described (p. 40) as being of the Appolt type. The coke-oven described (p. 42) as the Simon-Carvès is in reality a Carvès oven. The author appears to be ignorant of the existence of the principality of Catalonia, for the Catalan process is said (p. 54) to be carried on at "Catalan in the Pyrenees."

Altogether, the book compares very unfavourably with the author's work on assaying, and appears to have been hastily written. An illustration of the want of care displayed is afforded by the table of the specific gravities of eighteen metals (p. 11), in which in nine cases the figures differ from those given in the author's companion volume. With a little care, the author could have avoided such statements as—"An analogous compound, 'Boghead' of Scotland, which is a bituminous schist, is richer in bitumen than ordinary coal." Again, manganese, the author states (p. 74), "prevents the separation of carbon in the form of graphite, which is the opposite of silicon." The appendix of examination questions, covering 65 pages, appears to indicate that Mr. Hiorns's intention has been to write a cram-book for the elementary stage of the Science and Art Department's examination in metallurgy. It is, however, doubtful whether a student who made such blunders as occur in this book, would satisfy his examiners.

Weismann's Theory of Variation.

ACCORDING to Weismann ("Die Bedeutung der sexuellen Fortpflanzung für die Selektions-Theorie," Jena, 1886), heredity does not consist in the parent having the power to reproduce offspring in its own likeness, but in the property of the germ (ovum or spermatozoon) in each generation to develop into an individual of a certain invariable type. He starts from the fact that in development the germinal cells are separate from the beginning, are portions separated off from the original fertilized ovum. He distinguishes between actual and virtual differences. Different individuals developed from successive remnants of a given *Keimplasma* may show actual differences; but these are due to the action of conditions affecting the particular individual during its development and life: these differences are not inherited, cannot possibly be transmitted to the offspring, because

the germ-cells in this altered individual, which were originally continuous with the germ-cell from which the individual itself developed, remain entirely unaffected by the action of the conditions on the body, and when they begin to develop have exactly the same properties as the germ-cell in the generation preceding.

Heredity, then, according to Weismann, is simply the property possessed by a germ to develop into exactly the same type in each successive generation. He says: "Ich stelle mir vor, dass die Vererbung darauf beruht, dass von der wirksamen Substanz des Keimes, dem Keimplasma, stets ein Minimum unverändert bleibt," &c.

As the action of conditions can give rise to no hereditary individual differences, these must be due to some other cause. This cause, Weismann says, is to be found in sexual, or, as Haeckel calls it, amphigonous, reproduction. Sexual reproduction consists in the fusion of two complementary germ-cells or of their nuclei: each of these germ-cells has a specific molecular structure, on which depend the hereditary tendencies of the organism whence the germ-cell is derived. Thus, in fertilization, two hereditary tendencies are mingled, and thus the offspring does not resemble exactly either of its parents, but combines the characters of each together.

In order that there shall be no ambiguity about his argument, Weismann precisely states what, according to his view, and, as he believes, in actual fact, occurs in monogonous reproduction, *i.e.* in parthenogenesis, where there is only one parent instead of two. If, in a species reproducing parthenogenetically, all the individuals were perfectly similar, all the descendants throughout any number of generations would continue similar, leaving aside evanescent differences due to conditions, and which are not hereditary. In such a case no selection, Weismann says, would be possible, and therefore no evolution in any direction.

"Processes of selection in the proper sense of the word, those which produce new characters by the gradual increase of characters already present, are not possible in species which reproduce asexually."

"If it were once proved that a species reproducing itself solely by parthenogenesis had been transformed into a new species, thereby it would be proved at the same time that other causes of modification exist than processes of selection, for by selection the new species could not have been formed."

But with sexual reproduction it is quite otherwise. Weismann points out that no two individuals of different generations could ever be similar where reproduction is sexual, and even the individuals of one family, born of the same two parents, would not be similar, because the various tendencies in the parents are present in different intensities at different times, though he gives no reason for this assumption.

According to Weismann, the individual hereditary differences so produced are the basis on which selection acts; and these differences thus explained, summed up or combined in different ways by selection, give a complete and satisfactory explanation of all organic evolution.

Now, let us examine this theory a little. For the sake of simplicity we will in most cases consider the effect of the supposed processes on one organ. In the first place, what ground is there for assuming that *Vermischung* would ever cause an increased development in the offspring of an organ possessed by the parents? Heredity, as understood by Weismann, is nothing more than the property in the germ-cell of developing into an individual like that from which it was derived. If each parent possessed a given organ in the same degree of development, a degree unaffected by external conditions, then both the ovum and the spermatozoon will, on this view of heredity, have the property of developing into an individual with the same organ developed to the same degree. When the two properties are combined by fertilization, the fertilized ovum ought to have the property of developing this character with still greater certainty, but why should it have the property of developing the character to a higher degree than that reached in either parent? By *Vermischung*, in its literal sense, the union of the two hereditary powers cannot have this effect. If by *Vermischung* it is meant that the offspring is intermediate between the two parents, then the mean of two equal characters is the same character again. And if this is what Weismann means by *Vermischung*, then a character developed to a certain degree in one parent, and not at all in the other, would in the offspring be developed to exactly half the degree in which it existed in the one. And so on. But it is obvious that in this way no increase of any character could ever occur.

But of course *Vermischung* may mean something else. It may mean that the hereditary powers of ovum and spermatozoon are added together, that the result of copulation between the germ-cells is not the mean, but the sum, of the properties of both. In this case, evolution would be extremely rapid, for each child would be equal to both its parents rolled into one. If each parent, say, among cattle, had horns equally well developed, the offspring would have horns twice as big. And it is obvious that in this way no *decrease* could ever occur, for if one parent had an organ developed and the other had no trace of it, the offspring would have it in the same degree as the one.

Now, it seems to me that, if *Vermischung* does not mean either of these things, there is only one other meaning it can have, and that is, that the hereditary powers of the copulating germ-cells reinforce one another to some extent, but not to such an extent that the result is equal to their sum. If this be the meaning, then there can never be any decrease in a character once formed. For, if every individual of a species possesses a certain organ, let us take the hind-legs in a mammal, then if two individuals which have these organs less developed than any other individuals in the species, copulate, the offspring resulting must have hind-legs better developed than either of them. Thus the whale could never have been evolved.

It follows, therefore, that, on Weismann's theory of variation, evolution is impossible. And as acquired characters are not inherited, no other theory of variation can be discovered. Therefore evolution is impossible altogether: the extremes meet, and the Darwinian principle overstrained goes rather to prove the fixity of species than their plasticity.

J. T. CUNNINGHAM.

Mr. Howorth on the Variation of Colour in Birds.

ALLOW me to assure Mr. Howorth that I have no theory to maintain. I simply called attention (*supra*, p. 318) to an overlooked hypothesis, propounded long ago, and, so far as I know, still unrefuted. Neither have I any wish to argue the question. Indeed, controversy about it is happily almost impossible, since he admits the chief fact of which I reminded him to be what he now terms (*supra*, p. 365) "an elementary postulate"—an expression far stronger than I should venture to use; but had he before shown any disposition to recognize it, my remarks had not been written. On the contrary, he implied (*supra*, p. 294) that it was a recent discovery, as it certainly appears to have been to him. I trust he will excuse me for having pointed out its want of novelty, just as he seems to excuse Prof. Geikie for pointing out the antiquity of his views as to the former climate of Siberia; and at the same time I have to ask Mr. Howorth's pardon for demurring to some of the assertions in his last communication, especially that as to the avifauna of Siberia having been "worked out from end to end." I dare not hope to see the day when this shall be done; but then I am not of a sanguine temperament.

I take this occasion to mention that in line 3 of the second paragraph of my former letter (p. 318) the word "Russian" was omitted before "explorers and naturalists." Of course it will be understood to cover Poles, as well as all those foreigners who were employed by the Russian Government.

ALFRED NEWTON.

Currents and Coral Reefs.

MAY I be allowed space to call attention to a remarkable fact relating to the growth of coral reefs, which has apparently (as far as I can ascertain) had no explanation, and which might assist materially in the elucidation of some problems relating to ocean currents about which—although the broad facts are known—a great deal of doubt exists? It might also give us some idea of the flow of submarine currents, the direction of which it is very difficult to determine.

It will be observed that in all coral formations there are in some places remarkable extensions of them from the land, which is not accountable for by supposing the depths only to be shallower in those directions, and the only alternative we have then is that the food supply must come chiefly from that direction, and this supply could only be kept up by currents striking the reef at these points. To give an instance of this, I might

refer to the Bermudas as affording a good example of this action: there, will be seen a great extension of the reefs on the north-west side, and reefs are forming on the south-west—the Challenger and Argus Banks; and it should be noticed that these are on the edge of the Gulf Stream, and also that there are considerable eddy currents here which would cause a constant supply of food to be brought to these parts of the islands; whereas the conditions round the other parts of the islands are not so favourable, and consequently there is no extension of the reefs.

I have been much puzzled by the curious formations of coral reefs in the harbours of Suakim and Massaua and also round the island of Key West; and I have been unable to account for the peculiarities in the shape of the fringing reefs except by an hypothesis such as the above, in these cases the tidal currents taking the place of the ordinary currents.

DAVID WILSON-BARKER.

The Earthquake in Lancashire.

ON Sunday, February 10, at 10.40 p.m., there was felt here a shock as of a heavy falling body, which caused the windows to rattle loudly. Two or three seconds later a second thud-like shock was felt of somewhat greater intensity than the first. This was followed by gentle but distinct tremors, lasting, perhaps, twenty or thirty seconds more. The weather was calm at the time; the heavy snow-fall had just ceased; barometer rising after the considerable depression which had occurred during the day. The sounds appeared to come from the north-east, as if a heavy body had fallen outside a window having that aspect. Several other persons name the same quarter as that whence the sounds seemed to proceed, and in one instance, in a room having several aspects, there was a distinct statement that the north windows were the first to shake, then those in the south-west, thus indicating a possible line of movement. In most cases no direction was noted. Persons down-stairs thought something had fallen above, those in the upper stories rushed down to see what had happened below. Others, again, felt surrounded by the unwonted movement. A heavy slip of snow from the roof seemed to occur, as first thought, to most, then a colliery explosion—there are two coal-beds near—and finally an earthquake.

The chief physical effects observed here, beside the general vibration, were a violent shaking of windows, the rattling of glass and crockery, such as bed-room ware. Suspended gas-shades and pictures on walls swung as if with the wind. The doors of rooms and cupboards opened and shut, one or two ornaments fell from their brackets, and the floor is described as "rising." Most of those who slept were awakened, and seemed to suffer more alarm than those who had not retired. The movements had apparently been more severely felt by them, and they describe their beds as "rocking," and themselves being almost thrown out. None of our telephones were affected. Substantial buildings seemed less affected than those less solidly built. The various observers quoted were all in a good position to note what occurred.

T. R. H. CLUNN.

The County Asylum, Prestwich.

Can Animals count?

UNDER this heading, Sir John Lubbock, in his recent interesting book on "The Senses of Animals," gives several instances of apparent counting in the case of insects. He says:—

"One species of Eumenes supplies its young with five victims, one ten, another fifteen, and one even as many as twenty-four. The number is said to be constant in each species. How, then, does the insect know when her task is fulfilled? Not by the cell being filled, for, if some be removed, she does not replace them. . . . In the genus Eumenes, the males are smaller than the females. . . . In some mysterious manner the mother knows whether the egg will produce a male or a female grub, and apportions the quantity of food accordingly. She does not change the species or size of her prey; but if the egg is male, she supplies five, if female, ten, victims. Does she count? Certainly this seems very like a commencement of arithmetic."

Now, it seems to me that this can be explained in a far simpler and more probable manner than by supposing that insects have any power of counting. I think we may safely consider—

(1) That a certain *average amount* of food is required in each case.

(2) That a certain *average time* is required by the insect to collect this food.

(3) That the eggs of the insect follow one another at a *certain rate*, over which she has little or no control.

(4) That the eggs which are to produce *males*, being smaller, take less time to form, and follow at shorter intervals, than do those which are to produce *females*.

Now take the case of the Eumenes which provides ten victims. She makes the cell, and goes on adding caterpillars until the egg comes to maturity and is laid, and the cell finished off. She then repeats the process, laying the egg when it comes to maturity, as before; the interval between the laying of one egg and the next being long enough, on the average, to provide ten victims, or in case the egg is to produce a male, the smaller interval only allows of five being provided.

There is thus no need to credit the insect with any power of *counting*, or of knowing beforehand anything about the sex of the eggs. It is merely another instance of the perfect way in which, by the process of evolution, means are adapted to ends.

The same explanation applies to the cases mentioned on pp. 254–56 of "The Senses of Animals." The bee laboured to fill the cell (in which a hole had been made so that the honey ran out again), until, "when she had brought the usual complement of honey, she laid her egg, and gravely sealed up the empty cell: . . . in some mysterious manner the bee feels when she has provided as much honey as her ancestors had done before her, and regards her work as accomplished."

I should suggest that the bee merely goes on bringing honey until the *egg is ready*. She then starts another cell, and goes through the same routine until the next egg is ready, and so on; the average amount of honey collected being proportional to the interval between the laying of one egg and the next. According to the theory of evolution, this interval is just sufficient for enough food to be provided for the use of the grub.

St. Olave's Grammar School, Southwark.

Weight and Mass.

MR. ANDREW GRAY need only turn to p. 355 of the current number of NATURE to find an example of an engineer's dynamical terminology, and it would tend to some useful result in this interminable discussion if he would point out in what manner the language of the engineer must be modified to suit the requirements of the *precisionist*. We find on p. 355 "the working pressure is 175 pounds per square inch," "the total weight of the engine in working order is 37 tons," "probably having about 30 tons useful weight for adhesion," and so on.

Let Mr. Andrew Gray point out what he considers the errors of the engineers. Ought the engineer to say, "the working pressure is 175 pounds weight (or pound weights?) per square inch," "the total mass of the engine is 37 tons," "probably having about 30 tons useful (? mass or weight) for adhesion."

On former occasions in this controversy I have attempted to elicit definite expressions of opinion on the terminology of similar definite actual dynamical problems, but hitherto without success.

Detonating Meteor.

MR. MAXWELL HALL's letter on this subject is of considerable interest. When the great meteor-shower of November 11–15 was traced to the orbit of the comet of 1866, it was natural to suppose that the fine fire-balls which occur about this period belong to the same series. Plainly, however, the Jamaica fire-ball recorded by Mr. Hall had a southern radiant far distant from that of the well-known Leonid shower. The same thing was noticed in the case of the shower of aërolites which fell in France on the 13th of November, 1835, the motion being south-east to north-west; and in many other instances in which fire-balls or aërolites were observed within this period the phenomena seem to agree best with a southern radiant, though the descriptions are not as full as we could desire. It thus appears highly probable that almost concident in time with the well-known Leonid shower there is another shower, rich in fire-balls and aërolites, proceeding from a southern radiant. I hope it will be watched from southern stations in future.

Dublin, February 15.

Ice Planed.

PERHAPS it will interest some of those who are investigating the structure of different kinds of ice to know how blocks of it may, with ease and certainty, be shaped into bars and plates of any required dimensions. Some time ago I had occasion to prepare some specimens for experimental purposes. At first my success in working the ice into the required form was not very great, for it cracked in all directions under the action of a saw or chisel. After trying many devices, I at last resorted to a joiner's plane; a tool which may have been tried for the purpose before, though I do not remember having seen its use suggested. With it ice may be planed with greater ease than wood, the shavings coming away in powder, and leaving the ice with a clean, bright, sound surface. R. M. DEELEY.

39 Caversham Road, Kentish Town, N.W., February 16.

REPETITION OF HERTZ'S EXPERIMENTS, AND DETERMINATION OF THE DIRECTION OF THE VIBRATION OF LIGHT.

SINCE last October, Prof. Fitzgerald and I have been repeating some of Prof. Hertz's experiments, as occasion allowed; and it may not be without interest at the present time to give a short account of our work.

The first experiment tried was the interference of direct electro-magnetic radiation with that reflected from a metallic sheet. This experiment is analogous to that known in optics as "Lloyd's experiment."

The radiation was produced by disturbances caused in the surrounding space by electrical oscillations in a conductor. It was arranged in this wise. Two thin brass plates, about 40 centimetres square, were suspended by silk threads at about 60 centimetres apart, so as to be in the same plane. Each plate carried a stiff wire furnished at the end with a brass knob. The knobs were about 3

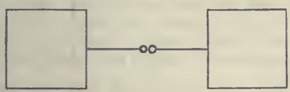

FIG. 1.

millimetres apart, so that on electrifying one plate a spark could easily pass to the other. This spark, as is well known, consists not simply of a transference of half the electricity of the first plate to the second—though this, which is the final state, is all that is observable by ordinary experimental methods—but the whole charge passes across to the second plate, then returns, and so on, pendulum-fashion, the moving part of the charge becoming less each time, till finally brought to rest, the energy set free at sparking being converted partly into heat in the wire and air break, partly into radiation into space, or in terms of action at a distance in inducing currents in other bodies.

The time taken by the charge to pass over to the second plate and to return, is a definite thing for a given sized arrangement, and depends on the connection between them. If C be the capacity of the plates, and I the self-induction of the connection, the time of each complete oscillation equals $2\pi\sqrt{CI}$. The time in the case of the particular arrangement used is, speaking roughly, about the 1/30,000,000 of a second.

If there be conductors in the neighbourhood of this "vibrator," currents will as usual be induced in each on every passage of the charge between the plates, each passage serving simply as a primary current.

Now, speaking briefly, the whole object of the experiment is to find out if these induced currents take place simultaneously in conductors situated at various distances from the primary current, and if not, to determine the delay. In order to do this we must, in the first place, be possessed of some means of even ascertaining that these currents occur, all ordinary methods being inadequate for detecting currents lasting only for such exceedingly short periods as these do. By devising how to determine the existence of these currents, Hertz made the experiment possible.

His method depends on the principle of resonance, previously suggested by Fitzgerald, and his current-observing apparatus is simply a conductor, generally a wire bent into an unclosed circle, which is of such a length that if a current be induced in it by a passage of a charge across the "vibrator" the return current or rush back of the electricity thus produced in the ends of the wire occurs simultaneously with the next impulse, due to the passage back across the "vibrator."

In this way the current in the "resonator" increases every time, so that at last the end charges, which are always of opposite sign, grow to be so great that sparks will actually occur if the ends of the wire are brought near together. Thus, Hertz surmounted the difficulty previously experienced by Fitzgerald when proposing electro-magnetic interference experiments.

The time of vibration in this circle is, as before, $2\pi\sqrt{CI}$, but on account of difficulties in calculating these quantities themselves, the length of the wire is most readily found by trial. To suit the "vibrator" we used, it was about 210 centimetres of wire No. 17. The ends of the wire were furnished with small brass knobs, which could be adjusted, as to distance between them, by a screw arrangement, the whole being mounted on a cross of wood for convenience in carrying about.

At first sight the simplest "resonator" to adopt would seem to be two more plates arranged similarly to the "vibrator," but it will be seen on consideration that it would not do, because no break for seeing the sparking could be put between the plates, for, if it were, the first induced current would be too feeble to jump the break, so that the reinforcement stage could never begin.[1]

The charging of the "vibrator" was effected by connecting the terminals of an induction-coil with the plates. In this way a continuous shower of sparks could be obtained in the resonating circle.

The circle in the interference experiment was held in the horizontal plane containing the axis of the "vibrator," the ends of the circle of wire being in such a position that a line joining the knobs was at right angles to the "vibrator." In this position only the magnetic part of

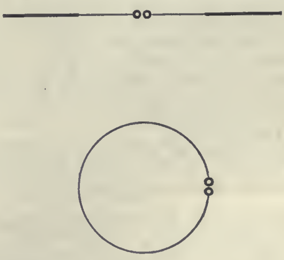

FIG. 2.

the disturbance could affect the circle, the "magnetic lines of force," which are concentric circles about the axis of the "vibrator," passing through the "resonator" circles.

When the knobs of the circle are brought round through 90°, so as to be parallel to the "vibrator," the electric part of the disturbance comes into play, the electric lines of force being, on the whole, parallel to the axis of the "vibrator." The electric action alone can cause a forced vibration in the knobs, even when the connecting wire is removed, if placed fairly close to the "vibrator."

[1] However, two pairs arranged in line, the pairs connected by a wire, could probably be got to spark between the centre plates.

Again, if the knobs be kept in this position, but the circle be turned through 90°, so that its plane is vertical, only the electric part can act, the magnetic lines of force just grazing the circle. In this way the disturbance can be analyzed into its magnetic and electric constituents.

Lastly, if the knobs be in the first position, while the circle is vertical, there will be no action.

To exhibit these alone forms an interesting set of experiments. It also makes a very simple and beautiful experiments to take a wire twice as long and fix it instead of the first, but with two turns instead of one; no sparking is then found to occur. This is, of course, quite opposed to all ordinary notions, double the number of turns being always expected to give double the electromotive force. In this way the reality of the resonance is easily shown.

Interference Experiment.—The sparking, of course, becomes less intense as the resonator is carried away from the "vibrator," but by screwing the knobs nearer together it was possible to get sparks at 6 and 7 metres away. On bringing a large sheet of metal (3 metres square, consisting of sheet zinc) immediately behind the "resonator," when in sparking position, the sparking increased in brightness, and allowed the knobs to be taken further apart without the sparking ceasing; but when the sheet was placed at about 2·5 metres further back, the sparking ceased, and could not be obtained again by screwing up the knobs. On the other hand, when the sheet was placed at double this distance (about 5 metres), the sparking was slightly greater than without the sheet.

Now these *three* observations can only be explained by the interference and reinforcement of a direct action of the "vibrator" with one reflected from the metallic sheet, and in addition by the supposition that the action spreads out from the vibrator at a finite velocity. According to this explanation, in the first position the reflected part combines with the direct and reinforces its effects. In the second position—that of no sparking—the reflected effect, in going to the sheet and returning, has taken half the time of a complete vibration of the "vibrator," and so is in the phase opposite to the incident wave, and consequently interferes with it.

If it were possible to tell the direction of the current in a "resonator" at any moment, then, by employing two of them, and placing one just so much beyond the other that the currents induced in them were always in opposite directions, we would obtain directly the half-way length. Now, by reflection we virtually are put in possession of two "resonators," which we are enabled to place at this distance apart, although unable to tell more than whether there be a current or not.

The distance from the position of interference to the sheet is a quarter of the wave-length, being half the distance between these simultaneous positions of opposite effects.

In the third position the reflected wave meets the effect of the next current but one in the "vibrator" after the current it itself emanated from, and since these two currents are in the same direction their effects reinforce each other in the "resonator." This occurs at half the wave-length from the sheet.

The first two observations alone could be explained by action at a distance, by supposing the currents induced in the metallic sheet to oppose the direct action in the "resonator" everywhere, and by also supposing that, in the immediate neighbourhood of the sheet, the direct action is overmastered by that from the sheet, while at 2·5 metres away the two just neutralize each other.

On this explanation, at all distances further the direct action should be opposed by that from the sheet, so that the fact of being increased at 5 metres upsets this explanation. Again, behind the sheet, evidently on this supposition, the two actions should combine so as to increase the sparking, but instead of this the sparking was found to cease on placing the sheet in front of the "resonator."

In performing these experiments the "resonator" circle was always placed in the position in which only the magnetic part of the disturbance had effect. Hertz has also used the other positions of the resonating circle, whereby he has observed the existence of an electric disturbance coincident with the magnetic one, the two together forming the complete electro-magnetic wave.

Ordinary masonry walls were found to be transparent to radiation of this wave-length—that is, of about 10 metres—and some visitors to the opening meeting of the Dublin University Experimental Society, last November, were much astonished by seeing the sparking of the resonating circle out in the College Park, while the vibrator was in the laboratory.

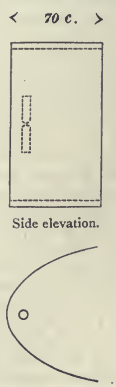
Attempts were first made last December to obtain reflection from the surface of a non-conductor, with the hope of deciding by direct experiment whether the magnetic or electric disturbance was in the plane of polarization; that is, to find out whether the "axis of the vibrator" should be at right angles to the plane of reflection or in it, when at the polarizing angle, for obtaining a reflected radiation. It is to be observed that in these radiations the electric vibration is parallel to the "axis of the vibrator" while the magnetic is perpendicular to it, and that they are consequently polarized in the same sense as light is said to be polarized.

Two large glass doors were taken down and used for this purpose, but without success; and until lately, when reflection from a wall was tried, the experiment seemed unlikely to be successful.

In working with the glass plate, the resonator circle was first placed so that the "vibrator" had no effect on it. Then the glass plate was carried into position for reflection, but without result, though even the reflection from the attendants moving it was amply sufficient to be easily detected.

To obviate a difficulty arising from the fact that the wave was divergent, we decided to try Hertz's cylindrical parabolic mirrors, for concentrating the radiation. Two of these were made with sheets of zinc nailed to wooden frames, cut to the parabolic shape required.

In the "focal line" (which was made 12·5 centimetres from the vertex) of one of these, a "vibrator" was



Side elevation.

Fig. 3.—Plan.

placed, consisting of two brass cylinders in line, each about 12 centimetres long and 3 centimetres in diameter, rounded at the sparking ends.

In order that the "resonator" wire may lie in the "focal line" of the receiving mirror, it has to be straight;

this necessitates having two of them. They each consist of a thick wire 50 centimetres long, lying in the "focal line," and of a thin wire, 15 centimetres long, attached to one end at right angles, and which passes out to the back of the mirror through a hole in the zinc, where the sparking can be viewed, without obstructing the radiation in front. The total length of each "resonator" is about two wave-lengths, the wave-length being about 33 centimetres, so that it may be that there are two vibrating segments in each of these "resonators."

With this apparatus it is possible to deal with definite angles of incidence. No effect was obtained with glass plates using these mirrors, whether the "vibrator" was perpendicular to the plane of reflection or in it. But with a wall 3 feet thick reflection was obtained, when the "vibrator" was perpendicular to the plane of reflection; but none, at least at the polarizing angle,[1] when turned through 90° so as to be in it.

This decides the point in question, the magnetic disturbance being found to be in the plane of polarization, the electric at right angles. Why the glass did not reflect was probably due to its thinness, the reflection from the front interfering with that from the back, this latter losing half a wave-length in reflection at a surface between a dense and a rare medium; and, as Mr. Joly pointed out, is in that case like the black spot in Newton's rings, or more exactly so, the black seen in very thin soap-bubbles. Hertz has pointed out several important things to be guarded against in making these

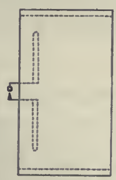


Fig. 4.

experiments. Ultra-violet light, for example, falling on the "vibrator," prevents it working properly, the sparking in the resonator ceasing or becoming poor. Also, the knobs of the "vibrator" must be cleaned, of burnt metal, and polished every quarter of an hour at least, to prevent a like result.

Both these effects probably arise, as suggested by Mr. Fitzgerald, from a sort of initial brush discharging (either ultra-violet light or points being capable of doing this), which prevents the discharging impulse being sufficiently sudden to start the oscillation in the "vibrator." For, to start a vibration, the time of impulse must be short compared with the time of oscillation. These precautions, therefore, become especially needful when working with small-sized "vibrators." Possibly, charging the "vibrator" very suddenly, after the manner of one of Dr. Lodge's anti-lightning-rod experiments, would save the irksome necessity of repeatedly cleaning the knobs of the "vibrator."

Several important problems seem to be quite within reach of solution by means of these Hertzian waves, such as dispersion. Thus, it could be tried whether placing between the reflector and the "resonator" conducting bodies of nearly the same period of vibration as the waves used would necessitate the position of the "resonator" being changed so as to retain complete interference. Or again, whether interspersing throughout the mass of a large Hertzian pitch-prism conductor with nearly the same period would alter the angle of refraction. In some such way as this, anomalous dispersion, with its particular case of ordinary dispersion, may yet be successfully imitated.

[1] Slight reflection was obtained at an incidence of 70°.

The determining the rate of propagation through a a large tile, or sheet of sandstone, could be easily made by means of the interference experiment, by placing it between the screen and the "resonator."

Fred. T. Trouton.

THE SCHOOL OF FORESTRY AT DEHRA DOON, INDIA.

Last year we gave an account of the newly-established School of Forestry at Cooper's Hill, the first of the kind in the United Kingdom, and explained what kind of instruction was there given, and how it was suited to the training of officers for the Indian Forest Department. We now propose to say something of its brother in India—an elder brother, indeed, by some eight years—the School at Dehra Doon, in the North-Western Provinces, now engaged in the education of those who may, not inaptly, be called the non-commissioned officers of the Department. The Dehra Doon is a long valley, which lies at the foot of that portion of the Himalaya which stretches between the great rivers Jumna and Ganges. It is shut off from the great Gangetic plain by a range of hills called the "Siwaliks," known well to all students of palæontological geology as the range in which were found the wonderful series of bones of extinct mammals described by Messrs. Falconer and Cautley. The valley itself lies about 2000 feet above the level of the sea, possesses a beautiful climate free from the blasts of the hot winds which, in April to June, sweep over the plains to the south of it; and is further known historically as having been the site of the first experiments made by the Indian Government in growing the tea-plant, experiments which proved its suitability to India, and made the Doon the fatherland of the great Indian tea industry—an industry which has gradually increased to such an extent that the exports of tea from India and Ceylon now very nearly rival in amount those from the Chinese Empire. Centrally situated in this beautiful valley, among plantations of tea, forests of sál-wood, and groves where the deodar of the Himalaya may be seen alongside of the mango, typical of the Indian plains, and feathery bamboos raise their heads from an undergrowth in which wild or semi-wild roses thrive with luxuriance, lies the town of Dehra Doon, the head-quarters of a Deputy-Commissioner, of the offices of the great Trigonometrical Survey of India, of a regiment of Ghoorka troops, and of the body-guard of the Viceroy. It is rather a straggling town, like most similar Indian stations; but, centrally situated and surrounded by gardens, is found the Forest School, of which we wish to convey some idea to our readers. The School was first started, in 1878, by the exertions of the then Inspector-General of Forests, now Sir Dietrich Brandis, K.C.I.E., and the first Director was Lieut.-Colonel F. Bailey, of the Royal Engineers.

At present the Director is Mr. W. R. Fisher, B.A. of Cambridge University, who is assisted by a Professor of Forestry, Mr. E. E. Fernandez, and a Professor of Geology and Chemistry, Dr. H. Warth. Mr. Fisher himself lectures on forest botany, while other officers, attached to the School for the management of the adjacent forests, teach mathematics, forest law, forest entomology, and surveying, the teaching of the last-named subject being especially fostered by the presence, in the same building, of the office of the Forest Survey, which is now engaged in the preparation of careful detailed maps of the great forest estate which Government possesses in India, and which bids fair to become, not only by its agricultural and climatic effects, but by its financial success, one of the most valuable of the revenue-yielding departments of the Empire.

Attached to the School is a well-equipped museum, containing a magnificent collection of accurately-named

Indian woods; an herbarium, a chemical laboratory, and a meteorological observatory; while the forests of three districts are attached to the School as a training-ground, in which the young students may learn, by personal and actual experience, the conduct of forest operations in the field. The students are usually selected in the different provinces by the Conservators of Forests, and are generally young officers who have seen already some preliminary service. Several have been deputed by the chief native States, such as Mysore and Baroda, and this shows the spread that an enlightened forest policy is making in the country. There are, besides, a number of independent students, who study in the hope of obtaining appointments if successful, either in the British territory or in the native States.

Two courses of study are carried on at the School, the higher in English, leading up to the ranger's certificate, which qualifies the students who succeed in obtaining it for the appointment as "Forest Ranger," on salaries rising from Rs. 600 to Rs. 3000 yearly; the lower, in Hindustani, leading to the forester's certificate, which qualifies the holder for appointments of from Rs. 240 to Rs. 480 per annum. The ranger's course lasts twenty-one months, of which eight are spent in theoretical instruction, and the rest in practical work in the field. The subjects taught are forestry, botany, the elements of zoology, chemistry, physics, geology, mathematics, and surveying, with elementary engineering, such as road-making and the construction of forest export works, and forest law. The forester's course lasts sixteen months, four in theoretical study, and the rest in the field, and the subjects taught are elementary forestry and botany, mathematics, surveying and plan-drawing, and departmental procedure.

The students wear a neat uniform of *kharki*, drill with a turban or helmet, and they are regularly exercised in drill, most of the European and Eurasian students, however, preferring to join the Dehra Doon Corps of Mounted Infantry. When on tour in the forests on practical instruction, each has a small tent, with furniture of a camp-table, chair, and bedstead, and some of them amuse themselves occasionally in sport, one student last year distinguishing himself by carrying off the first prize for shooting in the province.

The forests attached to the School Circle consist of those of the Dehra Doon, Saharanpore, and Jaunsar Forest Divisions. The two former contain chiefly forests of the sál tree (*Shorea robusta*), the chief gregarious tree of India, and the most valuable timber, for building purposes, after teak. They occupy respectively the northern and southern slopes of the Siwalik Range, and are carefully managed as training forests. The Dehra Doon forests are now being worked under a working plan prepared by Mr. Fernandez, the Professor of Forestry. These forests had, till some twenty years ago, been very badly treated, so that at present the older portion of the stock consists chiefly of trees which are crooked and unsound, the good and sound ones having previously been all cut out to provide sleepers for the East Indian, and Sind, Punjab, and Delhi Railways. The present working plan provides for a temporary rotation of twenty years, during which (1) all the old, unsound, and crooked sál trees which can be cut without letting in too much light are removed; and (2) all trees of the less valuable kinds that are not required for shade are cut away. These operations have now been carried on for a few years with the most beneficial results, for the ground is being rapidly covered with good and straight saplings and coppice shoots of sál. The forest operations, the selection of the trees to be cut, and their marking and enumeration, are all done by the students themselves, so that in this way they obtain a valuable amount of practical experience.

The forests of Jaunsar lie on the hills of the outer Himalaya at an elevation of some 5000 to 10,000 feet, and consist chiefly of coniferous trees. The deodar cedar (*Cedrus Deodara*) is, of course, the most valuable of these; then come the pines, the "kail" (*Pinus excelsa*), which so often accompanies the deodar, and the "chir" (*Pinus longifolia*), which forms gregarious forest at the lower elevations. The silver and spruce firs (*Abies Webbiana* and *Smithiana*) also occur, as well as oaks (*Quercus incana*, *dilatata*, and *semicarpifolia*) and other temperate trees. These forests are also carefully treated under working plans, and in them the students of the School learn the management of coniferous forests, the extraction of timber by roads and slides, the planting of blanks in the forest, and the measures necessary for protection against fire and frost.

At the end of their course, and on obtaining their certificates, the students return to the provinces from which they were sent, qualified to carry out ordinary forest works in their own country; and some of them have already obtained promotion into the higher staff of the Department as the reward of their good work, industry, and energy.

The Forest School at Dehra Doon may thus be said to be doing an excellent work, a work which cannot fail to have the best possible effect in the country, and to show the truth of Sir Edwin Arnold's saying that "the Forest Conservancy carried out by the British 'Râj' is one of the greatest benefits to the peninsula."

Soon, perhaps, the extension of forest work will necessitate the establishment of other or branch establishments in Madras, Burmah, and elsewhere; but it is to Dehra Doon that all will look up as the pioneer of scientific forest teaching for the natives of our great dependency.

THE GIANT EARTHWORM OF GIPPSLAND.

THE recently-issued first part of the Transactions of the Royal Society of Victoria contains an elaborate essay (of which we have something to say elsewhere to-day) by Mr. Baldwin Spencer, the newly-appointed Professor of Zoology in the University of Melbourne, on the anatomy of the Giant Earthworm of Gippsland, the largest earthworm yet known. This worm, of which some examples attain to the extraordinary length of six feet, was first described by Prof. McCoy in 1879, and named *Megascolides australis*. It belongs to a peculiar Australian group, of which five species are now known. Mr. Spencer gives us the following general account of its habits:—

Of all the species of *Megascolides* yet known, this one seems to be the largest, and is apparently confined to Gippsland; it is, when found at all, somewhat abundant, and lives principally on the sloping sides of creeks. At times it is found beneath fallen logs, and may be turned out of the ground by the plough.

When first seeking it, we were somewhat puzzled by some of those who were evidently well acquainted with the worm assuring us that the entrance to its burrow was indicated by a distinct "casting"; whilst others, evidently equally well acquainted with the animal, were quite as positive in asserting that it never produced any "casting." Whilst searching, we found what I believe to be the explanation of the contradictory statements, and soon discovered that the surest test of the presence of the worm underground was a very distinct gurgling sound, made by the animal retreating in its burrow when the ground was stamped upon by the foot. When once heard, this gurgling sound is unmistakable, and we at once learnt to regard it as a sure sign of the worm's presence.

The worm very frequently lives in ground riddled by the holes of the land-crab, as it is popularly called; this animal has a small circular burrow leading down to a

chamber hollowed out underneath containing a pool of water, and through these chambers the worms' burrows frequently pass. The "crab" almost invariably has a large conical "casting" at the entrance to its hole, and may raise this to a height of even a foot and more; but the true worm-burrow never, so far as yet observed, has any "casting" at its entrance, and all trace of this is wanting where the crab-holes are absent. The very frequent association of the "crab" and worm leads to the idea that the latter forms a cast; but one of the most noticeable features of the ground, which is at times riddled with worm-burrows only, is the entire absence of "castings." What the worm does with the immense quantity of earth which it passes through its body I cannot at present say, and it must also be noticed that only on very rare occasions can any trace be detected of leaves dragged down into the burrows.

It is no easy matter to extract the worm without injury, owing to its length, the coiling of the burrow, the rapidity of movement which it possesses when underground, and its power of distending either the anterior or posterior ends of the body, or both.

Directly the burrow is laid bare, the worm is seen gliding rapidly away, often producing the curious gurgling sound as it passes through the slimy fluid always

Megascolides australis. Drawing of McCoy's figure ("Prodr. Zool. Vict.," i. pl. vii.).

present in a burrow containing the living animal. Sooner than allow itself to be drawn out, it fixes, if held in the middle, both ends of its body by swelling them out till they are tightly jammed against the sides of the burrow; under these circumstances, pulling merely results in tearing the body. The worm has been described as brittle, but this term is most inapplicable, as its body is very soft, and capable of a great amount of extension before tearing. Its curious smell, when living, resembling somewhat that of creosote, has been already observed by Prof. McCoy, and, when dead, it is worse than ever, and very strong and characteristic; the body, in decaying, passes into an oily fluid, which, we were assured by one or two old natives of the district, is very good for rheumatism. Fowls refuse to touch the worm, living or dead.

When held in the hand, the worm, in contracting its body, throws out jets of a milky fluid from its dorsal pores to a height of several inches; if the burrow be examined carefully, its sides are seen to be very smooth, and coated over with a fluid exactly similar to that ejected from the pores. Whatever be the primary function of the fluid when within the body-cavity, there can be no doubt that it has the important and perhaps secondary function, when it has passed out of the body, of making the burrow walls smooth, moist, and slippery, and of thus enabling the animal to glide along with ease and speed.

The worm in its burrow moves rapidly by swelling up its anterior or posterior end, as the case may be, and then, using this as a fixed point, in doing which the setæ perhaps help, though to a minor extent, it strongly contracts the rest of its body. In the next movement, the end free in the first instance will be swollen out and used as a fixed point, from which expansion forwards can take place. These changes of motion follow each other so rapidly, that in the burrows the appearance of continuous gliding is given. Outside the burrow, when the whole body-surface is not in contact with the earth, the worm makes no attempt whatever to move, lying passively on the ground. Anyone who merely sees the beast removed from its burrow imagines it to be of a very sluggish temperament, and can form no idea of its active and rapid movements when underground.

So far as locomotion is concerned, its setæ seem to be of little or no use to it. The perichæte worms, on the contrary, when taken from the burrow, move along on the ground with remarkable speed, certainly using their setæ as aids to progression.

The burrows of the large worm measure $\frac{3}{4}$–1 inch in diameter; and in disused ones are often found (1) casts of the worms, or rather, what are probably the earthy contents of the alimentary canal, with clear indications marked upon them of the segments of the body; and (2) more rarely cocoons. The latter measure $1\frac{1}{2}$–2 inches in length, vary from light yellow to dark brown in colour, according to their age, and contain only one embryo each, which I have at present only been able to obtain in a somewhat highly developed state.

The cocoon itself is somewhat thin, and made of a tough leathery material, with a very distinct stalk-like process at each end; it contains a milky fluid, closely similar to that found in the body-cavity of the worm.

It is interesting to note the fact that at the present time we know of three especially large kinds of earthworms; that, of these, one comes from South Africa, another from the southern parts of India and Ceylon, and the third from the south of Australia. We know as yet little about the distribution of earthworms, but the same laws which governed the distribution of other animals must also have governed theirs, and it is just possible that these great earthworms may be the lingering relics of a once widely-spread race of larger earthworms, whose representatives at the present day are only found, as occurs with other forms of life, in the southern parts of the large land-masses of the earth's surface. Possibly careful search will reveal the existence of a large earthworm in the southern parts of South America.

NOTES.

In reply to his letter in our columns on the 7th inst. (p. 341), Mr. Sclater has received applications from several unexceptionable candidates for the post of Naturalist to the Pilcomayo Expedition. Out of these, Captain Page has agreed to select Mr. Graham Kerr, of the University of Edinburgh, to accompany him. Mr. Kerr is most highly recommended by Prof. Balfour, Prof. Geikie, and Prof. Ewart as in every way suited for the work. He will leave England for Buenos Ayres about the beginning of June.

It has now been definitely arranged that the steamer *Hvidbjörnen* shall leave Copenhagen on March 15 for Greenland, in order to bring back the members of the Nansen Expedition. The vessel will, however, not be back in Copenhagen until the beginning of June. After a few days' sojourn in that city, Dr. Nansen will proceed direct to Bergen, and prepare a work on his expedition and its scientific results.

In the presence of a distinguished company of men of science, the King of Sweden recently opened the sealed papers containing the names of the two successful competitors for the mathematical prizes offered by him five years ago. The successful competitors were found to be Prof. H. Poincaré, of the Faculté des Sciences, Paris, who receives £160, and M. Paul Appert, Professor in the same Faculty, who receives a gold medal valued at £40. The papers, with reports by Profs. Weierstrass and Hermite, will be published in the *Acta Mathematica*. Twelve papers were sent in for the competition.

We regret to have to record the death, at the early age of twenty-four, of a biologist of great promise, Mr. Richard Spalding Wray, B.Sc. Lond. The son of the Rev. William Wray, a Nonconforming minister in Yorkshire, he early developed a strong taste for natural history pursuits, which led him to become a student at the Normal School of Science at South Kensington, where he eagerly followed the teaching of Prof. Huxley and Mr. Howes. When, at the close of the year 1884, the present Director of the Natural History Museum was seeking some one to assist him in the formation of an elementary series of biological preparations to be placed in the great hall of the Museum, as an introduction to the study of the subjects more fully developed in the special galleries, he fortunately became acquainted with Mr. Wray, who entered with enthusiasm into the project, and soon showed that he possessed every natural capacity requisite for such a work. A neat-handed, skilful dissector, a good mechanician, an excellent draftsman, he displayed great taste and ingenuity in carrying out and often improving upon every suggestion made to him by the Director. While he was engaged in the formation of a series of preparations to illustrate the arrangement of the bones and feathers of the wings of birds, the very insufficient state of the knowledge upon the subject as recorded in ornithological works became apparent, and Mr. Wray made some valuable original observations, which were embodied in a paper "On some Points in the Morphology of the Wings of Birds," published in the Proceedings of the Zoological Society for 1887. This and two minor papers on kindred subjects were all that he was able to communicate to the world, for, unhappily, his powers were greatly diminished by long-continued ill-health, which finally developed into pulmonary phthisis, to which he succumbed on the 12th of this month. He has, however, left a lasting memorial of his patience, ability, and knowledge in the preparations which enrich the Museum; and his simple, modest, unaffected character, and the genuine earnestness with which he entered into the performance of every duty, will not be easily forgotten by those who had the pleasure and advantage of being in any way associated with him.

The Hunterian Oration was delivered on Thursday last, in the theatre of the Royal College of Surgeons, by Mr. Henry Power, senior ophthalmic surgeon to St. Bartholomew's Hospital. Speaking of Hunter's career as a student, Mr. Power pointed out that he took six or seven years to learn anatomy and surgery, whereas in the present day a medical student has only four years to acquire a knowledge of many more subjects. Mr. Power urged that another year is necessary, that it is, in fact, taken by the best students, and that it should be compulsory on all. This, he thought, could be easily obtained if every student were obliged to pass a thoroughly practical examination in chemistry, physics, and elementary biology, before being permitted to register.

In a letter addressed to MM. Henry, of the Paris Observatory, and printed in *La Nature* (February 16), Mr. J. A. Brashear says that the Photographic Society of San Francisco obtained 167 negatives of the recent solar eclipse, the majority of them being very successful. Mr. Brashear himself was able to do good work at Winnemucca, Nevada.

The Naples Correspondent of the *Times*, writing on the 14th inst., says:—"On the 12th inst. a perpendicular shock of earthquake was felt here, lasting about four seconds. It was stronger at the Observatory of Vesuvius, and in the towns at the foot. After the lapse of a minute another shock, the return shock, was felt at the Observatory. 'Meanwhile,' says a reporter from the spot, 'small streams of lava continue to run down on the eastern side, and at the time when we are writing the seismograph is less animated.'"

The Paris Correspondent of the *Daily News*, telegraphing on Tuesday, February 19, says:—"The district of Pont de Beauvoisin, in the Department of the Isère, was disturbed yesterday by a shock of earthquake which lasted about three seconds. Many houses were violently shaken. Field labourers were very much frightened. A good many villages suffered from it, but no lives appear to have been lost."

At the meeting of the French Meteorological Society on January 15, the President, M. Renou, on taking that office for the third time, delivered an address on the progress of meteorology since the establishment of the Society in 1853. He referred to the great improvement that had taken place in the construction and use of the various instruments, and to the progress made in weather prediction, and stated that in order to further improve the system more frequent and direct intercourse by telegraph between the various central offices was necessary, and the extension of telegraphic communication rather than refinement in observations. He also alluded to the importance of automatic or hourly observations at selected stations, and to the differences existing in thermometric exposure, the screens employed in different countries being far from uniform. (That used in France is open to objection, being liable to the influence of radiation.) M. Angot communicated the results of his discussion on the diurnal variation of the barometer, deduced from above fifty stations spread over the surface of the globe, and based on means varying from five to twenty years and upwards. The whole of the values will be published in the Annals of the French Central Meteorological Office.

Mr. H. C. Russell, the Government Astronomer of New South Wales, has published his results of rain and river observations for 1887, and of the meteorogical observations for 1886. The form of publication is the same as before (see Nature, vol. xxxvi. pp. 546 and 566), but the amount of valuable materials dealt with is continually increasing. The rain and river stations for which monthly and annual observations are given amount to 866.

In their fifth Annual Report on the Museum of General and Local Archæology, the Antiquarian Committee of the University of Cambridge call attention to a discovery of unusual interest made in Cambridge at the beginning of 1888. A field was being levelled at the back of St. John's College, when the workmen cut into a Saxon burying-ground. For several days no notice was taken of it; and during that time a number of skeletons and urns (the workmen said several hundreds) had been found and destroyed. As soon, however, as the discovery was made known, steps were taken, with the co-operation of the authorities of St. John's College and Christ's College, the owners and lessees of the land, to have the ground thoroughly examined, under proper supervision, in the interest of the Museum. The excavations occupied more than six weeks, during which time they were never left unwatched. At least thirty skeletons, one hundred urns, and a large quantity of ornaments were discovered. The entire "find" has been placed in the Museum, and forms a most valuable addition to the local Saxon collections.

In an interesting paper on the Eskimo of Hudson's Strait, reprinted from the Proceedings of the Canadian Institute, Mr. F. F. Payne says that, as a rule, the Eskimo deserve to be called

keen observers of Nature. When he was making collections of birds, insects, and plants, he found the natives of great assistance. "If an insect was shown them," he says, "they could usually take me where more of the same species might be found. On the approach of summer they watched with interest its signs, and often would bring to me insects which they believed were the first of the season."

MR. PAYNE found that the Eskimo of Hudson's Strait were much given to the habit of offering food and other things to spirits. By the graves of many of their dead were found scraps of food, tobacco, powder, shot, and other articles, and at first it was supposed that these were offered only to those who had died. To Mr. Payne's surprise, however, a number of like articles were found upon a beacon he had built in the shape of a man. When two cannons, found upon the shore near Cape Prince of Wales, that had undoubtedly been left by some of the early explorers, were made to stand on end, a quantity of bullets, shot, and other rubbish rolled out. On inquiry as to how these things had got there, Mr. Payne was informed they had been given as "an offering to the spirits."

THE extent to which variation may prevail among butterflies is well illustrated in some facts set forth in *The Entomologist* for February, by Mr. W. W. Smith, of Ashburton, New Zealand. The special subject of Mr. Smith's remarks is *Argyrophinga antipodum*, one of the few endemic species of New Zealand Rhopalocera. This butterfly in its season is generally numerous, and owing to its slow and somewhat laboured flight is easily captured. Among the specimens Mr. Smith has taken are some remarkable varieties, exhibiting all the phases or stages of variation to which a single species could be subject. Many individuals of both sexes differ considerably from each other in their ground colouring, the colours of the neuration, and in the number of ocelli. The typical colour of the male is given by Mr. A. G. Butler as "dark greyish brown, paler at base"; in Mr. Smith's specimens every shade of brown is developed, while some are partially melanic forms. Among the females there is also considerable distinction, the general colouring varying from whitish yellow to rich dark orange. In a typical specimen the hind wings are crossed with three small ocelli, the centre one in the male being slightly the largest; among them are several having a broad blackish band crossing the wing from the inner to the outer margin, and inclosing four distinct ocelli. Others have the three ocelli much enlarged and coalescent, while a number possess only two or one ocelli, and in one specimen (a male) they are obsolete on all the wings.

A NEW acid of tin has been obtained by Prof. W. Spring, consisting of two molecules of a higher oxide, SnO_3, combined with one of water. The new acid, $H_2Sn_2O_7$, or $2SnO_3 . H_2O$, is consequently analogous to disulphuric acid, $H_2S_2O_7$, and dichromic acid, $H_2Cr_2O_7$. The method by which Dr. Spring has prepared it is of peculiar interest. A saturated solution of about ten grammes of stannous chloride, in water containing sufficient hydrochloric acid to prevent decomposition into the oxychloride, was treated at the ordinary temperature with excess of peroxide of barium. The latter substance was obtained pure in the form of the hydrate, $BaO_2 . 6H_2O$, by precipitating clear baryta-water with oxygenated water. After the addition of the peroxide the liquid became very thick, and lost most of its limpidity, indicating a change resulting in the production of a colloidal substance. Neither by allowing to stand nor by filtration could any clearing of the solution be effected. But upon subjecting it to dialysis, chloride of barium diffused through the membrane, and was eventually entirely removed by changing the water in which the dialyzer floated every day during a period approaching three months. The contents of the dialyzer were now evaporated as low as possible upon a water-bath; when the evaporation was sufficiently advanced the contents of the dish became converted into a white opalescent jelly, and this eventually dried up into a white solid mass of the new acid. The analyses were most thoroughly carried out, the tin, water, and oxygen each being determined directly, and the numbers obtained are, within the usual limits of error, those required for the $H_2Sn_2O_7$. The oxygen was estimated by passing a current of pure hydrogen over a weighed quantity of the substance contained in a porcelain boat heated to redness in a combustion tube. The water obtained was absorbed by calcium chloride, and weighed, and after deducting the water contained in the substance, the oxygen present in the oxide was readily calculated. As a control, the residue of reduced tin was also weighed. These analyses prove beyond doubt that the tin is here present in the form of trioxide, and that at 100° C. one molecule of water remains combined with it. From certain secondary phenomena Dr. Spring is of opinion that the reaction really takes place in two stages; an oxychloride of tin being first formed by direct addition of oxygen to stannous chloride, $SnCl_2 + BaO_2 = SnOCl_2 + BaO$. This stannic oxychloride appears, then, to react with a further molecule of peroxide of barium with production of barium chloride and trioxide of tin, or hyperstannic anhydride, as Dr. Spring terms the new oxide:

$$SnOCl_2 + BaO_2 = BaCl_2 + SnO_3.$$

The baryta obtained as by-product in the first stage is of course dissolved by the hydrochloric acid present, and the barium is thus entirely removed as chloride upon dialysis.

MESSRS. TRÜBNER have in the press a work on ethics, by Mr. S. Alexander, Fellow of Lincoln College, Oxford, entitled "Moral Order and Progress: an Analysis of Ethical Conceptions." It will be in three books: Book I., Preliminary, dealing with conduct and character; Book II., Statical—Moral Order; Book III., Dynamical—Moral Growth and Progress. The work ought to be interesting to students of science, as the author's conclusions, if sound, will tend to confirm the theory of evolution by showing that the characteristic differences of moral action are such as might be expected if that theory were true. In Book III. he aims at proving that moral ideals follow, in their origin and development, the same law as natural species.

THE Clarendon Press has issued a fourth edition of the second volume of Prof. Minchin's "Treatise on Statics, with Applications to Physics." It is to a very great extent a reprint of the previous edition, but Prof. Minchin explains that it treats much more fully of conical angles; contains new articles on line- and surface-integrals and magnetic shells; and presents an improvement in the method of treating some questions of strain and stress, for which the author is indebted to Prof. Williamson.

THE *Annuaire*, for 1889, of the Royal Observatory of Brussels, by F. Folie, has been published. This is the fifty-sixth annual issue, and the work fully maintains the high standard of excellence attained in previous numbers.

THE first number of a popular scientific periodical—*Der Stein der Weisen*—has just been issued by H. Hartleben, Vienna. It will be published once a fortnight. The editor is A. von Schweiger-Lerchenfeld. If we may judge from the present number, the new periodical is likely to be a decided success. The articles are well written, and there are many illustrations.

MR. S. H. WINTLE contributes to the *Victorian Farmers' Gazette* an account of a mineral substance found in the slightly decayed heart of a beech-tree, *Fagus Cunninghami*, cut down, and split up for firewood, at Gladstone, Mount Camera, Tasmania. A mass of the substance, about one pound in weight, was sent to Mr. Wintle for examination. Analysis proved it to be oxalate of potassium—the "salts of lemon" of commerce. "Potash, as potash," says Mr. Wintle, "enters largely into the

composition of vegetable matter. It is to be found in the ashes of all timber and plants in association with lime and soda; but, in this case we find the potash, or more correctly speaking, the oxide of the metal potassium, is in chemical combination with oxalic acid; thus forming a compound salt, highly crystallized. The paradoxical feature of the phenomenon is presented by the query—Where did the oxalic acid come from to combine with the oxide of potassium? Analysis has failed to detect oxalic acid in the wood or leaves of the *Fagus*. There are certain well-known plants which furnish oxalic acid. Notably, the *Oxalis acetocella*, from which it used to be extracted before the great advances of chemistry enabled man to be independent of that plant as its source. Combined with lime it has been found in some lichens, while the roots of rhubarb and bistort contain it in small quantity in combination with potash; but this is the first instance, it seems, of this organic combination being found in a solid, compact, crystallized form, especially in the heart of a tree."

THE fiery sunsets which revealed the existence of the Krakatão dust in the atmosphere were also noticed by Prjevalsky in November and December 1883, as he was crossing the Gobi and the Northern Ala-shan. He describes them as follows in his "Fourth Journey to Central Asia":—"After a bright day, which is here the usual state of the weather during the winter, light cirrus and cirro-stratus clouds appeared in the west, just before sunset, or immediately after. Probably they were floating all day long in the upper strata of the atmosphere, but became visible when the sun went beneath the horizon. Immediately after that, the whole of the western part of the sky became lighted by a bright cream light, which soon acquired a violet colour in the upper parts, with stripes of shadows. At the same time the shadows of the night rose in the east, dark lilac in the lower parts, and violet in the upper parts. The violet colour vanished by and by in the west, and a segment of bright orange colour appeared close by the horizon, on a cream background. Sometimes it acquired a light red colour, but sometimes it became bright red or even blood-red. In the meantime the lilac colour disappeared in the east, and all the sky became of a gray-lilac colour. Amidst the changing colours in the west, Venus glowed like a diamond descending beneath the horizon at the time when the twilight, which lasted for about one hour and a half, came to an end. During nearly all that time the glow in the west was casting shadows, and all objects in the desert appeared in a fantastic light. The sunrise was accompanied by the same phenomena, but in a reverse order: sometimes the morning twilight began with the appearance of a blood-red colour. At full moon the phenomena were less striking, and in the atmosphere of Northern Ala-shan, which is charged with dust, we saw them less often than in the Central and Northern Gobi."

A HUGE Greenland whale, 90 feet in length, after having been seen in various parts of the Cattegat, lately went ashore in the Sound, and was killed. During the previous twenty years a whale had not been seen in these waters. The skeleton is to be forwarded to the Copenhagen Museum.

PROF. O. TORELL AND DR. TRYBOM have petitioned the Swedish Government for funds sufficient to enable them to continue their researches on the sea fisheries of Sweden, and to establish a biological station on the west coast.

LAST summer Dr. Th. Thoroddsen effected some further explorations in the interior of Iceland, visiting parts hitherto untraversed. It is said that in Norse times, in the district west of Hecla, by the River Thjorsaa, a numerous population inhabited a fertile valley, which was laid waste in 1343 by a terrible volcanic eruption of the Raudukambar Mountain. Dr. Thoroddsen now reports that this mountain is not a volcano at all, and that in historical times no volcanic eruption has devastated this valley; but he is of opinion that the colony in question was destroyed through an eruption of Hecla in the middle of the fourteenth century. Dr. Thoroddsen afterwards explored the desert land south of the Hofsjökul, particularly a mountain range, called Kjerlingarfjöll, close to the south of it. These mountains had never been explored before, and Dr. Thoroddsen found a country which he describes as very remarkable. It was known in the low lands that there were some valleys with hot springs, steam having been seen from a distance, but the springs had never been visited. Dr. Thoroddsen found grand sulphur springs in great numbers, which, he states, far excel the well-known ones at Myvain and Krisuvik. There are also numbers of large boiling mud pools—blue, red, yellow, and green in colour—whilst steam penetrates everywhere through fissures in the earth with terrific noise. One steam jet, 6 to 9 feet in height, kept up such a continual roar that it was impossible to hear the loudest shouts for a long distance. Several subterranean cavities were also found containing boiling clay pools, and around one of them the earth trembled far and wide, whilst far down below in the earth a noise was heard like that which might proceed from a gigantic butter-churn. The valleys in which these springs and mud pools are found are surrounded by extensive and deep snow-fields with innumerable fissures, through which the roar of the steam far below the snow can be heard in some places, whilst in others the steam escapes through them. The ground in these valleys is so hot that only with the greatest care is it possible to tread on the thin crust of clay covering the boiling mud below.

THE additions to the Zoological Society's Gardens during the past week include a Ring-tailed Coati (*Nasua rufa* ♀) from Brazil, presented by Mr. N. T. Williams; three Herring Gulls (*Larus argentatus*), British, presented by Mr. L. V. Harcourt; six Moorish Geckos (*Tarentola mauritanica*) from the south of France, presented by Masters F. and O. Warburg; a Thigh-striped Wallaby (*Halmaturus thetidis* ♀) from New South Wales, deposited; a White-throated Capuchin (*Cebus hypoleucus*), a —— Capuchin (*Cebus* sp. inc.) from Central America, purchased; an Eland (*Oreas canna* ♀), a Yellow-footed Rock Kangaroo (*Petrogale xanthopus* ♂), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE MULTIPLE STAR ζ CANCRI.—This remarkable stellar system has justly attracted much attention ever since Sir W. Herschel discovered in 1781 that it was really composed of three, not two stars, the principal star being itself a close double. But the interest with which the system was regarded was greatly increased by the remarkable paper which Prof. O. Struve produced upon the subject, and communicated to the Paris Academy of Sciences in 1874 (*Comptes rendus*, vol. lxxix. p. 1463), and in which he pointed out a noteworthy inequality in the motion of the distant companion C, having a period of about twenty years. The question was again taken up by Prof. Hugo Seeliger in 1881, in a paper entitled "Ueber die Bewegungverhältnisse in dem dreifachen Sternsystem ζ Cancri," and presented to the Vienna Academy of Sciences on May 5 of that year. Prof. Seeliger has continued his discussion of the observations of the star, and has recently published a further paper on the subject, which appears in the Memoirs of the Royal Bavarian Academy of Sciences, Munich, under the title "Fortgesetzte Untersuchungun ueber das mehrfache Sternsystem ζ Cancri." The result of his further labours has been in effect to confirm the results he had obtained in his earlier work, and those which Prof. Struve had brought out in 1874.

The three stars A, B, and C, have the magnitudes respectively 5·0, 5·7, and 5·3. The proper motion of the system amounts in a century to + 10″·6 in R. A., and to − 11″ in Decl. The close pair, A and B, first separated by Herschel, have a motion round one another in about sixty years, their apparent distance from each other varying from about 0″·6 to 1″·1; whilst C, the more distant companion, has moved through about 55° of position-angle round the other two since Herschel's

observation in 1781, its distance never very greatly varying from $5\frac{1}{2}''$. The motion of A and B round their common centre of gravity does not appear to be disturbed to any appreciable extent by the influence of C, which is so placed as not to affect their apparent relative motions, even though a very considerable mass be assigned to it, and as a fact Prof. Seeliger finds, for the most probable value of the mass of C, $\frac{m'}{1+m} = 2{\cdot}386$, where 1, m, and m' are the masses of A, B, and C respectively. But there is a periodical retrogression of C itself which is most easily accounted for by supposing the presence of a close companion, one hitherto undetected, and therefore either entirely dark, or but faintly luminous. The distance of this companion is probably only a few tenths of a second, the distance of C from the point, S_2, round which it appears to revolve, and which may be reasonably assumed to be the centre of gravity of itself and of D, the as yet undiscovered fourth member of the family, being only about one-fifth of a second.

The entire group therefore may be considered as a double-double, the following being the definitive elements derived for the two pairs:—

	For A and B.		For C about S_2.
T ...	1868·112	... ...	1860·127
☊ ...	109°·735	1850·0	71°·958
λ ...	80·190	1850·0	109·677
i ...	11·135	1850·0	17·352
e ...		... ...	0·1106
a ...	0″·853	... ...	0″·217
ϕ ...	22·450	... ...	
n ...	− 6·0898	.. ...	− 20·460

For the motion of S_2 round the optical centre of A and B:—

$$\rho_0 = 5''{\cdot}438.$$
$$p_0 = 145^\circ{\cdot}46 - 0^\circ{\cdot}513\,(t - 1850{\cdot}2).$$

The concluding portion of this valuable contribution to the study of a most interesting case in stellar physics is devoted to the consideration of personal errors in the observations, and a plate is added giving a graphical representation of the apparent motion of C, and bringing out in a striking manner the evidence the observations afford of the looping of the curve.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 FEBRUARY 24—MARCH 2.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on February 24

Sun rises, 6h. 57m.; souths, 12h. 13m. 21·5s.; sets, 17h. 30m.: right asc. on meridian, 22h. 31·6m.; decl. 9° 16′ S. Sidereal Time at Sunset, 3h. 49m.

Moon (New on March 1, 22h.) rises, 2h. 59m.; souths, 7h. 13m.; sets, 11h. 23m.: right asc. on meridian, 17h. 30·3m.; decl. 20° 54′ S.

M signifies maximum; m minimum.

GEOGRAPHICAL NOTES.

AN Antarctic Expedition is being again talked of. A New Zealand colonist (of Norwegian origin) has come to Europe for the purpose of taking out a contingent of his countrymen accustomed to fishing. His object is to endeavour to organize an Antarctic whale fishery. He hopes to equip two steamers with which to explore the region generally, and, if possible, he will leave a contingent of men on Victoria Land, or some other suitable point, for a whole year. One or more scientific men will be taken, so that if the proposed expedition be carried out we may expect some important results.

DR. HUGO ZÖLLER (sent out by the *Kölnische Zeitung*) has been doing some original exploring work in German New Guinea. He made an excursion for a considerable distance into the interior. In November last he ascended the Finisterre Mountains to a height of 9000 feet. Some of the peaks in this and the Bismarck Ranges rise to a height of over 10,000 feet.

CAPTAIN PAGE, who recently read a paper on the Gran Chaco at the Royal Geographical Society, proceeds shortly to the Argentine Republic for the purpose of thoroughly exploring the Pilcomayo. He will probably be accompanied by a naturalist.

THE French are endeavouring to raise the funds for a Congo railway which will pass entirely through French territory, in opposition to the scheme for a railway from Vivi to Stanley Pool, for which a survey has recently been made by Belgian engineers. The French railway would run from Brazzaville, on the north side of Stanley Pool, to the River Kwilu, 100 kilometres. Steps, it is stated, will be taken to render the Kwilu navigable, and so establish direct communication between the Congo and the Atlantic.

IN a long article in the new number of the *Mouvement Géographique*, the question of the origin and course of the Lomami, one of the great southern tributaries of the Congo, is discussed. The conclusion is that it is the same river which Cameron crossed far to the south, and which has been crossed at various points further northwards. It enters the Congo some distance below Stanley Falls. Its course is probably about 1000 miles in length.

DR. OSCAR BAUMANN contributes to the February number of *Petermann's Metteilungen* a short monograph (with map) on the district of Usambara, in East Africa. The monograph ought to be specially interesting to geologists.

THE February number of the *Scottish Geographical Magazine* contains several very useful articles. Colonel Cadell, Chief Commissioner of the Andaman Islands, gives a highly interesting account of the group, and especially of its people, who, he maintains, have been very much maligned from the days of Marco Polo downwards. The people are fast dying out. Dr. Guppy sends a preliminary note on the geological structure of the Sindang-Barang district on the south coast of Java. Dr. Guppy sums up the structure of this part of Java as follows: a basis of massive volcanic rocks overlain by submarine tuffs and volcanic muds as far as twelve miles from the coast, and by older and allied tuffs farther inland. The upheaval in post-Tertiary times has been very great, and can only be measured by several thousands of feet. Mr. S. P. Ford gives a brief *résumé* of our knowledge of the geography of the Transvaal; and Mr. W. A. Taylor supplies a real want in his account of the Philpпine Islands, compiled from various recent sources.

NOTES ON METEORITES.[1]

VIII.

THERE can be little doubt that it is to the varying conditions produced by the outflows in both directions along the radius vector, to which reference was made in the last article, that the various appearances put on by the axis of comets' tails are due. Thus, in Coggia's comet, to take an instance, the perihelion passage of which took place on August 27, on June 10 the axis was brighter than the rest of the tail, but by July 10 the bright axis was replaced by one of marvellous blackness, which was one of the features of the comet at that time, and this dark axis expanded as perihelion was approached.

The tail is always curved, but if the earth lie in the plane of the orbit the curvature cannot be seen.

FIG. 27.—Great comet of 1861, seen on June 30, when the earth was in the plane of the orbit.

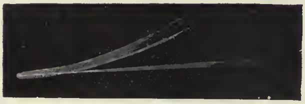

FIG. 28.—Same comet seen on June 15.

The accompanying woodcuts will explain how the solar repulsion produces this curvature, and how the curvature will depend upon the velocity due to repulsion.

FIG. 29.—Slight repulsion ; great curvature.

Fig. 29, which I owe to M. Faye,[2] represents the successive positions of a series of molecules emitted by the nucleus of a comet so as to constitute the axis of the tail. A density is imagined such that the repulsive force exactly counterbalances the solar attraction : thus their motion, solely due to the tangential velocity of the comet, takes place in a straight line. To again simplify matters, this rate is supposed constant, as if the orbit were a circle.

On the first day, the comet being at C^1, a molecule m^1 is detached and subsequently follows the line m^1 m^1 m^1. On the second day, a molecule m^2, likewise leaves the nucleus at C^2, and subsequently describes the tangent $m^2\, m^2\, m^2$. Similarly, on the third day, for a molecule m^3 ; and so on. If we join by a continuous line the series of positions occupied at the same time, the fifth day, by all these molecules, m^5, m^4, m^3, m^2, m^1, we shall have the curvilinear axis of the tail ; this will be, in this particular case, the involute of a circle. This construction accounts for the three laws which have been ascertained as the result of observation : (1) the tail, at its origin, is sensibly opposed to the sun, S ; (2) the tail is curved backwards on its path ; (3) the axis of the tail is a plane curve situated in the plane of the orbit.

If the density of these molecules were still smaller, the repulsive force would prevail over the solar attraction, and the molecules would describe no longer straight lines, but sections of an hyperbola whose convexity would be turned towards their common focus, S (see Fig. 30).

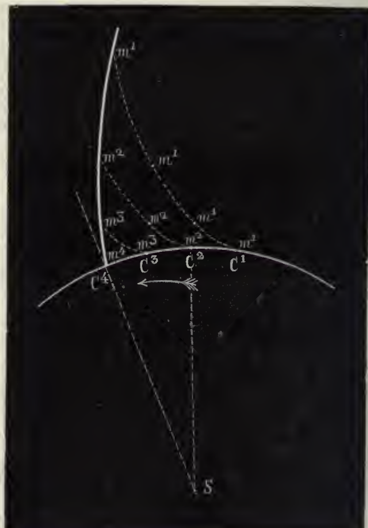

FIG. 30.—Here the velocity is greater and the tail is straighter.

The series of points m^1, m^2, m^3, m^4, emitted at C^1, C^2, C^3, C^4, by the comet, gives a curve like the former one, but with a curvature much less pronounced and nearer to the radius vector.

Now the single tail we have been considering will depend upon the repulsive action upon molecules of similar density, and that very small.

But suppose there are in consequence of collisions among the members of the swarm, several gases given off which can retain their gaseous form, and suppose they are of different densities. Then it is evident that a winnowing process will be set up, and that the molecules of smallest density will be repelled with the highest velocity ; and given these varying densities, we must get more tails than one—one, in fact, for each representative density.

M. Bredichin, of the Moscow Observatory, has in fact shown that there are three distinct types of tails. In the first class. the tails are long and straight, and the repellent energy of the sun upon the small particles is about twelve times as great as the energy of his gravitational attraction. The particles therefore leave the nucleus with a high velocity, generally about fourteen or fifteen thousand feet per second. The greater this velocity in relation to the rate of travel of the comet, the straighter of course will be the tail, because the particles forming it do not lag behind. In the second type, the energies of the

[1] Continued from p. 236.
[2] "Forms of Comets," NATURE, vol. x. p. 268.

attraction and repulsion balance each other, or nearly so, and the tails of this class are plumy and gently curved. In this case the particles which go to form the tail leave the head with a velocity of about 3000 feet per second. Tails of the third type are short and strongly bent, the repellent energy being only about one-fifth of the attractive energy of the sun, and the velocity of the particles leaving the head is only about 1000 feet per second.

Many comets exhibit tails of more than one type, and it was conjectured long ago that such tails were composed of different kinds of matter.

Bredichin went further, and defined the composition of the different kinds of tails which he had classified, by referring to the molecular weights of the materials which would give the relative values of the repulsive and attractive forces necessary for tails of the different types. He thus found that the long straight tails of the first type would be probably formed by hydrogen, since this substance, on account of its exceeding lightness, would be little influenced by gravity, while at the same time strongly influenced by the solar repulsion. The second type of tails he considered to be made of hydrocarbons, since hydrocarbons have a molecular weight such that the repellent and attractive forces of the sun upon their particles may be nearly equal. Iron, on the other hand, would be more subject to the action of gravity, on account of its greater weight, and was therefore taken as adapted to tails of the third type.

There is nothing extravagant in these suppositions, for we know that all the substances in question do exist in comets, and it is evident that much is to be learnt from a continuation of the inquiry, but at the outset we can see that iron vapour cannot in space remain as vapour to form a tail.

We know that the short-period comets get less brilliant with every approach to perihelion, and that some do not even throw out a tail, and we can easily ascribe both these results to the fact that after several such appulses the vapours liable to be driven out of the meteorites by temperature get less and less.

If this be so, we may regard a comet with many tails as one which for the first time undergoes perihelion conditions.

If it be conceded that the tails of comets are in part composed of hydrogen and compounds of carbon with gases such as oxygen, an explanation seems to be suggested of many recorded phenomena, while at the same time it seems more probable that the repulsive force would act continuously upon permanent gases rather than on condensable vapours, such as iron vapour, to take an instance.

Suppose that the sun has been formed by the coming together of meteors, whether brought by comets or not, it is obvious that with equal temperatures *of the sun* the repellent action would be the same on the permanent gases given off by the meteorites, whether in large or small groups. In the larger groups there would be possibly more collisions, and therefore greater possibilities of higher temperature *of the meteorites*.

This action would surround the sun, as it were, by a cordon, inside which, to take instances, neither hydrogen nor oxycarbon-compounds could enter. Hence we should have a sun without hydrogen, carbon, or oxygen.

But while, as demanded on this view, the quantity of carbon and oxygen is extremely small, even if the latter exists at all, the quantity of hydrogen is enormous.

This difference can, however, be accounted for by the idea which has been suggested on several other grounds, that the hydrogen which plays such an important part in the sun's economy and in the economy of all stars hotter than the sun is really produced locally by the dissociation of the vapours of the chemical elements which form the sun and the meteoritic constituents which still reach it in the shape probably of iron and silicates.

We know perfectly well (from Dunér's work chiefly, in stars of the class III.*b*) that when the sun gets cooler its atmosphere will consist almost exclusively of carbon compounds; and indeed one of the last scenes in the drama of world-formation seems to be the gradual approach of the "cordon" to which I have referred, as the radiant energy of the star is diminished, thereby enabling all the permanent gases in the system to gradually approach the primary; and it is not impossible that the great differences of density of the interior and exterior planets may be connected with this state of things.

Before passing on, it is well to recur to the question, Why should not *vapours* be also repelled from the cometary nucleus and its envelopes?

No doubt they are; but it is straining the facts to suppose that they would not be condensed by the cold of space before they had been repelled any great distance; the enormous lengths of some comets' tails would seem to negative any such possibility.

Some of these lengths may be given in miles:—

Comet	1843 (I.)	198,800,000 miles
,,	1680	149,000,000 ,,
,,	1847 (I.)	130,800,000 ,,
,,	1811 (I.)	109,400,000 ,,
,,	1860 (III.)... ...	21,700,000 ,,

With regard to the rate at which the tails are thrown out it may be stated that, in the case of Donati's comet, between September 23 and October 10 the tail had increased from 15,000,000 to 55,000,000 miles, or, speaking roughly, the tail had increased by 2,000,000 miles a day.

If we are justified in considering that the materials of the comet thus repelled to form the tail are non-condensable gases, such as the hydrogen and the carbon compounds which are actually found in meteorites, we have in this fact probably the *vera causa* of the so-called occlusion of these gases by meteorites. That is, one set of meteorites—a comet—may be giving off these gases, while other meteorites, which have never been members of such a large swarm, may occupy regions of space swept over by the gases repelled from the comet.

But if it be agreed that it is not probable that, say, the vapours of iron and magnesium could retain their vaporous condition so long as the hydrogen and the carbon compounds—there can be no doubt that they start on the common journey in consequence of the repulsive action outside the track of the comet—then we shall expect to find condensed particles of iron, nickel-iron, and magnesium or their compounds; and here again we have a *vera causa* for the chondrites which enter so largely into the composition of meteorites.

The tail of a comet being thus formed at the expense of the materials composing the head, the materials removed from the head can never be returned to it because of its insufficient gravitational power over them, and moreover they can no longer traverse the same orbit as the comet to which they originally belonged, because they have already been turned out of that course by the forces attending the development of the tail. The small tail-forming meteoric bodies thus become distributed throughout the space occupied by our system, and give no further trace of their existence, unless they happen to break into our atmosphere and appear as shooting-stars.

Comets must thus degenerate, so far at all events as their easily volatilized constituents are concerned, with each perihelion passage, but as the majority of them only approach the sun at long intervals of time they do not suffer much in this way. Some of the short-period comets get less and less brilliant at each successive perihelion passage, and others are then observed entirely without tails, all the available tail-forming material having been used up and dispersed into space.

It is a fact well worthy of consideration that on many occasions pulsations exactly resembling those observed in auroræ have been observed in comets' tails.

This subject is thus referred to in Guillemin's book on comets:—

"Kepler is the first observer who has made mention of the changes. 'Those,' he says, 'who have observed with some degree of attention the comet of 1607 (an apparition of Halley's comet) will bear witness that the tail, short at first, became long in the twinkling of an eye.' Several astronomers—Kepler, Wendelinus, and Snell—saw, in the comet of 1618, jets of light, coruscations, and marked undulations. According to Father Cysatus, the tail appeared as if agitated by the wind; the rays of the coma seemed to dart forth from the head and instantly return again. Similar movements were observed by Hevelius in the tails of the comets of 1652 and 1661; and Pingré, describing the observations of the comet of 1769, made at sea, between August 27 and September 16, by La Nux, Fleurien, and himself, thus describes the phenomenon of which he was a witness:—'I believe that I very distinctly saw, especially on September 4, undulations in the tail similar to those which may be seen in aurora borealis.' The stars which I had seen decidedly included within the tail were shortly after sensibly distant from it.

"M. Liais has given the following account of the observations made by him of the great comet of 1860:—'On the evening of July 5, whilst I was observing the comet at sea, I saw a rather

intense light from time to time arise in those portions of the tail that were furthest from the nucleus. Sometimes instantaneous, and appearing upon a small extension of the extremity of the tail, which then became more visible, the fugitive gleams reminded me of the pulsations of the aurora borealis. At other times they were less fleeting, and their propagation in rapid succession could be followed for some seconds in the direction of the nucleus near the extremity of the tail. These appearances then resembled the progressive undulations of the aurora borealis, but even in this case they were only visible in the last third of the length of the tail. The gleams in question were similar to those that I remember to have seen in the tail of the great comet of 1843, and which were observed by very many astronomers.'"

The American observers of Donati's comet in 1868 described a number of brighter bands "like auroral streamers" crossing the tail and diverging from a point between the nucleus and the sun.[1]

This point is one well worthy of subsequent inquiry. I have brought together evidence to show that in the aurora one of the chief factors in the production of the spectrum is meteoric dust.

If this be conceded, we have meteoric dust in all probability very slowly falling through our atmosphere at a height at which its pressure is very low, the luminosity both of the dust and the atmosphere being produced by electricity. Whether the electricity is produced by the movement is a matter on which at present we are quite ignorant, but if it be eventually shown that all auroræ follow well-recognized star-showers a certain amount of plausibility will be accorded to the notion.

However this may be, we must in the case of the aurora regard the permanent gases in the air as a constant, and the dust as the variable.

But if we wish to assimilate these displays with comets' tails, we must in the latter case consider meteorites in space as the constant, and the permanent gases repelled from the comet as the variable.

Prof. Tait, assuming that the head of a comet is a swarm of meteorites or stones, varying in size from a marble to boulders 20 or 30 feet in diameter, has shown that all the various cometary phenomena may be explained. His researches have not yet been printed *in extenso*, but the following general statement gives a summary of the results of his calculations which appeared in *Good Words* some time ago.

Firstly, with regard to the masses of the comets. The total mass of a comet cannot be very great, for, as we have seen, no measurable disturbance of planetary orbits has been known to be produced, and this small mass is just as likely to be due to scattered solid masses as to one continuous gaseous mass, and indeed we know that this is so. In the case of comets of but small masses, the component meteorites would be small and far apart. Then with regard to the transparency of the comet, it is calculated that a meteorite 25 feet in diameter at a distance of half a million miles from us could not totally eclipse a star of the same size as our sun, even if it were at such a distance as to be barely visible to the naked eye. Again, if some of the meteorites were large enough to eclipse the stars behind the comet, the eclipse would be of very brief duration, and we should see the star as if nothing had happened. In order for the comet to reduce the light of a star seen through it by one-tenth, it would require to be 300 miles thick, supposing the stones to be 1 inch cube and 20 feet apart.

While the swarm which builds up the comet is coursing round the sun as a whole, the individual members will themselves gravitate towards each other; and if we suppose the whole mass to be 1/1000 that of the earth, and the meteorites to be uniformly distributed in a sphere 20,000 miles in diameter, those coming from the outside to the centre of the group would have a velocity of about 500 feet per second. The stones colliding will generate heat, and some gas will be evolved; some members of the mass will be quickened, while other constituents of the mass will be retarded in their motion, and in this way we have a probably sufficient explanation of the various forms which the telescope has revealed to us. And then finally Prof. Tait goes on to show that the result of these collisions would be such a smashing up of the constituents of the swarm that much finely-attenuated material would be left behind, sufficient to reflect sunlight, and to give rise to the phenomena of the tail.

[1] Webb, p. 197.

If in the imaginary swarm the mass of each stone be 100 pounds, and its velocity, due to attraction, be 500 feet per second, the heat resulting from the impact of two of them would be quite sufficient to volatilize a portion, and to make the outsides of the stones white-hot. Stones of this weight would be about 10 inches cube, and in the swarm considered there would therefore be about 136,000,000,000,000,000,000 of them. At the rate of one collision per second, there being about 31,436,000 seconds in a year, there would be a possibility of one collision per second for 2,150,000,000,000 years. There would therefore be material for such collisions for a period of over two million years even at the extravagant rate of one million per second, and on the assumption that no stone comes into collision with another more than once.

The whole mass being 1/1000 that of the earth, and the space occupied being 250 times that occupied by the earth, the stones in question being 10 inches cube will only occupy about 1/8000 of the space through which they are distributed; the average distance apart would be about 17 feet. The swarm would reflect about half as much sunlight as a slab of the same material in the same place, but it would probably be too opaque to transmit starlight. By making the stones larger, and thus increasing the distances between them, the luminosity would be retained, while at the same time the swarm would be sufficiently transparent. It thus seems to suit the hypothesis better if we regard the separate stones to be greater than 10 inches cube.

J. NORMAN LOCKYER.

THE FORCES OF ELECTRIC OSCILLATIONS TREATED ACCORDING TO MAXWELL'S THEORY. BY DR. H. HERTZ.[1]

I.

Note by the Translator.

THE early part of the following paper is no doubt familiar to the more important persons in this country, and therefore need perhaps hardly have been translated. Nevertheless, as these experiments of Hertz form a sort of apotheosis of Maxwell's theory, it is natural to reproduce this portion as well as the rest; and inasmuch as Hertz did not at first express his discoveries in Maxwellian language, it is interesting to see how he regards the matter since his conversion, and how he now presents his ideas to foreigners.

I have translated the paper because it seems to me a remarkable example of clear theoretic insight in conjunction with great experimental skill, because it is pleasantly written, and because it deals in a powerful manner with a profoundly interesting subject.

I can hardly hope to have escaped errors in translating, but the original paper in *Wiedemann's Annalen* for January of this year is very accessible. OLIVER J. LODGE.

The results of the experiments on quick electric oscillation which I have carried out appear to me to lend to Maxwell's theory of electrodynamics an ascendancy over all others. At first I interpreted these experiments in terms of older notions, seeking to explain the phenomena in part by means of the cooperation of electrostatic and electro-magnetic forces. To Maxwell's theory in its pure development such a distinction is foreign. I wish, therefore, now to show that the phenomena can also be explained in terms of Maxwell's theory without any such distinction. If this attempt succeeds, questions about special propagation of electrostatic force, being meaningless in Maxwell's theory, are at once settled. And besides this special aim, a closer insight into the play of forces concerned in rectilinear oscillations is not without interest.

The Formulæ.

In what follows we have only to concern ourselves with forces in free ether. Let X, Y, Z, be the components of electric force acting on the points x, y, z; let L, M, N be the corresponding components of magnetic force; let t be the time, and let A stand for $\sqrt{(\mu K)}$. Then, according to Maxwell, the time-rate of change of the forces is dependent on their distribution in space in the following way:—

[1] Translated and communicated by Dr. Oliver Lodge.

$$\left.\begin{aligned} A\frac{dL}{dt} &= \frac{dZ}{dy} - \frac{dY}{dz} \\ A\frac{dM}{dt} &= \frac{dX}{dz} - \frac{dZ}{dx} \\ A\frac{dN}{dt} &= \frac{dY}{dx} - \frac{dX}{dy} \end{aligned}\right\} \quad \ldots\ldots (1)$$

$$\left.\begin{aligned} A\frac{dX}{dt} &= \frac{dM}{dz} - \frac{dN}{dy} \\ A\frac{dY}{dt} &= \frac{dN}{dx} - \frac{dL}{dz} \\ A\frac{dZ}{dt} &= \frac{dL}{dy} - \frac{dM}{dx} \end{aligned}\right\} \quad \ldots\ldots (2)$$

Originally, and therefore always, the following conditions must be satisfied:

$$\frac{dL}{dx} + \frac{dM}{dy} + \frac{dN}{dz} = 0, \text{ and } \frac{dX}{dx} + \frac{dY}{dy} + \frac{dZ}{dz} = 0 \quad . . (3)$$

The electric energy contained in a portion of ether of volume τ is—

$$\frac{1}{8\pi}\int(X^2 + Y^2 + Z^2)\,d\tau;$$

the magnetic energy is—

$$\frac{1}{8\pi}\int(L^2 + M^2 + N^2)\,d\tau;$$

the integration extending all through the volume. The total energy is the sum of both these portions.

These expressions form the essential ingredients of Maxwell's theory as it relates to the ether. Maxwell arrived at them by forsaking action at a distance, and by accummodating the ether with the properties of a highly dielectric medium. One can also get the same equations in another way. But hitherto no direct proof of the validity of these equations has been afforded by experience. It appears most logical, therefore, to regard them independently of any way in which they may have been arrived at, to consider them as hypothetical assumptions, and to let their probability depend upon the very great number of legitimate conclusions which they embrace. Taking this point of view, one can do without a series of auxiliary ideas, which render the understanding of Maxwell's theory more difficult, even if on no other ground than that, so soon as one finally excludes the hypothesis of immediate action at a distance, these notions possess no meaning.

Multiply equations (1) by L, M, N, and (2) by X, Y, Z; add the equations together, and integrate over the whole space, whose volume element is $d\tau$, and whose surface element is dS; we get—

$$\frac{d}{dt}\left\{E_e + E_m\right\}$$

$$= \frac{1}{4\pi A}\int\{(NY - MZ)\lambda + (LZ - NX)\mu + (MX - LY)\nu\}dS,$$

where λ, μ, ν are the direction-cosines of the normal to the surface.

This equation shows that the amount by which the energy of the space has increased can be regarded as having entered through its walls. The quantity entering through any single element of surface is equal to the product of the components of the electric and magnetic forces which belong to that element, multiplied by the sine of the angle between them, and divided by $4\pi A$. On this result it is well known that Prof. Poynting has founded a remarkable theory on the transfer of energy in the electro-magnetic field.

For the purpose of solving the equation, we limit ourselves to the special but important case where the distribution of the electric force is symmetrical about the axis of z, and hence that this force is absent at every point of the meridian planes intersecting in the axis of z, and only depends on the z co-ordinate of a point, and on its distance, $r = \sqrt{x^2 + y^2}$, from the z axis. We will denote the electric force in the direction of r, namely, $X\frac{x}{r} + Y\frac{y}{r}$, by R; and the component of the magnetic force which is normal to the meridian planes, viz. $L\frac{y}{r} - M\frac{y}{r}$, by P. We assert further that if Π is any function of r, z, and t, which satisfies the equation—

$$A^2\frac{d^2\Pi}{dt^2} = \nabla\Pi;$$

and if we put $Q = r\frac{d\Pi}{dr}$, the following is a possible solution of our equations:—

$$Z = \frac{1}{r}\frac{dQ}{dr},$$

$$R = -\frac{1}{r}\frac{dQ}{dz},$$

$$P = \frac{A}{r}\frac{dQ}{dt},$$

$$N = 0.$$

To prove this assertion we observe that

$$X = R\frac{dr}{dx} = -\frac{d^2\Pi}{dxdz},$$

$$Y = R\frac{dr}{dy} = -\frac{d^2\Pi}{dydz},$$

$$Z = \frac{1}{r}\frac{d}{dr}\left(r\frac{d\Pi}{dr}\right) = \frac{d^2\Pi}{dx^2} + \frac{d^2\Pi}{dy^2},$$

$$L = P\frac{dr}{dy} = A\frac{d^2\Pi}{dydt},$$

$$M = -P\frac{dr}{dx} = -A\frac{d^2\Pi}{dxdt},$$

$$N = 0.$$

One has only to insert these expressions into equations (1), (2), (3), to find equations (2) and (3) identically satisfied, and (1) also if we have regard to the differential equation for Π.

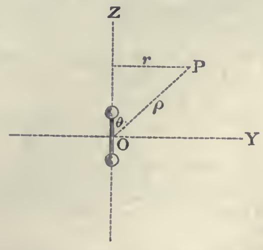
It may be mentioned that also inversely, neglecting certain practically unimportant limitations, every possible distribution of electric force which is symmetrical to the axis of z can be represented in the above form, but it is not necessary for the sequel to substantiate this assertion.

The function Q is of importance. The lines in which the surface of rotation Q = const. cut the meridian planes are the lines of electric force; the construction of the same for one meridian plane furnishes at every instant an immediate presentation of the force distribution.

If we cut the shell between Q and $Q + dQ$ by a surface of rotation round the axis of z, the product of electric force and surface which Maxwell calls the "induction" is for every such surface the same. If we arrange the system of surfaces Q = const. in such a way that Q increases in arithmetic progression, the same statement remains true when we compare the sections of the different shells with one another.

In the plane diagram which consists of sections of the meridian plane with the equidistant surfaces Q = constant, the electric force is inversely proportional to the normal distance of consecutive lines Q = const. only for the case when points compared lie at the same distance from the axis of z. In general the rule is that the force is inversely proportional to the product of this distance and of the co-ordinate r of the point considered.

If we introduce polar co-ordinates ρ and θ they will be like this.



The figure represents an electric oscillator at origin of co-ordinates as intended to be understood by Hertz.

The Forces concerned in a Rectilinear Oscillation.

Let E denote a quantity of electricity, and l a length; let $m = \frac{\pi}{\lambda}$ be a reciprocal length, and $n = \frac{\pi}{T}$ a reciprocal time; and let us put

$$\Pi = E\frac{l}{\rho}\sin(m\rho - nt).$$

This value satisfies the equation—

$$A^2 \frac{d^2\Pi}{dt^2} = \nabla\Pi,$$

so soon as we settle that,

$$\frac{m}{n} = \frac{T}{\lambda} = A,$$

and $\frac{\lambda}{T}$ will be the velocity of light. And, indeed, the introduced equation is satisfied everywhere, except at the origin.

In order to find out what electrical processes are set up by the distribution of forces specified by Π, we investigate its immediate surroundings.

We put ρ vanishing in comparison with λ, and neglect $m\rho$ in comparison with nt.

Then—

$$\Pi = E\frac{l}{\rho} \sin nt.$$

Since, now—

$$\left(\frac{d^2}{dx^2} + \frac{d^2}{dy^2}\right)\frac{1}{\rho} = -\frac{d^2}{dz^2}\left(\frac{1}{\rho}\right),$$

we have—

$$X = -\frac{d^2\Pi}{dxdz}, \quad Y = -\frac{d^2\Pi}{dydz}, \quad Z = -\frac{d^2\Pi}{dzdz}.$$

So the electric forces appear as the derivative of a potential—

$$\phi = \frac{d\Pi}{dz} = El \sin nt \cdot \frac{d}{dz}\left(\frac{1}{\rho}\right);$$

and this expresses an electrical [*Doppelpunkt*, by which I suppose is meant either an involution or a spherical harmonic] whose axis coincides with the z axis, and whose moment oscillates between the extreme values El and $-El$ with the period T.

Our force distribution, therefore, represents the action of a rectilinear oscillator which has the very small length l, and on whose poles at the maximum the quantities of electricity $\pm$ E are free.

The magnetic force perpendicular to the direction of the oscillator is, in the immediate neighbourhood,

$$P = -AEln \cos nt \frac{\sin\theta}{\rho^2}.$$

According to the Biot-Savart law, this is the force of a current element in the direction of the axis of z, of length l, whose intensity, magnetically measured, oscillates between the extreme values $\pm \frac{\pi AE}{T}$. In fact the motion of the electricity E corresponds to a current of that magnitude.

From Π we get—

$$Q = Elm \left\{\cos(m\rho - nt) - \frac{\sin(m\rho - nt)}{m\rho}\right\} \sin^2\theta,$$

and from this the forces Z, R, P follow by differentiation.

The formulæ are too complicated for it to be possible to obtain immediately from them in their general form a representation of the distribution of the forces. For some special cases the results are meanwhile proportionately simple. We get these at once—

(1) The immediate neighbourhood of the oscillator we have already treated.

(2) In the z axis, *i.e.* in the direction of swing, we have $dr = \rho d\theta$, $dz = d\rho$, $\theta = 0$; so then—

$$R = 0, \quad P = 0,$$

$$Z = \frac{2Elm}{\rho^2}\left\{\cos(m\rho - nt) - \frac{\sin(m\rho - nt)}{m\rho}\right\}.$$

The electric force acts always in the direction of the oscillator; it diminishes for small distances as the inverse cube, for greater distances as the inverse square, of the distance.

(3) In the xy plane, or $z = 0$, we have $dz = -\rho d\theta$, $d\rho = dr$, $\theta = 90$, and so—

$$P = \frac{AElmn}{r}\left\{\sin(mr - nt) + \frac{\cos(mr - nt)}{mr}\right\}$$

$$R = 0,$$

$$Z = \frac{Elm^2}{r}\left\{-\sin(mr - nt) - \frac{\cos(mr - nt)}{mr} + \frac{\sin(mr - nt)}{m^2r^2}\right\}.$$

The electric force in the equatorial plane through the oscillator is parallel to the oscillation, its amplitude being—

$$\frac{El}{r^3}\sqrt{1 - m^2r^2 + m^4r^4}.$$

The force decreases with distance, at first quickly as the inverse cube, later only slowly, and inversely as the distance itself. At great distances the action of the oscillator can only be noticed in the equatorial plane, not in the axis itself.

(4) At very great distances we can neglect higher powers of $1/\rho$, compared with lower ones. So we get at such distances—

$$Q = Elm \cos(m\rho - nt) \sin^2\theta,$$

whence—

$$P = A\frac{Elmn}{\rho} \sin(m\rho - nt) \sin\theta,$$

$$Z = -\frac{Elm^2}{\rho} \sin(m\rho - nt) \sin^2\theta,$$

$$R = \frac{Elm^2}{\rho} \sin(m\rho - nt) \sin\theta \cos\theta.$$

Thence follows—

$$Z\cos\theta + R\sin\theta = 0.$$

The direction of the force is therefore at great distances everywhere normal to the radius vector from the origin of force; the spreading out occurs in pure transverse waves. The magnitude of the force is equal to $\frac{Elm^2}{\rho}\sin(m\rho - nt)\sin\theta$, and decreases at a constant distance from the origin towards either axis, being proportional to the distance from this latter.

(*To be continued.*)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—A Report on the new Chemical Laboratory states that it has cost in all £33,697, an excess of £3000 above the estimate in 1885. The fittings and machinery have cost £1900 more than was estimated, and the foundations had to be made stronger at a cost of £450. The Financial Board state that they have every reason to believe that the University has full value for the outlay. The building and fittings are substantial and well adapted to their purpose. Prof. Liveing reports that the lecture-rooms are such that the audience can both see and hear, can sit comfortably and write with ease, and that the laboratories will bear comparison with the best of those to be found elsewhere.

£200 is asked for the purchase of additional apparatus for the Pathological Laboratory (the old Chemical Laboratory).

At Cavendish College eight scholarships of £30 per annum will be offered on July 23 next to students who will be under eighteen years old on October 1 next. One or more may be given for natural science (chemistry, physics, botany, geology, in all of which there will be a practical examination). Further particulars may be obtained from the Master of Cavendish College.

SCIENTIFIC SERIALS.

Bulletins de la Société d'Anthropologie de Paris, tome 11, fasc. 3, 1888.—Continuations of M. G. Hervé's observations on the cerebral convolution known as "Broca's." Great importance attaches to the discovery by the late eminent M. Broca of this anatomical characteristic in man, which he found to be absent in all animals below the Anthropomorpha, and while it appears in the latter only in a simple and rudimentary form, it is fully developed in the human brain. This fact in itself gives support to the hypothesis that intermediate types, now lost, must have been interposed between man and the still existing forms of the Anthropomorpha, and yet more important are the results yielded by recent physical researches, which clearly show that the normal human brain possesses a quadruple system of the frontal convolutions due to the doubling of the binary frontal lobes, while in Broca's convolution we must, moreover, recognize the origin and function of speech and memory. In the microcephali, in idiots, deaf-mutes, and in all persons of inferior intelligence, this convolution is more or less atrophied, especially within the insula or centre, where it unites with the other frontal convolutions near the extremity of the olfactory channel.—Close of the statistical inquiry regarding the colours of the eyes and hair in France, by M. Topinard. After having collected the results of 180,000 observations, M. Topinard an-

nounces that he is about to incorporate them in a chart for France. Three memoirs have already been published as parts of this inquiry, embracing Tunis, Denmark, and Pointe du Raz in France. Among various other interesting results the curious fact has been deduced that where the race is of a mixed blonde and brunette character the hereditary blonde colouring is especially manifested in the eyes, while the brunette element has a tendency to reappear in the hair.—On the origin and intellectual evolution of the pointer dog, by M. C. A. Piètrement. This is a *résumé* by the author of a special section of his great work regarding the legislative enactments in force under the Frank kings of the two earliest dynasties, concerning domestic animals. Beginning with a notice of the fourteen species of house and sporting dogs to be recognized on the monuments of Egypt, Assyria, and Nineveh, he goes on to the references in Greek and Roman writers to the dogs known in their time, in which he finds no indication that pointers and setters existed in their present stage of development as sporting dogs before our era; while, on the other hand, he proves by extracts from the lists of birds and other animals used in the chase, given in the capitularies of Dagobert, that falconry, whose introduction into Western Europe is usually ascribed to the Crusaders, was practised in Gaul as early as the seventh century. The article although long and verbose, contains much interesting information regarding sport among the Franks and Gauls since the time of the Romans.—On the long bones found at Spy, by M. Topinard. The sudden angular deviation of the tibial bones leads to the inference that the lower extremities of the men of Spy were half-flexed, as is generally the case in the arboreal Anthropomorpha.—Cut flints found at Pierrefitte, by M. Simoneau. These finds were taken from the lime-beds of Toucy, and were obtained through the agency of shepherd-boys, successfully enlisted in the work of collecting.—On the grouping of pyramidal cellules in the motor region of the limbs, by M. Mahoudeau. These researches prove the existence of microscopic functional centres in certain parts of the brain, which may be regarded as the true physiological elements of the cerebral organ.—Replies made by M. Bink, while stationed in New Guinea, to the Society's printed category of questions regarding sociology and ethnography.—Report of M. Nicolas on the graves found in the gravel beds of Gadagno (Vaucluse), which he assumed to be of the Stone Age, but which are now shown to have a Ligurian character.—On the dolmens of Kergo, Carnac, by M. Gaillard, who, in another communication, treats of a curious circumstance in regard to the system of arrangement followed in the lines of menhirs in Morbihan. Here he found that a single stone, having a rounded top, was interposed at irregular distances between the regular lines of menhirs, which it always exceeded in height. Continued observations showed that on different and special days of the year, the sun appeared, at its rising, to rest upon the summit of one or other of these isolated menhirs. —On graves containing cinerary vessels belonging to the Polished Stone Age, in the *commune* of Montigny-l'Engrain, by M. Vauvillé.—Observations on the restoration of the tumulus of Kerlescan, by M. Gaillard. The cromlech, which has here been readjusted, consists of twenty-nine of the ancient menhirs, which had escaped destruction.—On the form of the wrist in supination and pronation, and on the differences of outline exhibited by the metacarpal bones when observed on the skeleton, or when the cuticle has been removed, and the muscles have been laid bare, by M. Cuyer, who writes for the artist rather than the anatomist, and illustrates his remarks by various useful woodcuts.—On the relative length, among various peoples, ancient and modern, of the index and ring finger, by Colonel Duhousset.—On the relative length of the two first toes in the Mongolian races, by Dr. Maurel.—On the significance of the practice of measuring the throat of young women, common among the peasantry of Brittany, as well as various Kabyle tribes, by M. Letourneau. Among these remotely separated peoples, similar notions prevail as to the connection between the volume of the neck in women and the age of puberty. The practices that have arisen from a popular belief in regard to this relation are so nearly alike in both instances as to suggest some common origin.—The importance of studying the character of the masticatory process and apparatus, in judging of the nature and habits of mammals, when considered from an anthropological point of view, by Dr. Fauvelle.—On the survival of communal proprietorship in the Morbihan, by M. Letourneau. In this district, various ancient customs still prevail, and in the Islands of Hœdic and Houat, the *curé*, assisted by a council of notables, governs the islands after a patriarchial or fatherly fashion.—A communication, by M. Variot, concerning a new method of effacing the traces of tattooing.

Rivista Scientifico-Industriale, December 31, 1888.—The Chladni figures and Wheatstone's methods, by Prof. Lodovico Malavasi. Here the author proposes to apply Wheatstone's theory on the acoustic vibrations of square plates to the explanation of the figures observed by Chladni in rectangular plates.—The same number contains some remarks by G. Cariati on Mr. Edison's perfected phonograph; and on the solar photographs taken by Prof. Riccò at the Observatory of Palermo.

SOCIETIES AND ACADEMIES.

London.

Linnean Society, February 7.—Mr. C. B. Clarke, F.R.S., Vice-President, in the chair.—The Rev. E. S. Marshall exhibited several interesting varieties of British plants collected by him in Scotland, and made remarks thereon.—Mr. E. M. Holmes exhibited a new British seaweed from Bognor, *Rhododermis elegans*, var. *polystromatica*, a variety new to science.—A paper was then read by Mr. A. D. Michael on three new species of parasitic *Acari* discovered by him in Derbyshire during the autumn of 1888. These were a *Myocoptes*, proposed to be called *M. tenax*, parasitic on the field vole, *Arvicola agrestis*; a *Symbiotes*, proposed to be called *S. tripilis*, parasitic upon the hedgehog; and *Goniomerus masculinus* (gen. et sp. nov.), a minute parasite found on the ear of the field vole. Specimens of all three were exhibited under the microscope, and a discussion followed, in which Profs. Mivart, Stewart, and Howes took part.—Prof. Martin Duncan then gave the substance of an important paper which he had prepared, entitled "A Revision of the Families and Genera of the *Echinoidea* Recent and Fossil." Reviewing the labours of his predecessors, Prof. Duncan traced the growth of the literature of his subject, and showed that, although many lists and papers had been published from time to time, no general review of the class *Echinoidea* had been attempted since 1846. Dealing with all the material at his command, he found it necessary to propose certain alterations in the classification, and to dispense with a good many genera and sub-genera which he considered had been needlessly founded. Above all, he had set himself the task of revising the descriptions of the genera, giving positive instead of comparative characters, a course which he believed would prove of great utility to students. The paper was criticized by Mr. Sladen, Prof. Stewart, and Mr. Breeze, all of whom testified to the necessity which had arisen for some authoritative revision of the subject such as had been undertaken by Prof. Duncan, whose researches would undoubtedly lighten very considerably the labours of future inquirers.

Physical Society, February 9.—Annual General Meeting. —Prof. Reinold, President, in the chair.—The Reports of the Council and Treasurer were read and adopted. From the former it appears that the number of members has only slightly increased during the year, due, it is supposed, to the advantages offered by the Society not being generally known, and a fly-leaf has been prepared, giving a short account of the Society's objects and procedure, copies of which may be obtained from the Secretaries. During the past year vol. i. Part 1, of "Physical Memoirs selected and translated from Foreign Sources," has been printed and issued to members; and the translations of important memoirs by Fourier, Hittorf, and Volta are well advanced, and will be published shortly. The Treasurer's Report showed the financial position of the Society to be very satisfactory. Owing to the lamented death of Prof. Clausius, a vacancy has occurred in the list of honorary members, to fill which Prof. R. W. Bunsen was nominated by the Council and duly elected. The following gentlemen were elected to form the new Council:—President: Prof. A. W. Reinold, F.R.S.; Vice-Presidents: Dr. E. Atkinson, Prof. W. E. Ayrton, F.R.S., Shelford Bidwell, F.R.S., the Right Hon. Lord Rayleigh, Sec. R.S., ; Secretaries: Walter Baily, Prof. J. Perry, F.R.S.; Treasurer: Prof. A. W. Rücker, F.R.S.; Demonstrator: C. Vernon Boys, F.R.S.; other Members of Council: Hon. R. Abercromby, T. H. Blakesley, W. H. Coffin, Conrad W. Cooke, Prof. O. Lodge, F.R.S., Prof. W. Ramsay, F.R.S., W. N. Shaw, Prof. S. P. Thompson, H. Tomlinson, and Dr. G. M. Whipple. Cordial votes of thanks were passed (1) to the Lords of the Committee of Council on Education for the

use of the rooms and apparatus of the Normal School of Science; (2) to the Council and Officers of the Society for their services during the past year; and (3) to the Auditors, Mr. Inwards and Prof. Minchin, for examining the accounts. In returning thanks for the Council and Officers, the President attributed the great success of their meetings to the indefatigable zeal displayed by the Hon. Secretaries.—The meeting was then resolved into an ordinary science meeting.—Prof. A. S. Herschel, F.R.S., read a paper on physico-geometrical models, and exhibited a collection of geometrical figure models illustrating elementary forms of crystallographical and chemical form constructions. The subject, he said, had suggested itself to him as an important one for study some five years ago, from the possibility which he then discovered of effecting a four-limbed mechanical cycle, similar to a thermodynamic cycle, with a conically revolving pendulum, the mathematical conditions of whose motion involved the logarithum of the circle radius of the knob's revolution, as a quantity equivalent to entropy in the thermal cycle. The mechanical cycle may be effected as follows. Suppose the pendulum knob to be revolving at velocity V_1, and radius r_1; imagine the controlling force to decrease so that the radius varies from r_1 to r_2, the velocity remaining constant at V_1; then increase the controlling force to its original value, and simultaneously impart velocity to the knob to keep the radius constant at r_2, the final velocity being V_2. Next, further increase the controlling force so as to cause the radius to decrease to r_1 at velocity V_2; and finally, decrease the controlling force to its initial value, simultaneously retarding the knob till the velocity is V_1 at radius r_1. The net energy concerned in the operations was given as $W = (V_1^2 - V_2^2)\phi$; where $\phi = \log \frac{r_1}{r_2}$, and the cycle affords an illustration of transformation of gyratory motion into energy of reverberatory push along the axis. The logarithm ϕ is also measured by the area of a hyperbolic sector, and is connected (as was shown) with a sector of the circle which a lamp's conical beam would inscribe upon a square glass screen or plate dividing a long room of square cross-section into two parts. The conical beam prolonged through the glass then traces, on the walls beyond, hyperbolas, whose sectors from their summits are related to the circle's corresponding sectors by a well-known hyperbolocyclic trigonometrical connection. From this mode of constructing the connection, and from a discordance which it shows at the asymptote extremities with Euclid's definition of parallel straight lines, the author concludes that cubic space cannot be continuous in its structure, but must be, in a physically constructive sense, like material particles indestructively atomic or molecular. The models showed modes of constructing cubic space in various ways, chiefly by means of tetrahedra, octahedra, and dodecahedra, the common element of form in these being also shown to be the right-angled tetrahedron or "biquoin" obtained by dividing a cube into six equal parts by three planes through its diagonal. A model of Sir W. Thomson's soap foam figure, and some wooden models representing Haüy's polyhedral atoms and their combinations, were exhibited to illustrate the structural view thus taken of geometry; and chemical-figure models of the ring of tetrahedral carbon molecules in benzene, and of the asymmetric groups of similar atoms in active and inactive tartaric acid, were shown.

Zoological Society, February 5.—Dr. St. George Mivart, F.R.S., Vice-President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of January 1889.—Mr. Sclater exhibited a living specimen of the Thick-billed Lark (*Rhamphocoris clotbeyi*) lately received by the Society from Southern Algeria, and called attention to its structural peculiarities.—Mr. G. A. Boulenger read a paper on the species of Batrachians of the genus *Rhacophorus*, hitherto confounded under the name of *R. maculatus*, and pointed out their distinctions.—Mr. Sclater pointed out the characters of some new species of birds of the family Dendrocolaptidæ, which were proposed to be called *Upucerthia bridgesi*, *Phacellodomus rufipennis*, *Thripophaga fusciceps*, *Philydor cervicalis*, and *Picolaptes parvirostris*.—A communication was read from the Rev. O. P. Cambridge on some new species and a new genus of Araneidea. Two of these species (*Pachylomenus natalensis* and *Stegodyphus gregarius*) were based on specimens living in the Insect-house in the Society's Gardens.—A communication was read from Prof. F. Jeffrey Bell, containing descriptions of new or rare Holothurians of the genera *Plexaura* and *Plexaurella*.—Dr. Günther, F.R.S., exhibited and made remarks on some fishes which had been dredged up by Mr. John Murray off the west coast of Scotland, and were not previously known to occur in British waters, viz. *Cottus lilljeborgii* (Collett), *Triglops murrayi*, sp. n., *Gadus esmarckii* (Nills.) *Onus reinhardti* (Collett), *Fierasfer acus* (Brünn.), *Scopelus scoticus*, sp. n., and *Stomias ferox* (Rnhrdt.).—Dr. Günther also exhibited and described a specimen of *Lichia vadigo* (Risso), a species of which only a few specimens were previously known from the Mediterranean and Madeira. This specimen was obtained by Captain MacDonald on September 17, 1888, off Waternish Point, Isle of Skye. He also exhibited a hybrid between the Roach (*Leuciscus rutilus*) and the Bleak (*Alburnus alburnus*), sent to him by Lord Lilford from the River Nun, Northamptonshire.—Mr. Beddard read a paper descriptive of the coloured epidermic cell of *Æolosoma tenebrarum*.—Mr. Boulenger exhibited and made marks on a series of living specimens of Tortoises of the genus *Homopus* from Cape Colony, lately received by the Society from the Rev. G. H. R. Fisk, C.M.Z.S.

Geological Society, February 6.—W. T. Blanford, F.R.S., President, in the chair.—The following communication was read:—On the occurrence of Palæolithic flint implements in the neighbourhood of Ightham, Kent, their distribution and probable age, by Joseph Prestwich, F.R.S. The author stated that Mr. Harrison, of Ightham, has discovered over 400 Palæolithic implements lying on the surface at various heights and over a wide area around Ightham. A description of the physiography of the district and of the distribution of the various gravels and drifts was given, and in the absence of fossils, attention was called to the different levels at which the deposits occurred, and to their physical features and characters. Besides the river-gravels, two groups of unclassed gravels were described, one occupying a low level, and the other levels higher than that to which the river-drifts reach; the latter is of varied composition. In the case of the Shode valley, only beds below the contour-level of 350 feet in its upper part, and of 300 feet or less in its lower part, can be referred to the former action of the Shode, and those above this belong to a high-level drift of uncertain age. The composition of the various gravels was described in detail. The implements are found on the surface of the land at all levels up to 600 feet, and Mr. Harrison has discovered them at forty localities in the hydrographical basins of the Shode, the Darent, the Leybourne stream, and in part of the Thames basin. Two groups of implements extend far beyond the limits assigned to the river-drifts formed since the present hydrographical basins were established, and must be accounted for by some other means than those in connection with the former *régime* of the existing streams. A description of the general characters and variations observable in the implements was given. It is evident from the condition of most of the implements, that they have been embedded in some matrix which has produced an external change of structure and colour. In the case of the river-gravel sites, the question presents no difficulty. Three cases of implements have been found: (i.) where the flint still shows some of its original colour; (ii.) those of which the surface has turned from black to white, has been altered in structure, and acquired a bright patina, and which show no trace of wear; (iii.) those of which the flint has also lost its original colour, but has been stained, and is with or without patina,—these are generally much rolled. The characters of the first call for no comment. Those of (ii.) and (iii.) are very marked, and there is no difficulty in referring each to a distinct matrix. The implements of class ii. have been embedded in a stiff brick-earth, generally of a reddish colour, and those of class iii. seem to have lain in ferruginous beds of sand or gravel. Reasons were given for supposing the surface to have been once covered with a deposit of clay or loess, since denuded except where preserved in pipes, and that a continuous plane descended from the high range of the Lower Greensand to the Thames Valley, which has since been lowered 300 feet or more. It was also shown that the high-level deposits were formed anteriorly to the post-glacial drifts of the Medway and Thames Valleys. It is probable that the loess is a deposit from flood-waters, and that some of it may be referred to the Medway flowing at a higher level; but the highest deposits cannot be so accounted for, and the author referred to the possibility of glacial action, without insisting on it. The deposit on the chalk-plateau is abruptly cut off by the river-valleys, and the rudest forms of implements, such as those of Ash and Bower Lane, occur on this plateau at from 500 to 550 feet, and the author thinks they may possibly be of pre-glacial age. The changes which have taken place in the

physiography of the district, and the great height of the ol chalk-plateau, with its clay-with-flints and southern drifts, poin to long intervals of time, and to the great antiquity of the rude implements found in association with these drifts. That the removal of the material indicates the existence of agents of greater force than those operating under the present river *régime* closes up the time required for the completion of the great physical phenomena, though the author's inquiry tends to carry man further back geologically than is usually admitted. After the reading of the paper there was a discussion, in which Dr. Evans, Mr. Topley, and others took part.

Entomological Society, February 6.—The Right Hon. Lord Walsingham, F.R.S., President, in the chair.—The President announced that he had nominated Captain H. J. Elwes, Mr. F. Du Cane-Godman, F.R.S., and Dr. Sharp, Vice-Presidents for the session 1889-90.—Lord Walsingham exhibited a larva of *Lophostethus dumolini*, Guer., sent to him by Mr. Gilbert Carter, from Bathurst, West Coast of Africa.—Mr. G. T. Porritt exhibited several melanic specimens of *Boarmia repandata* from Huddersfield, and, for comparison, two specimens from the Hebrides. Mr. McLachlan, F.R.S., remarked that melanism appeared to be more prevalent in Yorkshire and the North Midlands than in the more northern latitudes of the United Kingdom.—Captain Elwes read a paper entitled "On the Genus *Erebia*, and its Geographical Distribution." The author, after referring to the number of species and named varieties, many of which appeared to be inconstant as local forms, made some remarks on the nomenclature of the genus, and suggested that a better system of classification might be arrived at by anatomical investigation. It was stated that little was known of the early stages and life-history of species of this genus, the geographical distribution of which was Alpine rather than Arctic. The author remarked that it was curious that there was no species peculiar to the Caucasus, and that no species occurred in the Himalayas, where the genus is replaced by *Callerebia*; that none were found in the Himalo-Chinese sub-region, and none in the Eastern United States of America. He also called attention to the similarity of the species in Colorado and North-West America to the European species. Lord Walsingham, Mr. Waterhouse, Mr. O. Janson, Mr. McLachlan, Dr. Sharp, and Mr. Jenner-Weir took part in the discussion which ensued.—Mr. W. Warren read a paper entitled "On the *Pyralidina* collected in 1874 and 1875 by Mr. J. W. H. Traill in the basin of the Amazons."—Mr. C. J. Gahan read a paper entitled "Descriptions of New or little-known Species of *Glenea* in the Collection of the British Museum."—Dr. J. S. Baly communicated a paper entitled "Notes on *Aulocophora* and Allied Genera."

Paris.

Academy of Sciences, February 11.—M. Des Cloizeaux, President, in the chair.—On the loss of gaseous nitrogen during the decay of organic substances, by M. Th. Schlœsing. In continuation of his previous communication of February 4, he gives the results of some of the experiments already described.—Fresh researches showing that the toxic property of exhaled air does not depend on the carbonic acid, by MM. Brown-Séquard and d'Arsonval. In three previous communications (November 28, 1887, and January 9 and 16, 1888) the authors showed the nature of the relations existing between pulmonary tuberculosis and the air exhaled from the lungs of human beings and domestic animals, as well as the toxic property of one or more substances derived from the lungs. Fresh researches here described show that the poison or poisons escaping with the exhaled air may kill even in small doses, and even without being injected directly into the arterial or venous blood. Subcutaneous injection killed seventeen of eighteen rabbits operated on, generally within twelve to twenty-four hours. In a large number of cases they found that pure carbonic acid (not charged with the vapours of hydrochloric acid) may be inhaled in considerable quantity in the atmospheric air by human beings, dogs, rabbits, and other mammals. The authors themselves breathed for over one or two hours an atmosphere containing 20 per cent of CO_2 without any marked inconvenience, and especially without any lasting consequence. Other still more crucial experiments satisfied them that the fatal results are due, not to the carbonic acid, but to some other toxic substances exhaled by patients suffering from pulmonary affections.—On the invasions of locusts in Algeria, by M. J. Künckel d'Herculais. A careful study of the available documents has convinced the author that the most disastrous years (1845, 1866, 1874) are those that coincide with the simultaneous appearance of the indigenous species (*Stauronotus maroccanus*) and of the foreign variety (*Acridium peregrinum*) arriving from Central Africa.—Observations of the new planet discovered on February 8 at the Observatory of Nice, by M. Charlois. This planet, which is of 12·5 magnitude, is the second discovered by the young astronomer within a fortnight.—On the reductions of the problem of n bodies preserving certain mutual distances, by M. Andrade. It is here shown that the already communicated solution of this problem for a particular case is the most general possible.—On the phenomena of electrolysis, by MM. Violle and Chassagny. The decomposition of water by means of an energetic current is accompanied by luminous and calorific phenomena, which were described by Fizeau and Foucault over forty years ago, and afterwards studied by many physicists. By employing a Gramme machine of 40 amperes with an electromotor force of 110 volts, the authors have been enabled easily to produce these phenomena, to observe them under clearly defined conditions, and to record some hitherto unnoticed circumstances, which are here described.—On the actinometric observations made at Kief, by M. R. Savelief. These observations had special reference to the phenomenon of solar radiation during the year 1888, and to the determination of the solar constant at Kief. M. Savelief's paper was followed by some remarks by M. A. Crova, who directed attention to the great interest it presented, as showing that the law of the annual variations of solar radiation is practically the same at Kief as at Montpellier; that the calorific transparency is greater at the former than at the latter station, and that the solar constant determined on a clear winter's day in Russia may attain the value of 3 calories. This is higher than any recorded at Montpellier, and approached only by the records of an actinometer placed on the summit of Mount Ventoux, which are about the same as those obtained by Mr. Langley during his remarkable researches on the top of Pike's Peak, Colorado.—On some reactions of the chlorides of mercurammonium, by M. G. André. After concluding his researches relative to the decomposing action of water on the amidochloride (*Comptes rendus*, cviii. p. 233), M. André determines the conditions under which the chloride of dimercuriammonium is transformed to amidochloride at contact with sal-ammoniac.—On amorphous bismuth, by M. F. Hérard. The author has succeeded in obtaining this substance by applying to bismuth the same process that he had already employed to obtain amorphous antimony, as described in the *Comptes rendus* for August 13, 1888.—Syntheses effected by means of cyanosuccinic ether, by M. L. Barthe. In a previous note (*Comptes rendus*, cvi. p. 143), MM. Barthe and Haller described the preparation of cyanosuccinic ether, obtained by making monochloracetic ether react on sodium cyanacetic ether. By means of that ether they have now obtained the following syntheses: (1) methyl cyanosuccinic ether; (2) ethylcyanosuccinic ether; (3) ethylethenyltricarbonic ether; (4) propylcyanosuccinic ether, of which the respective formulas are given.—Discovery of a new Quaternary station in Dordogne, by M. Émile Rivière. This station, to which M. Rivière has given the name of Pageyral, in honour of M. Mercier-Pageyral, lies about 2 kilometres from the celebrated Cro-Magnon Cave on the left bank of the Vézère nearly opposite Laugerie, and facing the islet of Malaga. A first exploration has yielded the remains of the reindeer, *Cervus elaphus*, *Cervus capreolus*, *Sus scrofa*, *Canis aureus*, besides various objects of human workmanship characteristic of the Madeleine epoch, such as flint knives, scrapers, arrow-heads, cores, and numerous chippings.

Berlin.

Physiological Society, January 18.—Prof. du Bois-Reymond, President, in the chair.—Dr. Baginski gave an account of his further researches on the Bacteria which occur in the fæces of children fed on milk. Of the two Bacteria which are thus found—namely, *Bacterium lactis* and *Bacterium coli*—he had previously experimented with the first, and proved that it does not induce a lactic acid, but an acetic acid fermentation of milk-sugar, and should hence more appropriately receive the name of *Bacterium aceti*. Recently he has investigated the *Bacterium coli*. Sown in a solution of milk-sugar it produces no change, but when some white of egg is mixed with it a fermentation is set up, not only when the access of air is permitted, but also when it is prevented. The products of this fermentation were proved to be, by an elaborate series of chemical investigations, lactic, acetic, and formic acids, the occurrence of the latter being proved by crystallographic measurements of its barium salts. Both the Bacteria exert an influence which is antagonistic to the development of any alkaline fermentations or decompositions.—Dr. A. König gave an account of his experiments on the action of

santonate of soda on the perception of colours. As is well known, a distinction is drawn between congenital and acquired anomalies of the colour-sense (colour-blindness); of these the first only gives rise to colour-blindness to red or green, while colour-blindness to violet is never observed as a congenital defect. On the other hand, it was supposed that, in the anomalous perception of colour which results from the action of santonin or santonate of soda, we had to deal with a typical case of acquired colour-blindness to violet. The speaker had hence been led to make a number of experiments with santonate of soda on himself, and, apart from the fact that as soon as its action is manifest all objects appear of a yellow colour, had established the following phenomena. The spectrum ceases to be visible on the hinder side of the blue, and not a trace of violet is ever visible; the neutral point, as deduced from closely-agreeing measurements, is situated at wave-length 573—that is to say, exactly at that point which is complementary to the missing violet. The speaker based upon these observations the conclusion that the visual phenomena which are observed after the administration of santonin are not really of the nature of colour-blindness to violet, but can be completely explained by the assumption that the violet rays are absorbed by those media of the eye which have been affected by the drug. Prof. Preyer was unable to agree with the above conclusion, speaking with the experience of the experiments he had himself made with santonate of soda in 1868. The fact that after the administration of the drug the violet part of the spectrum can be seen when it is looked at not directly but indirectly, is opposed to Dr. König's views—that is to say, when its image is allowed to fall upon peripheral parts of the retina. Moreover, Prof. Preyer stated that he experienced a distinct sensation of violet when he had taken the drug while his eyes were closed, and then opened them after the action of the drug had become manifest. He believes that the visual phenomena which accompany the action of santonin can only be explained by assuming that it affects the central nervous system, and that this view is supported by the abnormal gustatory, olfactory, and auditory sensations which are simultaneously observed.—The President communicated some instances of the occurrence of real gustatory and olfactory dreams.

Physical Society, January 25.—Prof. von Helmholtz, President, in the chair.—Dr. A. König spoke on the dependence of visual acuteness upon the intensity of light when objects are illuminated by spectral colours, his remarks being based upon experiments made by Dr. Uhthoff. Earlier researches have shown that, for red, yellow, and green light, the visual acuteness increases at first very rapidly, then more slowly, and then finally shows scarcely any further change as the intensity of the illumination is increased; and that the curve of visual acuteness on the abscissæ which represent the varying intensity of illumination is a parabola, whereas with blue light the curve is a straight line. Dr. Uhthoff had repeated these experiments with spectral colours, taking care that the several lights used were in all cases of equal intensity, a result obtained by altering the width of the slit. The speaker described fully the apparatus he had used, and the series of preliminary experiments he had made, by which he had proved that the narrower the slit is in the screen upon which the spectrum falls, the greater is the acuteness of vision, and that the observations are more trustworthy when a dark mark on a light ground is used as the object whose brightness is to be determined than when a light mark on a dark ground is employed. As regards the apparatus it may be mentioned that the dispersion is produced by a fluid-prism 1 decimetre in diameter. The result of these experiments, as of former ones, was that the visual acuteness increases with the intensity of light in the blue part of the spectrum. When the visual acuteness is compared in the different spectral colours, the intensity of light being in all cases the same, a curve is obtained with a maximum lying near its centre. When the intensity of the light is less, the curve of acuteness on the abscissæ of the spectral colours becomes more pointed, and the maximum moves simultaneously towards the red end. When the intensity of light is the least possible, the maximum for the visual acuteness coincides with the point of greatest brightness in the spectrum. The above holds good not only for the normal trichromatic eye, but also for the dichromatic or red- and green-colour-blind eye.—Prof. Kundt exhibited a photograph of the spectrum of cyanogen extending from the line H up to about the line L, which had been sent to him by Prof. Keyser, of Hanover. For size, beauty, and clearness of the several groups of lines, this photograph is scarcely likely to find its equal.

AMSTERDAM.

Royal Academy of Sciences, January 26.—M. Buys Ballot communicated the results of his observations during the last forty years at the Meteorological Institute at Utrecht, and stated how much temperature, air-pressure, and rain deviated to the right or left from the mean values, and how long this occasionally continues on a stretch before compensation comes about.—M. Beÿerinck spoke on a method of determining the action of different substances on the growth and on some other vital functions of micro-organisms, and illustrated his assertions by preparations. The method consists in applying small quantities of various substances on gelatine plates, either pure or prepared for the purpose, and infected with yeast or Bacteria of some kind or other, and then watching if the micro-organisms in the centres of diffusion of those substances—whether remaining pure or meeting each other on their way—multiply or not, or if they do so in a greater or less degree.

THURSDAY, FEBRUARY 28, 1889.

THE ZOOLOGICAL RESULTS OF THE "CHALLENGER" EXPEDITION.

Report on the Scientific Results of the Voyage of H.M.S. "Challenger" during the Years 1873–76, *under the command of Captain George S. Nares, R.N., F.R.S., and the late Captain Frank T. Thomson, R.N.* Prepared under the superintendence of the late Sir C. Wyville Thomson, Knt., F.R.S., &c., Director of the Civilian Staff on board, and now of John Murray, LL.D., Ph.D., &c., one of the Naturalists of the Expedition. Zoology—Vol. XXVIII. Published by Order of Her Majesty's Government. (London: Printed for Her Majesty's Stationery Office, and sold by Eyre and Spottiswoode, 1888.)

THIS volume contains but one Report, that on the Siphonophoræ collected during the voyage of the *Challenger*, by Ernst Haeckel, M.D., Ph.D., &c. The manuscript was received in instalments between February 8 and July 5, 1888.

In the editorial note we read:—" Prof. Haeckel, through his long-continued and elaborate investigations of living Siphonophoræ and Medusæ in the Mediterranean, Indian and Atlantic Oceans, was in a very special manner fitted to undertake such a task as this Report; and it must be regarded as fortunate that he should have been willing to undertake the work on condition that some of his own unpublished observations should be incorporated. This important and masterly Report has thus become a monograph of the whole class more complete than hitherto published; the classification has been reformed and placed on a new basis. The introduction, giving a general account of the morphology of the order, was translated from the German manuscript by Mr. J. Arthur Thomson, M.A. All the remaining part of the Report was written by Prof. Haeckel in the English language."

It may be fearlessly asserted that no living biologist is more capable of writing a Report on the *Challenger* Siphonophoræ than Prof. Haeckel, and but little objection could be taken to the request that his previous original work should be incorporated with that more particularly devoted to the results of the *Challenger's* expedition; nay, personally, we are inclined to think that a Report should benefit immensely by the incorporation of such work, the more especially in the case of a class like that of the Siphonophoræ, where the drawings from the life are of paramount importance.

It is well known to all interested in the beautiful and graceful forms which constitute the class of the Siphonophoræ, that Prof. Haeckel's " System der Siphonophoren, auf phylogenetischer Grundlage entworfen" appeared in the *Jenaische Zeitschrift* for May 1888; and in the present Report (p. 356) he himself tells us that a separate edition of this important paper was published in December 1887. The general introduction to the Report, which the editor informs us was translated from the German manuscript furnished between February and July 1888, is declared by Prof. Haeckel to be translated from the general part of the above-mentioned separate edition; and, as a matter of fact, a reference to the *Jenaische Zeitschrift* shows this to be the case, with an addition of three pages on " the fundamental form (promorph)." This is but a small matter, but the statement in the preface is certainly one apt to mislead the reader, who ought to have been informed of the previous publication of the general introduction, without being left to stumble upon the statement of the fact on almost the last page of the volume.

Since the publication of the memoir on the Siphonophoræ in the *Jenaische Zeitschrift*, the classification of the group has been but little " reformed," and has certainly not been placed "on a new basis." In the " System" there are seventy-five genera enumerated, which are included in twenty-two families, divided into five orders. In the Report the orders remain the same, two of the subfamilies are elevated to the rank of families, and some half-dozen of the genera are subdivided. Their numerical arrangement is unaltered, but letters are added to the running numbers of the " System"; thus Genus 75 in both the " System" and the Report is Physalia, Lamk., while in the Report the genus Caravella, Hkl., is added as 75*b*. There being no index of genera and species, this partly numerical and partly alphabetical systematic arrangement of the genera makes the volume difficult of reference.

That this Report, able as it is, cannot be regarded as a " monograph" of the order will be generally acknowledged when the following facts are considered. The first order, Disconectæ, contains three families; the first of these, with a circular and regular octoradial umbrella, and with mouthless blastostyles, is called Discalidæ; it contains two genera, Discalia and Disconalia. Of the former two species are named, both inhabitants of the deep sea, and both found by Haeckel in the *Challenger* collection; the first species is described and beautifully figured as *D. medusina*, the second species, *D. primordialis*, n. sp., was captured in the tropical Pacific, at Station 274, and at a depth of 2750 fathoms; but we read, p. 46, " as its state of preservation was not sufficient, I give only the description of the first well-preserved species." Of the genus Disconalia, " two species (both deep-sea inhabitants) were found by me in the *Challenger* collection, one from the Southern Pacific (Station 181), the other from the Indian Ocean, south of Australia (Station 157). The latter (*Disconalia pectyllis*) had much longer and less ramified tentacles, and a larger pneumatocyst, than the former (*Dis. gastroblasta*); but its state of preservation was not sufficient for a full description" (p. 48); nevertheless, we are promised that *Disconalia pectyllis* will be described afterwards in " my 'Morphologie der Siphonophoren'" (p. 357). These two instances occur within the margins of the first two dozen pages of the descriptive portion of the Report; and when we call to mind the really wonderful way in which, from a few fragments, Prof. Haeckel has, in this very volume, diagnosed and even figured some of the *Challenger* species, we regret all the more that he has not here given us, at the very least, those descriptions which he has reserved for elsewhere. Among the list of *Challenger* species apparently good enough for future description, but though named yet not described in this Report, we note the following: *Eudoxella didyma*, Hkl. (Station 343, p. 108),—this genus is quoted from the " System" as Eudoxella, Hkl.; but in the " System," we find it printed as Eudoxon, Hkl., which name would

have priority; *Anthemodes articulata*, Hkl., *Bathyphysa gigantea*, Hkl.

Numerous are the species named from living or preserved specimens, for the descriptions of which the readers of this "monograph" are referred to the forthcoming "Morphology," such as *Strobalia cupola*, Hkl. "This beautiful species was observed living by me in the Indian Ocean, and will be described in my 'Morphology of the Siphonophoræ'; a fragment of a similar species, *S. conifera*, was collected by the *Challenger* in the South Pacific (Station 288)" (p. 243); and again, "*Auralia profunda*, the single species of this genus which I have examined, was taken in the depths of the tropical Atlantic, and will be described in my 'Morphology,' &c." (p. 301).

We have probably quoted enough to show the very uneven treatment that has been meted out to the species of this class. Two hundred and forty of them are referred to by name, but only a small percentage of these are diagnosed; of those that are, some of them were found during the voyage of the *Challenger*, some of them were found by Prof. Haeckel during his own memorable and fruitful sojourns at Madeira and Ceylon, but for many of them we have nothing more than names. There is no doubt that to have made this Report a "monograph" a larger volume, perhaps another volume, would have been needed; but had it been kept within the limits of a Report on the *Challenger* species, it would not have occupied the space it at present does.

The volume contains 380 pages, and is illustrated by 50 plates, several of which are beautifully printed in colours. The plates were in some instances printed off before the text was printed; and of those coloured, all but one are after original coloured drawings of the author's. Amidst the number of strange, beautiful, and interesting forms described and figured, it is hard to make a selection; perhaps the greatest interest will be taken in the forms belonging to the new order of the Auronectæ. In this order there is present a peculiar and most remarkable organ, called the air-bell or aurophore: "it seems to be the modified umbrella of a medusome, and is adapted for the production and emission of the 'gas' contained in the large pneumatophore; the trunk of the siphosome is also thickened and bulbous, and traversed by a network of anastomosing canals, similar to the fleshy or cartilaginous cœnosome of the Alcyonidæ." There are two families, Stephalidæ and Rhodalidæ. The family Stephalidæ has two genera, Stephalia and Stephonalia. Of the former genus, the single species *S. corona* was found by Dr. Murray during the *Triton* Expedition, in the Faroe Channel; and of the second genus the single species *S. bathyphysa* was found by the *Challenger* in the South Pacific. The family Rhodalidæ also contains two genera, Auralia and Rhodalia. Of the first of these, *A. profunda*, as before mentioned, "the single species of this genus which I have examined was taken in the depths of the tropical Atlantic, and will be described afterwards in my 'Morphology of the Siphonophoræ.' Its external appearance is similar to that of *Stephalia corona*; but the nectophores of the simple corona are more numerous and the tentacles are of the same shape as in Rhodalia." As this is all we are told about the species, we cannot be certain whether it was a *Challenger* form or not. Rhodalia likewise has but one species, *R. miranda*. This wonderful form is described from specimens taken at Station 320, south-east of Buenos Ayres, and is figured on Plates 1-5.

Prof. Haeckel thinks that these Auronectæ are permanent deep-sea Siphonophoræ, which may move up and down within certain limits of depth, but never come to the surface. He regards their discovery as one of the most splendid made during the cruise of the *Challenger*; yet for a knowledge of what is known about them we must look beyond the pages of this Report.

A species of Anthophysa, taken at Station 334, has been called *A. darwinii*. Several other species are alluded to by name; it seems possible that Merten's manuscript name Anthophysa, published by Brandt, in 1835, is preoccupied by Bory de Saint Vincent for a genus of flagellate Infusoria.

In addition to the author's preface, and the general introduction, there is the usual description of the families, genera, and species, the deficiencies in which we have sufficiently alluded to. This is followed by a bibliography of the Siphonophoræ; a list of the families, genera, and species; a very useful glossary of the terms used in Latin, English, and German; and lastly, a statistical synopsis, from which we learn that 85 genera are enumerated, these containing 240 species. The diagnoses of 47 new species are given in this Report, of which 27 were found by the *Challenger*.

The characteristics of the orders and families are given in most satisfactory detail, and this portion of the Report would in itself constitute a most important and valuable general history of the group, and must serve for the ground-work of all future writings on the subject.

If too much has been claimed for this meritorious contribution to natural science from a monographical point of view, such a claim in no way takes from its merits as a profoundly important contribution to natural science.

THE ENCYCLOPÆDIC DICTIONARY.

The Encyclopædic Dictionary. Vol. VII., Part II. (London: Cassell and Co., 1888.)

ALL concerned in the production of this work may be congratulated on the completion of their undertaking. It is a work of more than ephemeral interest, and well deserves the favourable reception which has already been accorded to it. It was planned seventeen years ago, and the first divisional volume appeared in 1879. The intention at that time was that the Dictionary should consist of twelve divisional volumes, but, as the execution of the scheme went on, it became obvious that, unless the contents of the concluding volumes were to be presented in a very inadequate form, two additional divisional volumes would be necessary. It was arranged that these volumes should be supplied, and thus ample opportunity was provided for the maintenance, to the end, of a high standard of excellence.

The scale on which the work has been done may be seen from the fact that in round numbers it contains some 180,000 words or headings. This is a great advance on earlier dictionaries. The new edition of the Imperial Dictionary, which stands next, has 130,000 headings; the latest edition of Webster's Dictionary, with supplement, has 118,000; the early edition of Webster had

70,000; and Todd's edition of Johnson's Dictionary had 58,000. Even a general statement of the number of headings does not give an adequate impression of the amount of the contents of the present work, because, as pointed out in the preface, each word has been subdivided as far as possible into the various meanings which it has assumed at different times.

Judged simply as an ordinary dictionary, the work has high merits. No doubt, when Dr. Murray's vast undertaking is completed, both this and all other existing dictionaries will seem in many respects deficient; but for the present we do not know that anyone wishing to possess, for frequent reference, a sound, thoroughly trustworthy dictionary, could anywhere find his want more satisfactorily supplied than in these volumes. The question, what words can legitimately claim admission, had of course to be met at the outset, and it has been settled in a way that will commend itself to the judgment of all persons competent to form an opinion on the matter. All technical terms, so far as known, have been included; slang words, colloquialisms, and provincialisms have not been wholly omitted; specially coined words have also, in some instances, been recognized; and due respect has been shown to semi-naturalized words and to hybrid compounds. The department of etymology, we need hardly say, has received much careful attention; and great pains have been taken to provide quotations illustrative of every sense of each word, with references as full as could be given. The pronunciation of words is clearly indicated, and the adoption of various styles of type makes it easy for persons using the Dictionary to distinguish between various divisions and subdivisions of words.

As the title indicates, it is not merely as a dictionary that the work should be estimated. The aim has been to combine the advantages of a dictionary with those of an encyclopædia, and this idea has been realized with a remarkable degree of success. No one will expect to find here, under any heading, full information, such as one reasonably looks for in a great encyclopædia. Nothing of this kind has been attempted. But under each heading the thing is described as well as the word; and although the descriptions are necessarily brief, they are, so far as they go, clear and accurate, and no one who refers to them will afterwards have to unlearn anything they may have taught him. The short articles relating to the various branches of natural science are especially well done—a fact which will be readily understood when we say that the editor and publishers acknowledge the services of many eminent scientific workers, including Prof. Huxley, Dr. Sclater, Dr. Günther, and Mr. Carruthers.

OUR BOOK SHELF.

Manuel Pratique de Cristallographie. G. Wyrouboff. (Paris: Gauthier-Villars et Fils, 1889.)

MANY books have been written about crystallographic calculation, and their size and the uninviting appearance of their contents have probably created an impression that there is something peculiarly difficult in the subject. M. Wyrouboff's manual will not, we fear, dispel this erroneous idea, for about 300 of his pages are devoted to an exposition of the methods of calculation; but the book, being eminently practical, consists almost entirely of examples, which are fully worked out by simple and intelligible methods, while very little space is wasted upon the geometrical principles involved. The work is therefore very different in character from the geometrical treatises which have frequently adorned the subject, and will doubtless be of great use to the class for whom it is written—namely, "those to whom crystallography is only a means for the determination and description of species," to whom and to all who are attempting to acquire a practical knowledge of crystallography it may be warmly recommended. We would only suggest to such two words of caution: in the first place, the calculations are in each case conducted in two ways, by means of plane angles and solid geometry, and by means of spherical trigonometry,—the former method is unnecessary and undesirable; in the second place, the Millerian axes and notation of three indices should certainly be used in the rhombohedral system in preference to the notation of four axes.

M. Wyrouboff is so well known as the author of valuable contributions to the science of crystallography (by which we mean the knowledge of the relation between the physical, chemical, and geometrical characters of crystals as distinguished from either the study of mineralogy or the art of crystal-measurement), that the following remarks, taken from his preface, deserve particular attention:—

"How far more advanced would be our knowledge of the intimate structure of bodies if chemists were to describe accurately the form of the innumerable substances which issue from their laboratories, and which, being sometimes accidentally obtained, difficult to reproduce, or prone to rapid decomposition, are lost to science; and if, on the other hand, physicists were accustomed to connect the properties which they discover with the symmetry which belongs to the crystalline exterior. It is true that in doubtful cases, or such as are of particular interest, they both have willing recourse to the professional crystallographer; but, apart from the fact that he is not always at hand, experience teaches that such a division of labour rarely gives good results. Forms placed in arbitrary positions without regard to the forms of allied substances often serve only to conceal the analogies which are professedly sought," &c.

From which we gather that the position of crystallography in France is much the same as in England, and that such books as that of M. Wyrouboff, although not liable to be choked by the thorns of competition, are at present somewhat likely to fall upon the stony ground of indifference.

Assistant to the Board of Trade Examinations. By Captain D. Forbes, F.R.A.S. (London: Relfe Bros., 1888.)

IN preparing candidates for the Board of Trade examinations for officers' certificates, Captain Forbes has felt the want of a handy book of reference to the various questions asked, and he hopes to supply that want by the little book before us. In these examinations, the candidate has to show his knowledge by answering a number of a set of questions which is the same from year to year, although those selected by the examiner may be different. The questions put to the candidates, and the answers to them which the author suggests, are given in this little book. As examples of brevity, the definitions given of the various astronomical terms are unequalled in any book we are acquainted with. Thus, right ascension is defined as "the distance which a heavenly body is eastward of the first point of Aries"; while not the slightest idea is given of the meaning of the latter term. On p. 14, sidereal *time* is stated to begin when the first point of Aries is on the meridian, and to *end* when it returns to it

again; how much information this will convey to a student we leave our readers to judge. The answers to the various questions which are asked on the sextant are far better than the definitions, as are also the answers to the questions on cyclones. The questions on the deviation of the compass, for masters' certificates, are also fairly well answered, although a little further explanation of Napier's diagram, which forms the frontispiece, might have been given with advantage.

For reference to the questions given, the book will no doubt be very useful to intending candidates, but the answers given are good examples of the system of cramming for examinations, which cannot be too strongly condemned.

Guatemala: The Land of the Quetzal. By William T. Brigham. (London: Fisher Unwin.)

MR. BRIGHAM, an American author, has made three journeys in Guatemala, and in the present volume he has brought together all that seemed to be important in the notes written during his travels. The work is one of great interest, and ought to be not less welcome to the general reader than to persons who have special reasons for studying the subject. Mr. Brigham is a keen observer, and records his impressions clearly, simply, and effectively. No one who, in imagination, attends him in his course across the continent to Coban, from Coban to Quezaltenango, from Quezaltenango to the Pacific, will fail to be attracted by what he has to say about the physical features of the country and about the manners of its inhabitants. There are also excellent chapters on Guatemala city, and on Esquipulas and Quirigua. A sufficiently full account is given of the vegetable and animal productions of Guatemala, and of its earthquakes and volcanoes. In an introductory chapter, Mr. Brigham has something to tell us about Central America generally, and it may be worth noting that these regions will one day, in his opinion, be "the garden and orchard of the United States, not necessarily by political annexation, but by commercial intercourse." Great care has been taken to secure the accuracy of the illustrations, most of which are direct reproductions from negatives.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Weismann's Theory of Variation.

I THINK it may be reasonably objected to Mr. Cunningham's ingenious *reductio ad absurdum* of Weismann's theory, that because we cannot exactly state what happens in the mysterious fusion of sperm- and germ-nucleus, it by no means follows that such fusion does not largely account for the observed variation. I say largely, because Prof. Weismann's more recent paper, "Ueber die Zahl der Richtungskörper und über ihre Bedeutung für die Vererbung" (Jena, 1887), completes in a most important manner the paper quoted and criticized by Mr. Cunningham.

The argument is briefly as follows. The expulsion of the second polar body by sexual eggs is the removal of half the ancestral germ-plasms in order to make room for those which are added in fertilization. For this reason we must suppose that an equivalent reduction of the sperm-nucleus also takes place. If this reduction did not occur, the number of germ-plasms would be doubled in each sexually-produced generation—an unthinkable result.

If there were only one kind of germ-plasm in each nucleus, and sexual reproduction commenced, there would be 1024 distinct germ-plasms in each of them at the end of ten generations. But the number of generations must be so vastly in excess of ten that the number of ancestral germ-plasms in each sperm- and germ-nucleus must be considered to be infinite, or at any rate so large that the expelled halves would never be the same. It therefore follows that no two sperm- or germ-nuclei can be alike, and individual variation must follow. A little consideration also shows that while the children of the same parents must differ, they must also resemble each other more than the children of other parents, and while they must differ from their parents they must also resemble them more than the parents of other children.

The occurrence of atavism may be explained as a direct consequence of an unusual predominance of ancestral germ-plasms; the fact that atavism is a rare exception also follows from the fact that the expulsion of half the germ-plasms in each generation will nearly always prevent such predominance.

It is impossible to carry the subject further in the scope of a letter, or one might refer to the evidence for the absence of variability in parthenogenetic species, in which the second polar body is not expelled from the ovum; and to the identity of twins produced from a single ovum which has presumably divided after fertilization.

E. B. POULTON.

Oxford.

A Correction.

WITH reference to my communication in last week's NATURE, Prof. Oliver Lodge has called our attention to the fact that we had made a mistake in stating that the wave-length of the vibration was 33 centimetres. It is the semi-wave-length that is 33 centimetres; the wave-length is 66 centimetres, as is evident on consideration of the size of the "vibrator."

FRED. T. TROUTON.

Temperature Observations in Rivers.

THE Committee appointed at the Bath meeting of the British Association to investigate seasonal variations of temperature in rivers and streams was able to arrange through local scientific Societies for thirty observers, commencing work in January 1889. Of these there are ten in England, ten in Scotland, and ten in Ireland. Each observer is supplied with a specially designed thermometer (costing *2s. 6d.*) which has been compared with a standard instrument, and books for recording the observations and full instructions are provided by the Committee. It is desirable to extend the observations to rivers not yet taken up, and I therefore wish to direct the attention of local scientific Societies, of meteorological observers and others interested in similar work, to the opportunity now offered of taking part in a systematic investigation, the preliminary results of which show many interesting features. I shall be pleased to answer any inquiries of intending observers.

HUGH ROBERT MILL,
Secretary Brit. Assoc. Committee.

Heriot-Watt College, Edinburgh, February 20.

"Bishop's Ring."

IN your review of the Report of the Krakatão Committee of the Royal Society, it is stated that "Bishop's ring" has quite disappeared. Now this is hardly correct, for although I have not heard of anyone perceiving it in the middle of the day for a long time past, it is still visible about sunrise and sunset, though becoming on the whole gradually fainter. I presume that it is really the same phenomenon. At the time when "Bishop's ring" was most conspicuous in the full day-time, it was always far more so when the sun was rising and setting.

Sunderland, February 20. T. W. BACKHOUSE.

Peripatus in Australia.

Peripatus has been found not only in Queensland and Victoria, but also at Cassilis, in New South Wales, by Mr. A. S. Olliff, of Sydney. The Victorian and New South Wales localities are recorded in a postcript appended to my monograph of the genus as reprinted from vol. iv. of the "Studies from the Morphological Laboratory of the University of Cambridge." My knowledge of them is due to Mr. Olliff, who was kind enough to send me his specimen and his description of it (Proc. Linn. Soc. of

New South Wales, November 30, 1887). The New South Wales species is, I think, identical with that found in Queensland, and I should be inclined to doubt the distinctness of the Victorian species recorded by Mr. Dendy in NATURE (p. 366), and previously by Mr. Fletcher.

Mr. Dendy appears to lay some stress on the differences of colour as between his specimen and the specimens of *P. leuckarti* hitherto described, but it must be remembered that in some species of Peripatus—*e.g. capensis* and *novæ-zealandiæ*—the range of individual colour-variation is very considerable.

All the species that I have seen are very beautiful when alive; but the beauty, which is partly due to the texture of the skin, is very hard to reproduce in a drawing.

It is a remarkable fact that a creature which lives so entirely in the dark as does *Peripatus* should present such rich coloration and such complicated markings.

The egg of *Peripatus leuckarti* is heavily yolked and of a fair size, but smaller apparently than that of the New Zealand species. Its development cannot fail to be of the greatest interest, and it is sincerely to be hoped that the Australian zoologists will lose no time in working it out.

A. SEDGWICK.

Trinity College, Cambridge, February 18.

Anthelia.

I HAVE been following with much interest your notices of anthelia, and was about to add my mite to the information given, when, by the mail just in, I have your issue of October 25 last, wherein is a notice of the phenomenon as observed in Ceylon. I have witnessed it there scores and scores of times in my early tramps bird collecting, and I have also seen it at the Cape, in Brazil, on the Amazon, in Fiji, and in this island. On turning up my dear old friend Sir E. Tennant's book on Ceylon, I find that at p. 73, vol. i., he gives a very fair figure of the effect produced. It may be, as he says, that the Buddhists took from it the idea of a "halo" or "flame" for the head of Buddha, but there is one peculiarity about these flames that always struck me. In whatever position you find the Buddha, the flame is invariably in a straight line with the body even if the figure is recumbent. In form it always resembles the "tongues of fire" depicted by old painters as falling on the apostles on the Day of Pentecost.

I have seen many instances of what I suppose may be called "anthelia" in calm water, but the appearance is usually more *rayed*. I have an exquisite engraving in my print collection of the "Madonna and Dead Christ" by Aldegrever (1502–58). It has often occurred to me, in looking at it, that the artist has taken his idea of the halo round the Virgin's head from the appearance presented by the "anthelia" in water. There is the same luminous centre, and then the divergent rays. The halo round the head of the dead Christ in her lap is a four-cornered luminous star, issuing rays, of which three points only are visible—like nothing in nature with which I am acquainted.

E. L. LAYARD.

British Consulate, Noumea, January 3.

Mass and Inertia.

I AM pleased to see that Dr. Lodge has adopted my suggestion made in the *Engineer* about four years ago of using the term inertia for the quantity mass-acceleration. In making the suggestion I considered that I merely asked a return to the meaning implied by Newton in the phrase "*vis inertiæ*."

Unless this is the meaning of the term, the reason why Σmr^2 is called moment of inertia is almost incomprehensible. With it the connection is obvious; for, if ψ is the angular acceleration of a body about an axis, and r the distance of any particle, its linear acceleration is ψr, its inertia $m\psi r$, and its moment of inertia $rm\psi r$, or $m\psi r^2$. As the angular acceleration is the same for all particles of the body, the moment of inertia of the body is $\psi\Sigma mr^2$.

As Dr. Lodge mentions that he is bringing the matter before the British Association Committee on Units and Nomenclature, might I suggest that in future Σmr^2 should be called the *moment of inertia constant*, thereby implying the existence of the *variable factor* ψ, the angular acceleration, in the expression for moment of inertia.

E. LOUSLEY.

Royal College of Science, Dublin, February 16.

To find the Factors of any Proposed Number.

IT has long been a desideratum of mathematicians to discover a formula or method for ascertaining the factors of any proposed number, and also determining whether it be a prime or not. Their endeavours during the twenty centuries that have elapsed since Eratosthenes (B.C. 276–196) made the first recorded attempt to produce a practical rule for the purpose have not been attended with success.

As it may interest many readers of NATURE, and others, I propose, with a few preliminary remarks, to make known a simple arithmetical method by which this desideratum can now be attained.

Factors of an even number can readily be found, as 2 is always one of them, but it is not always so easy to find the factors of an odd number, especially if it be a high one, and, if the number be the product of two primes, the difficulty in this respect is still greater, because they are its only factors. Hitherto they could be ascertained only by trying in succession, as divisors, the prime numbers of less magnitude than its square root.

To find by such process the factors of 8616460799 (the square root of which is between 92824 and 92825), it might, possibly, be necessary to try 8967 prime numbers as divisors (out of the 8969 that there are) before they could be ascertained. By my process, division sums are altogether avoided. This high number occurs in a chapter on "Induction as an Inverse Operation," in "Principles of Science," by Stanley Jevons, second edition. His emphatic remarks as to the difficulties attending on inverse operations in general, and particularly those with reference to finding the factors of this number, were the incentive to my endeavouring to discover some process for ascertaining them which might possibly have escaped being previously tried. He states:—"The inverse process in mathematics is far more difficult than the direct process. . . . In an infinite majority of cases it surpasses the resources of mathematicians. . . . There are no infallible rules for its accomplishment. . . . It must be done by trial, . . . by guess-work. . . . This difficulty occurs in many scientific processes. . . . Can any reader say what two numbers multiplied together will produce 8616460799? I think it unlikely that anyone but myself will ever know. They are two prime numbers, and can only be discovered by trying in succession a long series of prime divisors, until the right one be fallen upon. The work would probably occupy a good computer many weeks. It occupied only a few minutes to multiply them together."

Mr. Jevons adds: "There is no direct process known for discovering whether any number be a prime or not, except by the process known as the 'sieve of Eratosthenes,' the results being registered in tables of prime numbers."

In the article on prime numbers in "Rees's Cyclopædia" (ed. 1819), the writer states: "It is in fact demonstrable that no such formula" (for discovering whether a number be a prime or not) "can be found, though some formulæ of this kind are remarkable for the number of primes included in them."

The difficulty of finding the factors of numbers is also referred to by the eminent writer (at that time President of the Mathematical Society)—under the initials C. W. M.—of an interesting review of "Glaisher's Factor Tables," in NATURE, vol. xxi. p. 462. In course of his remarks he mentions the number 3979769, and respecting it says: "It would require hundreds of division sums to ascertain by trial that it had 1979 for a divisor, and that consequently it was the product of 1979 × 2011;" and he adds, ". . . . there is no general mathematical principle which enables us to dispense with the trial, or even to shorten it, so as to bring it within practical limits."

These extracts afford conclusive evidence that no direct rule or method has hitherto been known, by which the factors of a number could be ascertained, and also that it is considered it would be a task of almost insuperable difficulty to devise one. Yet it seemed to me not unreasonable to think that, as two factors multiplied together formed a product, it ought to be possible to unmultiply or split up (as "C. W. M." expresses it) that product into its factors again, "without the enormous labour of trying for its divisors."

Strongly impressed with this idea, I attempted to realize it, and before long succeeded in discovering a simple arithmetical process for the purpose, and different from any previously tried. When applied to find the factors of 8616460799, instead of "many weeks being occupied" in the task, it showed, within a very reasonable time, that they were 96079 × 89681. When

applied to find the factors of 3979769, instead of "hundreds of division sums" being requisite,—about two minutes of time, no division sum at all, only one of subtraction, showed them to be 2011×1979.

My method or rule consists in finding the next higher square (call it "A") to the proposed number, from which, if the proposed number be deducted, the difference, or remainder, will be a square number (call it "B"). Then the square root of A plus the square root of B will be one factor, and the square root of A minus the square root of B will be the other.

It is essential to state, in addition to this general rule, that, when the "difference" between the proposed number and the higher square first used (not necessarily the next higher square to it) is a square, the process is virtually ended, for the factors can then be readily found by the directions given above. But if "the difference" be not a square, successive additions must be made to it of a progressive series of numbers, whose common difference is 2, and commencing with twice the square root of the square first used, plus 1, until their sum becomes a square number, which will be that called B in the paragraph above.

This is simply an easier mode of ascertaining what the differences may be between the proposed number and the higher squares, than by subtracting one from the other at each step of the process. The aggregate sum of the additions, taken at any step, is always equal to the square of the square root corresponding to it, minus the proposed number. The square root corresponding to any step is always half the serial number then added, plus $\frac{1}{2}$.

Hence my method may also be said to consist in the successive addition to the difference between any proposed number and a higher square, of a series of numbers as specified above, until their sum becomes a square.

The length of the process varies, and is longest when the difference between the factors of the proposed number is greatest, and especially if it be a high prime. But in many cases it can be shortened very considerably. It would require many examples to show how this can best be done under many varying circumstances. At present I give only a few examples to show the operation according to the general rule, and of one or two ways of shortening the work.

Examples.—Find factors of 1443, 57, 110467, 8616460799, and 3979769.

Proposed number 1443
Next higher square 38^2 1444

Difference ... $1 = 1^2$

Then ... ... $38 + 1$ $38 - 1$

Factors are ... $39 \times 37 = 1443$.

Proposed number 57
Next higher square (8^2) 64

Difference ... 7

Add $8 \times 2 + 1$ (or $8 + 9$) ... $17 = 24$
„ $9 \times 2 + 1$ (or $9 + 10$) ... $19 = 43$
„ $10 \times 2 + 1$ (or $10 + 11$) ... $21 = 64 = 8^2$

Then ... ... $11 + 8$ $11 - 8$

Factors are ... $19 \times 3 = 57$.

Proposed number 110467
Next higher square (333^2) 110889

Difference ... 422
Add $333 \times 2 + 1$ (or $333 + 334$)... 667

$1089 = 33^2$

Then ... ... $334 + 33$ $334 - 33$

Factors are ... $367 \times 301 = 110467$.

Jevons's proposed number 8616460799
Next higher square (92825^2) 8616480625

Difference ... 19826
Add $92825 \times 2 + 1$ (or $92825 + 92826$) $185651 = 205477$ (not a sq.)
„ $92826 \times 2 + 1$ $185653 = 391130$ (not a sq.)

therefore, add fifty-four more serial numbers, to $92880 \times 2 + 1$; the sum of the additions will then be found to correspond with—

$$\left.\begin{array}{r} 92880^2 = 8626694400 \\ - 8616460799 \end{array}\right\} = 10233601 = 3199^2$$

Then ... ... $92880 + 3199$ $92880 - 3199$

Factors are ... $96079 \times 89681 = 8616460799$.

"C.W.M.'s" proposed number ... 3979769
Next higher square (1995^2) 3980025

Difference ... $256 = 16^2$

Then ... ... $1995 + 16$ $1995 - 16$

Factors are ... $2011 \times 1979 = 3979769$.

To find the lowest factors of 12267—

$$\left.\begin{array}{lr} \text{Proposed number ... ...} & 12267 \\ \text{Sum of digits being 18 it is divisible by } 3^2 = & 9 \end{array}\right\} = 1363$$

Next higher square (37^2) ... ... $= 1369$

Difference 6
Add $37 \times 2 + 1$ or $37 + 38$ 75

$81 = 9^2$

Then ... ... $38 + 9$ $38 - 9$

Lowest factors... $47 \times 29 \times 3 \times 3 = 12267$.

To find the factors of 73, by the general rule, 28 steps in the process are requisite, until the sum of additions to first difference reaches a square, $1296 = 36^2 = 37^2 - 73$.

Then $\left.\begin{array}{l} 37 + 36 = 73 \\ 37 - 36 = 1 \end{array}\right\}$ the only factors, therefore 73 is a prime.

Instead of 28 steps being taken, the process may be shortened thus:—

Proposed number 73
Next higher square (9^2)...81

— 36 64 (even squares)

First difference ... 8 . . . 28 . . . 56
Add $9 \times 2 + 1$ (or $9 + 10$)...19 (diff. 6) (diff. 2)

Second difference... 27 . . . 22 . . . 54

49 81 (odd squares).

It must be noted that the first difference (8) is an even number, and that the second (27) is an odd one. In line with 27, put down difference (22) between it and next higher odd square (49), and in line with 8, the difference (28) between it and the even square (36) next below 49. As the difference 6 (between 28 and 22) will not divide either without a remainder, the process must be repeated, with the succeeding higher even (64) and odd (81) squares, for each line, until we obtain two numbers, divisible by their difference, without remainder. In this example we find that the second step gives what is required. The difference (2) between 56 and 54, divides either.

Then $\frac{56}{2} = 28$, and $28 + 9$ (9 is first square root used) $= 37$;

or $\frac{54}{2} = 27$, and $27 + 10$ (10 is second sq. root used) $= 37$;

and $\left.\begin{array}{r} 37^2 = 1369 \\ - 73 \end{array}\right\} = 1296 = 36^2$, as stated above.

The following example of a shortening process is applicable only to proposed even numbers. As such are divisible by 2, it may not be of much practical use; and only of interest to show what can be done. If the proposed number be 328, 18 steps are requisite by general rule; but 7 steps are sufficient, thus:—

Proposed number	328	
Next higher square (19^2) ...	361	
Difference	33	
Add $2 \times 19 + 1$ (or $19 + 20$)	39 =	72
(or $20 + 21$)	41 =	113
(or $21 + 22$)	43 =	156
(or $22 + 23$)	45 =	201
(or $23 + 24$)	47 =	248 = 8 below 16^2.
(or $24 + 25$)	49 =	297 = 8 above 17^2.

It must be noted that at the 6th step the sum of additions is 248, or 8 less than the next higher square ($256 = 16^2$), and at the 7th step it is 297, or 8 more than the next lower square ($289 = 17^2$). The mean of these consecutive roots is 16½. The consecutive square roots, corresponding for the 6th and 7th steps, are seen to be 24 and 25. The mean is 24½.

$$\left.\begin{array}{l} \text{Then } 24\tfrac{1}{2} + 16\tfrac{1}{2} = 41 \\ \phantom{\text{Then }} 24\tfrac{1}{2} - 16\tfrac{1}{2} = 8 \end{array}\right\} \text{therefore } 41 \times 8 \text{ are factors of } 328.$$

There are other short ways of working the process, varying with different numbers. For high numbers, when the difference between the factors is very great, I have not completed a shortening process that is altogether satisfactory, but I hope to succeed before long.

The examples given above are worked out by means of "increasing squares, roots, and numbers." Similar results may generally be obtained by operating with "decreasing squares, roots," &c., but I prefer the "increasing" method. To show the process by "decreasing squares," &c., I give two simple examples—

Proposed number	65
Next lower square (8^2)	64
Their sum is	129
Deduct $2 \times 8 - 1$ (or $8 + 7$) ... =	15
	114
,, $2 \times 7 - 1$ (or $7 + 6$) .. =	13
	101
,, $2 \times 6 - 1$ (or $6 + 5$) ... =	11
	90
,, $2 \times 5 - 1$ (or $5 + 4$) ... =	9
	$81 = 9^2$

$$\begin{array}{lccc} \text{Then} & 9 & & 9 \\ & +4 & & -4 \\ \text{Factors are} & 13 & \times & 5 = 65. \end{array}$$

Proposed number	60	
Next lower square (7^2)	49	
Their sum	109	
Deduct $7 \times 2 - 1$ (or $7 + 6$) =	13	
Mean 5½	$96 = 4$ from 10^2	Mean 9½
($6 + 5$) =	11	
	$85 + 4$ above 9^2	
Deduct $6 \times 2 - 1$ (or $5 + 4$) =	9	
Mean 3½	$76 - 5$ from 9^2	Mean 8½
($4 + 3$) =	7	
	$69 + 5$ above 8^2	
Deduct $5 \times 2 - 1$ (or $3 + 2$) =	5	
	$64 = 8^2$	

$$\begin{array}{lccccccccccc} \text{Then} & 8 & & 8 & \text{or} & 8\tfrac{1}{2} & & 8\tfrac{1}{2} & \text{or} & 9\tfrac{1}{2} & & 9\tfrac{1}{2} \\ & +2 & & -2 & & +3\tfrac{1}{2} & & -3\tfrac{1}{2} & & +5\tfrac{1}{2} & & -5\tfrac{1}{2} \\ & 10 & \times & 6 & & 12 & \times & 5 & & 15 & \times & 4 \end{array}$$

Showing 3 sets of factors for 60.

A table of squares and square roots, such as Barlow's, is requisite for enabling the operator to ascertain readily, as his work proceeds, when the sum of the additions to the difference between the proposed number and the higher square, first used, becomes a square; and also to show, in connection with shortening processes, to what extent they may differ, at any step, from being square numbeis.

Whether the principle of this method or rule be useful in working algebraical or other problems I am at present unable to say, but it can no longer be said there is not a direct rule for ascertaining the factors of any number, and consequently of showing whether it be a prime or not. It may be impossible to devise an algebraical formula, but there certainly is this simple arithmetical method, applicable to all numbers.

17 Morden Road, Blackheath. CHARLES J. BUSK.

THE FORMATION OF LEDGES ON MOUNTAIN-SLOPES AND HILL-SIDES.

IT is well known that Darwin attributed to the castings of earthworms the principal part in the formation of these ledges; although he mentions in his book the case of a valley in Westmoreland, where it was "in no way connected with the action of worms." "It appeared," he concludes, "as if the whole superficial, somewhat argillaceous earth, while partially held together by the roots of the grasses, had slided a little way down the mountain-sides; and in that sliding, had yielded and cracked in horizontal lines, transversely to the slope."[1]

Ledges of this description are exceedingly common on the mountain-slopes round Caracas, and indeed almost everywhere in Venezuela. They attracted my attention on my arrival in this country, and they did so all the more as it appeared to me impossible to admit the explanation given by the people, that they were the result of the trampling of cattle, for there were no cattle grazing on these slopes, nor could anybody give me trustworthy information that such had been formerly the case. I was pretty soon convinced that this peculiar feature of the surface was due to a downward sliding of the superficial layer, and after having read Darwin's book, a copy of which I had been so happy as to receive from himself in November 1881, I at once wrote to him about the ledges, stating that I believed the real cause of their formation to be what he had suggested in the passage quoted above. (Having no copy of my letter, I cannot give the exact wording of it.) The 3rd of April (only a fortnight before he closed his great life), he answered me as follows:—"Should you observe the ledges on the mountains, I shall like much to hear the results, though I do not suppose that I shall ever again publish on the subject. Since the appearance of my book, I have become doubtful whether I have not exaggerated the importance of worms in the formation of the ledges. Perhaps they may be due to the sliding down and horizontal cracking of (the) whole of the surface soil."

Since that time I have given a good deal of attention to the subject, and the result is, at least in this neighbourhood, absolutely in accordance with this latter suggestion. There is no reason for giving any importance to the action of worms, these animals being extremely rare in the soil of the slopes. I find in my note-book only six instances of their castings having been observed; and three, when by the tearing out of plants a worm was brought to light.

Our mountains are mainly built up of gneiss, which is rather easily converted on the surface into a kind of sandy loam. This surface soil is covered by a dense

[1] Darwin, "The Formation of Vegetable Mould through the Action of Worms" (London, 1881), p. 283.

vegetation of grasses with a number of other small plants, their roots being matted together in an almost continuous mass, possessing a certain degree of elasticity. During the rainy seasons this stratum absorbs a considerable quantity of water, getting thus much softer and offering less resistance to the underlying loam and its downward thrust. The whole mass is therefore in a state of plasticity, and consequently a sliding motion begins more or less as if it were a glacier. The slope not being uniform in all its parts, nor the disintegration of the rock everywhere of the same depth and degree, it follows that the sliding too will be unequal, and so an extraordinarily complicated system of stresses and counter-stresses is developed, which of course causes the surface to take a wrinkled or wavy appearance. I have tried in vain to find numerical values for the limits of sloping which allow of the formation of these surface-waves or ledges; the fact is that it depends to a considerable degree on the interior conditions of the soil and subsoil, which are not visible from outside. The lowest slope, however, that I have seen covered with ledges, was between 8° and 10°, the steepest 45°. The total amount of sliding soil is in some places far from being insignificant. I remember a locality in this neighbourhood, where there was twenty-five years ago a shallow depression, in which during each rainy season a small pool formed with *Najas microdon*, A.Br., *Wolffia Welwitschii*, Hegelm., and even *Marsilea subangulata*, A.Br. This depression has gradually been filling up, and is now on the verge of disappearing altogether, the material having been derived from a grassy slope on its northern side, which is covered by finely developed ledges.

My observations refer to the valley of Caracas; but as identical causes must be at work in other countries, it appears to me that everywhere the formation of ledges on mountain-slopes and hill-sides will probably depend, first of all, on the conditions of the ground and its vegetation, the action of earthworms being of secondary importance.

Caracas, January 6. A. ERNST.

FIG. 1.

A MOVABLE ZOOLOGICAL STATION.

IN Bohemia, much attention has been given for more than twenty years to the study of the fauna of ponds and lakes, but the work has been rendered difficult by the impossibility of the organisms being examined instantly in their habitats. The transportation of the material a long way has led to most of the finer objects being destroyed. Last year, a little movable station, suitable for real biological work, constructed after a sketch drawn by Dr. Ant. Fritsch, was presented by Mr. Ferdinand Perner to the Committee for the Physical Exploration of Bohemia; and there is good reason to hope that the use of this structure may be attended by important scientific results. There is room (12 square metres) for from two to four workers. The building consists of eighty pieces, the

total weight being 1000 kilogrammes. Two windows on the northern side are closed by wooden covers, which, when opened, present two ample working tables. The building-up of the station at the first place to which it was sent (a pond near Biechovic) required two hours and a half.

The scientific work began in the second half of June, and since that time, every week or fortnight, Dr. Fritsch with his assistants has visited the station. After the temperature of the air, and of the water on the surface and at different depths, has been noted, the surface fauna is taken by a tow-net (Fig. 2, 1). This contains mostly Copepods, Rotators, and *Daphnia kahlbergensis*, Schœdler. Then the fauna at a depth of 1 metre is taken by a net fixed on a long bamboo (Fig. 2, 2). The net contains generally the genera Daphnia, Bosmina, and Leptodora. Next, the fauna at a depth of 2 metres is taken by a long net (Fig. 2, 3), on which weights are fixed, and which is drawn out of the water by a string that closes the net by tightening it in the centre. This manipulation prevents the fauna from a depth of 2 metres from being mixed with that of the higher portions of the water. Large Daphnids are found here in great numbers. The same instrument is used in deeper parts of the pond. Mud is carried up by a strong net (Fig. 2, 4), and washed in sieves (7 and 8). The *Allona leydigii* is a common appearance there. These operations finished, the littoral fauna at various places is taken, consisting most commonly of large Sida and Lynceus. Fishing has been carried on in the same way by night, in January, under the ice-cover. Sometimes carp (*Cyprinus carpio*) have been taken at night, that the contents of their alimentary canal might be examined. The living material acquired in this manner is carefully killed by osmic and chromic acids, and preserved in strong alcohol.

The investigations will be continued throughout the year, and the results afterwards published in the *Archiv für naturwissenschaftliche Landesdurchforschung von Böhmen*. The station will, by and by, be transferred to some of the ponds in Southern Bohemia, or to one of the mountain lakes.

Fig. 2.

NOTES.

Arrangements are being made by the Berlin Academy of Sciences for an interesting scientific undertaking. During the summer of this year a ship is to be despatched for the investigation of the pelagic fauna of the Atlantic, especially along the coast from Greenland to Brazil. Prof. Hensen, of Kiel, will be at the head of the party, which is expected to start in July.

The death of M. G. Meneghini is announced. He had been Professor of Geology at Pisa from 1849, and died at the age of 78.

We have also to record the death of Dr. Heinrich Ernst Karl von Dechen, the eminent geologist and mineralogist, well known for his numerous works on geology. He was born at Berlin on March 25, 1800, and died at Bonn on February 15.

A LADY, Mdlle. G. Cattani, has been appointed a *privat-docent* of general pathology in the Faculty of Medicine at Turin.

PROF. E. WIEDEMANN has issued a circular about a matter which has considerable interest for men of science. Journals devoted to particular branches of science very often, as he points out, reprint papers which have been originally published by scientific Societies, and omit to indicate the sources from which the papers are taken. It also happens sometimes that articles are sent simultaneously to various periodicals, and appear sooner or later in all of them, either in the original language or in translations. The consequence is that those whose duty it is to look out for the latest information on any subject are put to a vast amount of inconvenience, since it is frequently impossible for them to feel sure that communications which seem to be new are really new. Prof. Wiedemann—who has of course had much experience, in connection with the *Annalen der Physik und Chemie*, of the trouble caused in this way—appeals to men of science generally, and to the scientific Press, to indicate, in every case in which a paper is reprinted, the fact that it has appeared before, and to state whether the paper has been shortened or expanded or otherwise changed.

ACCORDING to *Die Natur*, Dr. Otto Zacharias, of Hirschberg, Silesia, intends to establish a zoological station for the observation of fresh-water fauna. It is considered that the banks of the Plöner Lake in Holstein would be suitable for the purpose, and funds for maintaining the station for four years are now being collected.

AT the half-yearly meeting of the Forth Railway Bridge Company, held the other day in Edinburgh, very favourable reports as to the progress of the works were submitted. During the past six months the work of erection has proceeded more rapidly and satisfactorily than in any previous half-year, and at the present time the total weight of steel work erected, including the viaduct approach, is 43,500 tons. The last bays of the cantilevers are in an advanced state of manufacture in the shops, and the material is being delivered for the central girders connecting the cantilevers, the erection of which will complete the bridge.

DR. HANS REUSCH, the well-known Norwegian geologist, invites through the Press reports respecting the recent severe earthquakes in Norway. From those to hand it appears that the earthquake of December 23, at 12.15 p.m., was felt along the whole coast of the North Bergenhus province and in the districts around the Stat promontory. On December 27, about midnight, another shock was felt at Bremanger; and on January 6, at 8 p.m., one at Florö, also on the Bergen coast. On January 12, at 4.7 p.m., a fourth shock was felt in and around Bergen. Finally, a shock was felt in the neighbourhood of Christiansand on December 27, at 11.44 a.m.

WE have received from the Hydrographer of the United States a discussion, by Lieut. Everett Hayden, U.S.N., of the great storm of March 11–14, 1888, known as the New York "blizzard." In NATURE, vol. xxxviii. p. 204, we referred briefly to the behaviour of this memorable storm over the land; the discussion now in question deals with its action over the ocean, and more particularly off the Atlantic coast of the United States, from all data at present available. The meteorological conditions at noon (G.M.T.) for the area included between latitude 25° and 50° N., and longitude 50° and 85° W., are exhibited on charts for each of the above four days. The charts show that on the 11th a trough of low pressure was extending from the coast of Florida towards the southern limits of Hudson Bay, and was moving towards the coast at the rate of 600 miles a day. On the morning of the 12th the centre of the storm passed almost directly over New York, blowing with hurricane force, the barometer reading 29·2 inches. On the 13th, the storm area was still skirting the coast of the United States, the centre being about midway between New York and Boston, and the barometer had fallen to 28·9 inches. By the 14th, the great wave of low barometer had overspread the entire western portion of the North Atlantic. The discussion furnishes an instructive example of a somewhat uncommon class of storms, where the usual law founded on the circular theory was to a large extent inapplicable.

THE Pilot Chart of the North Atlantic Ocean for February, issued by the Hydrographer of the United States, shows that the weather in the Atlantic during January was somewhat milder than usual. No severe storms were reported during the first three weeks of the month. There was a noticeable increase in the amount of fog encountered, but it was confined principally to the neighbourhood of the Grand Banks and the British Isles. A supplement to the Pilot Chart describes the remarkable cruise of the derelict American schooner *W. L. White*, which was abandoned off Delaware Bay during the great blizzard, on March 13, 1888. She started off to the southward under the influence of the in-shore current and the north-west gale. Upon reaching the Gulf Stream she turned away to the eastward, and commenced her long cruise towards Europe. On reaching the mid-ocean, between latitude 44° and 51° N., and longitude 33° and 44° W., she followed a remarkable zig-zag track, from the beginning of May till the end of October, being drifted backwards and forwards by the Labrador current and the Gulf Stream, and during these six months alone she was reported by thirty-six vessels. On January 23 she was stranded on one of the rocky islands of the Hebrides, after drifting for ten months and ten days, and traversing a distance of more than 5000 miles.

THE Hydrographer of the Navy has issued a notice that storm-signals are now shown at Manilla (Philippine Islands). The signals consist of (1) a drum (colour not stated), indicating a storm at a great distance, in an unknown direction; (2) a cone, point upwards or downwards, indicating that a cyclone will pass some distance to the northward or southward, respectively; (3) a cone, point upwards over or under a drum, indicating that a cyclone will pass close to the northward or southward; (4) a ball, signifying that a typhoon is approaching, and that all traffic is prohibited. The signal-staffs are painted white.

IT is estimated that the magnificent stalactite cave lately discovered near Reclère, Canton Berne, is about 1600 metres long, 600 metres broad, and from 4 to 20 metres high. The greater part of it has not yet been investigated. A pool has been discovered, measuring 25 metres square, and it is supposed to be the only one in the cave.

A WRITER in the American *Monthly Microscopical Journal*, calls attention to what seems to be a real danger in connection with the kissing of the Bible in courts of law. "The lips," he says, "are most sensitive to the reception of disease-germs, and from the motley throng of dirty and diseased persons who appear in court and kiss the book, what infectious germs may not be obtained through this medium of distribution? It would be interesting for microscopists to examine such greasy and worn backs of court Bibles as they can have access to, and to report the kinds and amounts of Bacteria found thereon. . . . In a Massachusetts school where scarlet fever and measles had prevailed, some text-books fell into disuse, were put away for a time, and, when wanted, got out and re-distributed, several months having

elapsed. In but a few days after the re-issue of the books the children began to come down with measles. There can be little doubt that scarlet fever is transmitted in the same way."

SIR HENRY PEEK has compiled an interesting catalogue of his collection of birds at Rousdon. The catalogue consists of two parts. The first is accompanied by an outline index plate of each case, by means of which one may identify every bird in the case, and find out its name and some other details regarding it, by consulting the list. The second part consists of an alphabetically arranged list of both the English and the scientific names of every bird, with reference to its case, compartment, and number on the index plate, so that any particular bird required may be found without difficulty. The index plates, as Sir Henry Peek points out in the preface, save the necessity of affixing labels or numbers to the birds, which would have interfered with the artistic appearance of the groups.

UNDER the title "The True Position of Patentees," Mr. H. Moy Thomas has published, through Messrs. Simpkin, Marshall, and Co., a little book in which the patent laws and regulations at home, abroad, and in our colonies and dependencies, are explained for the information of English inventors.

MESSRS. MACMILLAN AND CO. will publish in September the Eleventh Book of Euclid, Propositions 1–21, with alternative proofs, exercises, and additional theorems and examples, by Mr. F. H. Stevens, of Clifton College, joint editor of Hall and Stevens's Euclid, Books i.–vi. Later on it is the intention of Mr. Stevens to issue a book on elementary solid geometry and mensuration, containing the matter included in the above-mentioned volume, with a section on polyhedrons and solids of revolution, treated geometrically and numerically, with exercises on the mensuration of plane and solid figures.

MESSRS. LONGMANS AND CO. have in the press "A Handbook of Cryptogamic Botany," by A. W. Bennett and George Murray. No general hand-book of Cryptogamic botany has appeared in the English language since Berkeley's, published in 1857. The present volume will give descriptions of all the classes and more important orders of Cryptogams, including all the most recent discoveries and observations.

A NUMBER of remarkable salts of hydrazine or amidogen have been prepared by Drs. Curtius and Jay, in the course of their work upon the hydrazine compounds, which has so successfully resulted, as noticed in these columns a fortnight ago (p. 377), in the isolation of the hydrate of amidogen, $N_2H_4 . H_2O$. Amidogen, as indicated by the strong alkalinity of its hydrate, and by the well-known reactions of its organic substitution-products, is a powerful base, and combines with acids to form salts of considerable stability at ordinary temperatures. Perhaps the most interesting of these salts, and the one utilized for the preparation of the liquid hydrate itself, is the di-hydrochloride, $\begin{array}{l} NH_2 . HCl \\ | \\ NH_2 . HCl \end{array}$. This salt possesses a most striking resemblance to ammonium chloride, crystallizing in the cubic system, and depositing, on rapid evaporation, in the same beautiful feathery forms. It differs, however, from ammonium chloride in being very deliquescent. When heated to 198° C., it fuses, with evolution of hydrochloric acid, to a clear glass consisting of the mono-hydrochloride, $\begin{array}{l} NH_2 . HCl \\ | \\ NH_2 \end{array}$. On further heating to 240°, it is entirely decomposed, with evolution of free nitrogen and hydrogen and sublimation of ammonium chloride—

$$2 \begin{array}{l} NH_2 . HCl \\ | \\ NH_2 . HCl \end{array} = 2NH_4Cl + N_2 + H_2 + 2HCl.$$

Contrary to the usual behaviour of bases of the ammonium type, platinum chloride in acid solution gives no platinochloride; the reducing action comes so violently into play that the platinic salt is reduced to platinous chloride, with copious evolution of nitrogen gas. The sulphate, $\begin{array}{l} NH_2 \\ | \\ NH_2 \end{array} . H_2SO_4$, like ammonium sulphate, is anhydrous, and crystallizes in optically biaxial prisms. It is the most insoluble of the hydrazine salts in cold water, and is precipitated from cold solutions of all the other investigated salts by dilute sulphuric acid; it readily dissolves, however, in hot water. On heating it melts at 254° with explosive evolution of gas, breaking up into ammonium sulphite, sulphurous acid, sulphuretted hydrogen, and, most remarkable of all, large quantities of free sulphur. The carbonate is obtained by saturating a solution of the hydrate with carbonic acid gas, and evaporation *in vacuo* as a highly deliquescent mass. The nitrate can readily be obtained from the carbonate by treatment with nitric acid; it crystallizes well, and is also extremely soluble. The acetate and oxalate have also been obtained in fine crystals. All these salts possess the same exceptional reducing powers, free nitrogen and water being formed in the process. They all decompose on heating with formation of salts of ammonium, and of gaseous nitrogen and hydrogen. One of their most important properties is their reaction with nitrous acid; on mixing any salt of hydrazine with a salt of nitrous acid, free nitrogen is evolved with almost explosive violence. It is finally of considerable significance that those which crystallize well appear to be isomorphous with the corresponding ammonium salts.

A BELGIAN, M. Nizet, of the Royal Library of Brussels, proposes to issue a periodical catalogue or table of all papers published in all the periodicals in the world. Of course the titles of the papers are to be methodically grouped under a certain number of divisions.

THE following are the arrangements for science lectures at the Royal Victoria Hall during the month of March:—Tuesday, March 5, "A Visit to the Moon: how we got there and what we saw," by Prof. Carlton Lambert; Tuesday, March 12, "A Tramp among the Mountains at Home and Abroad," by Prof. Kennedy, F.R.S.; Tuesday, March 19 and 26, two lectures, by Prof. H. E. Armstrong, on the "History of a Crime unravelled by a Piece of Rusting Iron, a Horse-shoe, and a Match."

THE *Indian Forester*, in a review of the work of the Forest Department under the rule of Lord Dufferin, says that the total number of prosecutions for offences against the forest laws has been steadily diminishing. The area under protection from fire has risen from 15,570 to 18,691 square miles. Large areas have been withdrawn from nomadic grazing; and, generally speaking, the old and wasteful methods have been displaced by an entirely new system, which is only now making itself felt. The influence of forest conservancy on the rainfall, the temperature, and the water-supply is becoming appreciated by the people of India. Large additions have been made to the teak plantations of Burma, and great quantities of mahogany have been planted at Nilambur. The revenue has risen from 67 lacs in the years 1876–80, to 94 lacs during the viceroyalty of Lord Ripon, and to 116 during that of Lord Dufferin. These figures do not include the money received from Upper Burma, where the loosely-drawn leases have given infinite trouble to the officials. The staff is too weak for the work, but a reorganization scheme is under consideration. The forest class at Cooper's Hill, and the working of the Dehra Dun School, will no doubt improve the standard of knowledge of the officials.

IN the recent Report of the Bombay Chamber of Commerce it is said that the opinion of the Chamber was solicited as to the advisability of introducing a uniform standard of weight through-

out the Presidency. A Committee was appointed, but there was some difference of opinion amongst the members as to the most convenient standard. Some were in favour of adopting the scale used by the railway companies in Bombay—that is, 180 grains = 1 tola, and so on up to 1 candy; but the majority thought that the English system of hundredweights, quarters, and pounds would be the best, and to this view the Chambers of Commerce of Bengal, Madras, and Kurrachee have assented. The Committee, however, refrained from urging on the Government to alter the present standards. The Government of India have appointed a Commission to inquire into the whole matter.

M. RESIN has published, in the *Izvestia* of the Russian Geographical Society, interesting sketches of the natives of Kamchatka, made during a cruise on the schooner *Sibir*. It appears that the Kamchadales and the Aleutes are rapidly abandoning their mother language, and speak a very broken Russian—the more broken as the Russians themselves, in order to be better understood, speak a language which has hardly any likness to their mother tongue. The population of Kamchatka, which was carefully registered in 1878 and 1879, shows a regular decrease; since the time of Krasheninnikoff's journey (in 1741) the population seems to have been reduced to one-half of what it was 148 years ago. Years of scarcity of fish, the staple food of the population, are quite common. In such cases the Lamutes and the Koryaks usually bring to the Kamchadales a number of their reindeer; but this voluntary help is not sufficient to prevent starvation. Hunting becomes less and less profitable. The following figures represent the results of hunting during the winter of 1884–85: 2,915 sables, 159 foxes, 321 otters, 302 ermines, 120 mountain sheep, and 767 reindeer. It is noteworthy that no diminution of population is remarked among the Tchukches on the coasts of the Arctic Ocean.

LAST week we quoted from Prjevalsky's "Fourth Journey to Central Asia" a description of fiery sunsets he had observed in crossing the Gobi. The same work contains the following remarks as to the action of wind upon the soil in the deserts of Central Asia:—"One must see the wind blowing in the desert to appreciate its force. Not only dust and sand fill the atmosphere, but sometimes smaller gravel is lifted into the air, while larger stones are rolled over the surface of the soil. At the foot of the Altyn-tagh, in the neighbourhood of the Lob-nor, we saw how stones as big as a man's fist, having been whirled into the hollow of a larger piece of rock by the storm, were making deep holes, and had even pierced through a slab of sandstone 2 feet thick." In accordance with Richthofen's views, Prjevalsky was inclined to explain the formation of loess by the force of wind, but he was not aware of the geographical distribution of loess—that is, its disposition as a girdle along the foot of all the mountains of Central Asia, and its absence on the plateaus, even in the parts which are protected from wind. On the other hand, the winds of the desert really afford an explanation of the strange coarse gravel, quite devoid of any particles of finer sand and loam, which covers the Gobi. The winds must have blown away the finer parts of the gravel.

WE have received the Triennial Calendar of the Tungwen College of Pekin, at which over a hundred students are prepared for the Government service. The full course, literary and scientific, extends over eight years, the first three being devoted exclusively to foreign languages, and the remainder to the acquisition of scientific and general knowledge through the medium of these languages. After the completion of the general course, students may, if they please, remain in the College, or be sent abroad at the option of the Government, for the pursuit of special studies with a view to professional use. The method of paying the students is thus described in the Calendar:—The object of the College being to train men for special service, the number is limited, and all admitted are, with a few exceptions, paid by the Government. During the first year the student is on probation, and receives his food and lodging only. He then gets an allowance of about three taels (14*s.* or 15*s.*) a month. In two or three years this stipend is doubled if the student progresses satisfactorily, and it is again increased to ten taels a month at the end of five or six years. If a student is sent to pursue his studies in foreign countries, the allowance is one hundred taels a month, which is increased to two hundred taels when he is made a third-class interpreter. The preparation of books for the diffusion of scientific and general knowledge is part of the work of the College. Amongst those prepared and published already are works on natural philosophy, chemistry, practical economy, chemical analysis, mathematical physics, anatomy, astronomy, &c.

IN the "Note" last week about a Greenland whale which went ashore in the Sound (p. 398), *for* "90 feet in length" *read* "60 feet in length."

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♀) from India, presented by Mrs. Nicol; an Indian Chevrotain (*Tragulus meminna* ♀ juv.) from India, presented by Mr. George Score; a Hybrid Polecat (between *Mustela putorius* and *M. furo*), British, presented by Mr. J. Herbert B. Cowley; an Owen's Apteryx (*Apteryx oweni*) from New Zealand, presented by Prof. T. Jeffrey Parker, C.M.Z.S.; a Common Buzzard (*Buteo vulgaris*) from Spain, presented by Captain J. V. Harvey; eight Common Swans (*Cygnus olor*), European, deposited; seven Common Gulls (*Larus canus*), from Holland, five White's Tree Frogs (*Hyla cœrula*) from Australia, purchased; a Collared Fruit Bat (*Cynonycteris collaris*), born in the Gardens.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 *MARCH* 3–9.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on March 3

Sun rises, 6h. 42m.; souths, 12h. 12m. 3·0s.; sets, 17h. 42m.: right asc. on meridian, 22h. 57·9m.; decl. 6° 37′ S. Sidereal Time at Sunset, 4h. 29m.

Moon (at First Quarter on March 9, 18h.) rises, 7h. 48m.; souths, 13h. 35m.; sets, 19h. 35m.: right asc. on meridian, 0h. 20·7m.; decl. 3° 6′ S.

GEOGRAPHICAL NOTES.

THE paper read at Monday's meeting of the Royal Geographical Society was by Captain Vangèle, giving an account of his exploration of the Welle-Mobangi river, the great northern tributary of the Congo. His first exploration was made in the end of 1886 in a flat-bottomed boat, the *Henry Read*, with a stern paddle-wheel. On this first journey Captain Vangèle did not succeed in getting beyond Mr. Grenfell's furthest, the Zongé Falls, just where the river turns sharply to the east. He gives an interesting account of the Ba-Ati, the people who inhabit the banks of the river, and who are in every way of a superior type, though cannibals. A little distance above its mouth the Mobangi or Ubangi measures about 2730 yards in breadth ; its greatest depth is 5 fathoms, its lowest 1 fathom ; it flows at the rate of $3\frac{1}{4}$ feet a second. Under the 4th degree, just below the rapids, it still has a breadth of 1300 yards, a depth of 4 fathoms, and a velocity of 4 feet a second. Between these two points, though continually varying in breadth, it never exceeds about 4000 yards, including the islands. The general appearance of the river is pretty much the same as that of the Congo near Bolobo—strewn with islands, and having low wooded banks. The colour of the water is a light brown. Captain Vangèle's second journey was made a year later, and with better means of forcing his way up the rapids of the Mobangi. This time, though he encountered several obstacles, he managed to push his way up the river to over 22° E. longitude, and to within sixty miles of Junker's furthest point on the Wellé. This has been accepted as clearly proving the identity of these two rivers, so that the long-standing problem of the Wellé may be regarded as solved. At his furthest point Captain Vangèle had to turn back owing to the hostility of the natives, the only instance in which he met with real opposition. Between rocks and islands, rapids and cataracts, the navigation of the lower Mobangi is beset with difficulties, though it is evidently practicable with suitable vessels, and a thorough knowledge of the river. The river is subject to great variations of level, according to the season of the year. Above the Zongo Falls, the people, named Bakombé, differ considerably from those on the lower river, and evidently spread far inland. From above the Zongo rapids the river opens out, flowing straight from the north-east, and the outlook is described as superb. It is free from all obstacles, from 900 to 1000 yards wide, with a depth of $12\frac{1}{2}$ fathoms, flowing between banks 6 to 10 feet high, grassy plains alternating with clusters of trees. After thirty miles in the north-east direction the river turns due east, which direction it maintained to the end of the voyage, 170 miles. The banks are densely inhabited, and provisions of all kinds abound. Between the Zongo Falls and the steamer's furthest point only one tributary was met with—the Bangasso—coming from the north. After the paper was read, Sir Francis De Winton made some remarks with regard to the position of Mr. Stanley. He totally disbelieves the conjecture of Lieut. Baert that Stanley has any intention of taking Khartoum. On the contrary, Sir Francis believes he is now on his way home by the east coast.

IN the last issued number (4ᵉ trimestre, 1888) of the *Bulletin* of the Paris Geographical Society will be found a very complete examination of the route for a proposed Euphrates Valley Railway, by M. A. Dumont. M. Adrien Blondel contributes a detailed account of the Island of Réunion. M. Jules Marcou, in concluding his paper on the origin of the name of America, decides against Vespucci and in favour of an aboriginal place-name.

IT has been arranged that the eighth German *Geographentag* shall be held at Berlin from April 24 to 26 next.

THE *Ceylon Observer* states that Mr. Stephens, who has recently been amongst the Veddas of Ceylon, and who subsequently explored New Guinea, is now in Ceylon on his way to Singapore to organize an expedition at the instance of Prof. Virchow to explore the unknown portions of the Malayan Peninsula. Mr. Stephens's instructions are to start from Malacca and travel north-north-west through the vast expanse of unexplored territory which stretches northwards for some 500 miles. There are on the coast various settlements near mines and plantations, but the greater portion of the interior has been hitherto unexplored. The inhabitants are said to be jealous and bloodthirsty.

M. LŒWY'S INVENTIONS AND RESEARCHES.[1]

IT is now my pleasing duty to lay before you the grounds on which the Council have awarded the gold medal to M. Maurice Lœwy for his invention of the equatorial *coudé*, of a new method of determining the constant of aberration, and for his other astronomical researches.

On examining the series of memoirs in which M. Lœwy has set forth his new methods of astronomical research, we are at once impressed by the originality of conception which characterizes all his ideas, and by the thoroughness with which he has worked out the details necessary for the practical application of his new methods of observation. Observational astronomy has for many years past proceeded on such well-defined lines, that we have not unnaturally come to look rather to improvements of detail than to the introduction of new instruments for the advancement of our knowledge. It is, therefore, a matter of great satisfaction to find that M. Lœwy has placed at our disposal various methods of observation based on entirely new principles, and calculated to give astronomers improved and quite independent means of attacking several of the most important problems in our science.

The first of these new instruments with which I will deal is the equatorial *coudé*.

It was in the year 1871 that M. Lœwy proposed his new form of equatorial, to which the name of "equatorial *coudé*" has been given, and M. Delaunay, then Director of the Paris Observatory, was so struck with the value of the principle that he arranged for the construction of an instrument on this plan. M. Delaunay's death, however, interrupted the work, and the first equatorial *coudé*, having an object-glass of 0·27 metre, or about $10\frac{5}{8}$ inches aperture, was not completed till the year 1882. The success of this instrument was so marked that its value could not fail to be recognized, and it was not long before the construction of several larger equatorials on the same principle was commenced. At the present time six equatorial *coudés* have been completed, and four of these are already mounted and in regular use at the Observatories of Paris, Lyons, Besançon, and Algiers. The other two are intended for the Observatories of Paris and Vienna.

In principle the equatorial *coudé* may be described as an adaptation of the form of transit instrument with axial view to the requirements of an equatorial, by the addition of a plane mirror inclined at 45° outside the object-glass, this mirror being capable of rotation about the axis of the telescope, so as to reflect into the latter the rays from any object in a perpendicular plane. The axis of the instrument is mounted as a polar axis between two piers, the telescope being broken at a right angle near the lower pivot, so that the rays from the object-glass are reflected by an internal mirror up the polar axis to the hollow upper pivot, where the image is formed. The rotation of the outer mirror thus brings into the field the image of any object in the hour-circle perpendicular to the object-end of the telescope, and by the rotation of the polar axis, as in an ordinary equatorial, the telescope is directed to any hour-angle. The declination-axis in the equatorial *coudé* is the axis of the object-end of the telescope about which the outer mirror turns, and the declination-circle placed at the eye-end, in the same plane with

[1] Address delivered by the President of the Royal Astronomical Society, Mr. W. H. M. Christie, F.R.S., Astronomer-Royal, on presenting the Gold Medal of the Society to M. M. Lœwy at the anniversary meeting on February 8, 1889.

the hour-circle, is connected with the axis of the outer mirror by gearing, so that the observer at the stationary eye-piece has both the hour and declination circles immediately under his eye. He can thus direct the instrument to any object without moving from his chair, and his observations are made under the most favourable conditions for his own comfort, similar to those under which the microscope is used by the student of natural history. The observing-room, which may be artificially warmed, is quite separated from the object-glass, and other external parts of the instrument. These latter are protected from the weather by a suitable hut, which can be rolled away on rails before observing, so that the optical parts of the equatorial are in the open air under the best conditions for establishing an equilibrium of temperature.

The importance of obtaining the favourable conditions for observation secured by M. Lœwy's equatorial *coudé* has long been recognized, and various attempts have been made to enable the observer to command any part of the sky without changing his position. In 1858, Dr. Steinheil proposed[1] a new method of mounting a reflector, so that the axis of the concave mirror formed the polar axis, the rays from a star being reflected down the axis to the concave mirror by a plane mirror, which could be rotated about a declination-axis and a polar axis. The observer looked down the polar axis through a hole in the plane mirror, but with this arrangement he could not observe stars much north of the equator unless the plane mirror were made very large, and the range of the equatorial was thus very restricted. A more extended range might be obtained by interchanging the concave and plane mirrors, so that the observer would look up in the direction of the pole; but the concave mirror and its support would block out the view of the region near the pole, and of all the sky below the pole. Sir H. Grubb has applied the same principle to the construction of a siderostatic refractor.

As compared with Dr. Steinheil's form, the equatorial *coudé* possesses the great advantage of commanding every part of the sky, the arm of the telescope below the elbow being made long enough to project beyond the sides of the observing-room when viewing objects near the meridian.

The siderostat of Foucault, though useful for many purposes, is open to the same objection as Dr. Steinheil's, of not permitting of a view of every part of the sky; and there is the further difficulty that the apparent direction of the diurnal motion is continually changing. In the equatorial *coudé* this direction changes with the declination, but M. Lœwy has now arranged that the micrometer is turned with the declination-circle, and is thus always set to the zero of position-angle.

The success obtained by M. Lœwy in the construction of the equatorial *coudé* is due to the following circumstances:—

(1) The absence of flexure in the mirrors, which are made much thicker than usual.

(2) The more perfect achromatism secured by the greater focal length which this form of mounting allows of.

The first condition was established by careful experiment, which showed that in order to avoid deformation by flexure the thickness of a mirror should be between one-fifth and one-sixth of the diameter, instead of one-ninth or one-tenth as had been usual hitherto.

As regards achromatism, M. Lœwy urges that, in order to be able to see better with a larger object-glass, the achromatism must be made more perfect, and that, therefore, the ratio of focal length to aperture must increase with the aperture in order to diminish the effect of the secondary spectrum.

Notwithstanding the two reflections, the definition obtained with the equatorial *coudé* appears to be very good, the components of ω Leonis, distant only 0″·5, having been separated with the Paris instrument, which has an object-glass of 0·27 metre or about $10\frac{5}{8}$ inches. With one of the new instruments of 0·31 metre, or $12\frac{1}{4}$ inches aperture, M. Trépied, at Algiers, easily divided γ^2 Andromedæ. The loss of light by the two reflections from silvered mirrors is computed by M. Lœwy at only 12 per cent., and it would seem that it is at any rate very small, as successful observations of a minor planet of 13·5 magnitude were obtained with the Paris instrument as well as of very faint nebulæ and comets. The comet 1885 *d* (Fabry) was discovered with this instrument.

One of the objects which M. Lœwy had in view in planning his equatorial *coudé* was to obtain greater stability than is attainable with ordinary equatorials, and to make the measurement of large angular distances possible. The form of mounting of the equatorial *coudé* seems peculiarly adapted to give great stability, provided the fixity of the mirrors in their cells can be secured, and this is a condition to which M. Lœwy has given special attention. Each mirror rests in its cell on thick felt or flannel, and is held by three clips, which are just brought into contact with it when in the horizontal position, as tested by the disappearance of the least trace of light between the clip and its reflected image. This adjustment being made for the horizontal position, in which the weight of the mirror has its full effect, perfect contact between the mirror and its clips will be maintained in all positions.

M. Lœwy, in conjunction with M. P. Puiseux, has investigated very completely the theory of the instrumental adjustments of the equatorial *coudé*, including the effect of flexure of the polar axis and of the telescope arm, and has shown the relation of his formulæ to those for ordinary equatorials. He arrives at the two following conditions of optical adjustment as sufficient for astronomical purposes:—

(1) The axis of the telescope arm should be perpendicular to the polar axis.

(2) The interior mirror should reflect to the centre of the field a ray entering the telescope along the axis of the arm, supposed to be perpendicular to the polar axis.

The discussion of the instrumental errors of the Paris instrument, partly by astronomical observations, and partly by means of a collimator attached to the mounting of the exterior mirror, shows a very satisfactory accordance in the determinations on different days, and in the result the instrumental errors were found to be very small, the largest amounting only to 23″. The coefficients of flexure are, however, rather larger quantities, being 91″ and 53″ for the polar axis and telescope arm respectively, as found by means of the collimator. It may be expected that in the new instruments the effects of flexure would be very much less, as important improvements have been made in their mechanical construction.

It is not a little remarkable that the first instrument made on this new principle should have given such excellent results, both optically and mechanically; and its success is evidence of the thoroughness with which M. Lœwy has worked out his idea, and of the skill with which MM. Henry and M. Gauthier have respectively carried out the optical and mechanical portions of the instrument.

I now pass on to M. Lœwy's new method of determining the constant of aberration. It is hardly necessary to insist on the importance of this constant, not only for obtaining the true positions of the stars, but, in a higher degree, for the determination of the solar parallax by means of the velocity of light. It must be admitted that the nine independent determinations of the constant of aberration made at Pulkowa with three different instruments show a satisfactory accordance, but in the opinion of M. Nyrén, who has published the latest researches on the subject, none of these can be asserted to be free from systematic error. M. Nyrén's definitive value is 20″·492, exceeding by 0″·047 W. Struve's original value, which has hitherto been generally used by astronomers. Under these circumstances, M. Lœwy's method, which is based on differential measures with an equatorial, constitutes a new departure of great value in astronomy of precision, and its value is enhanced by the circumstance that it is also applicable to the determination of the constant and law of refraction.

The principle of M. Lœwy's method is the measurement of the angular distance between two stars by means of a double mirror, formed by silvering two faces of a large prism of glass and placed in front of the object-glass of an equatorial. The double mirror is capable of rotation about the axis of the telescope, so that by reflection from the two silvered surfaces the images of two stars in different parts of the sky may be brought into the field side by side, and the distance between them measured in the direction of the common plane of reflection. In his memoir on the determination of refraction by the new method, M. Lœwy proves that the projection of the distance between the two images on the trace of the common plane of reflection is independent of the rotation of the equatorial, of any movements of the double mirror, and of the displacement of the images by the diurnal motion, when the observation is not made rigorously in the plane of reflection.

M. Lœwy's exposition of his method of determining the constant of aberration is contained in a series of communications made to the French Académie des Sciences and published in the *Comptes rendus*, vols. civ. and cv. In giving an account of this

[1] *Astron. Nachrichten*, No. 1138; *Monthly Notices*, vol. xix. p. 56.

investigation, I will proceed at once to the general method for determining aberration, which M. Lœwy discusses after treating some special cases.

The determination of aberration requires the measurement of the distance between a pair of stars at successive epochs when the effect of aberration on the angular distance is reversed. The observations are made when the two stars have the same altitude, so that the effect of refraction is a minimum, and the comparison of the two measures gives a multiple of the constant of aberration, which is independent of all instrumental errors and also of precession and nutation, as the distance between two stars is unaffected by any movements of the earth's axis or of the ecliptic. There is the further advantage in the new method, that the effect of aberration as measured is much greater than in the ordinary methods of observation.

But the result might be affected by change of refraction or by alteration in the angles of the double mirror resulting from thermal expansion between the two epochs of observation, and M. Lœwy has therefore imagined a general method of observation which eliminates any possible effects of the kind, as well as methods applicable to special cases which determine any changes due to refraction or expansion of the mirror.

The essence of the general method is that two pairs of stars are observed, the four stars being selected so that at the time of observation they are all simultaneously at the same altitude, and that the effects of aberration on the two arcs connecting the stars of each pair are large and of opposite sign. Thus the two arcs formed respectively by the two pairs of stars are compared simultaneously both at the first and at the second epochs.

The first point for investigation is the effect of aberration on the angular distance between a given pair of stars. From the geometrical conditions, M. Lœwy arrives readily at the result that the effect is proportional to the cosine of the angle between the median[1] of the arc and the direction of the earth's motion.

Calling Δ the angular distance between two stars, p the angle between the median of the arc joining them and the direction of the earth's motion, and k the coefficient of aberration, the effect of aberration is given by the formula—

$$d\Delta = 2k \sin \frac{\Delta}{2} \cos p.$$

It readily follows from this that the effect of aberration on the difference of the two arcs connecting two pairs of stars will be greatest when the two medians are on the same vertical circle on opposite sides of the zenith. Under these circumstances, the effect of aberration on the difference of the two arcs is equal to

$$4k \sin \frac{\Delta}{2} \sin \frac{\Delta'}{2} \cos \mathrm{L},$$

Δ' being the angular distance between the two medians, and L the angle between the direction of the earth's motion and the line of intersection of the vertical plane through the medians with the horizon. Thus the effect is proportional to the cosine of this angle, and the greatest effect will be obtained when the vertical plane of the medians, the ecliptic and the horizon intersect in the same line, and the observations are made at the two epochs six months apart when the direction of the earth's motion coincides with this line, L having the values 0° and 180° at the two epochs respectively. In that case the effect of aberration on the difference of the two arcs has opposite signs at the two epochs, and the comparison of the two sets of measures of the two arcs gives

$$\mathrm{E} = 8k \sin \frac{\Delta}{2} \sin \frac{\Delta'}{2},$$

where E is the difference of the two measures of difference of arcs at the first and second epochs respectively.

The next point for consideration is the choice of the angle for the double mirror, their angular distance (Δ) between the two stars in each pair being necessarily twice this angle. Obviously the altitude at which the observation of the four stars is made diminishes as Δ and Δ' increase, and M. Lœwy shows that the maximum effect at any given altitude is obtained by making $\Delta' = \Delta$, or the angular distance between the medians the same as that between the two stars in each pair. He then gives the following table of the altitude h and of the effect of aberration $\frac{\mathrm{E}}{k}$ corresponding to the several values of the angle of the double mirror α:—

α	30°	35°	40°	45°	50°	55°	60°
h	48° 35′	42° 9′	35° 58′	30° 0′	24° 24′	19° 12′	14° 29′
$\frac{\mathrm{E}}{k}$	2·0	2·6	3·3	4·0	4·7	5·4	6·0

M. Lœwy concludes that the angle of the double mirror should not exceed 50°, and he considers that, on the whole, it would be well to make it 45°, so that the altitude of the stars would be 30°, and the angular distance for each pair 90°. Under these conditions, observations made at two epochs six months apart would give as the quantity measured four times the constant of aberration, while the ordinary methods of observation only give at the maximum a measure of twice the constant. But, in order to avoid daylight observations, M. Lœwy thinks it would be advisable to be satisfied with a slightly smaller coefficient of k (the constant of aberration), say three instead of four, which would reduce the interval between the two epochs to about ninety-eight days; and, by combining the observations in the first five weeks with those in the last five, a series of equations would be obtained, in which the coefficient of k would vary from three to one, the mean value being about two. All the observations could then be made in the night hours.

Besides the general method of observation just described, M. Lœwy has, as already mentioned, devised two methods applicable to special cases which are well suited to give independent determinations of the constant of aberration.

The first method consists in the observation of two pairs of stars, of which one pair gives, at the end of two or three months, the measure of twice the constant of aberration, and the other, completely unaffected by aberration, exhibits the effect of temperature on the double mirror. The first pair of stars should be in the neighbourhood of the ecliptic; the second pair is, as will be seen from geometrical considerations, to be chosen so that the latitudes of the two stars are the same, and that their longitudes differ by 180°, in order that the arc joining them may be unaffected by aberration.

This method is, however, not applicable at observatories within 20° of the equator, and on this account, as well as to give another independent determination of the constant of aberration, M. Lœwy proposes a second method, according to which the angular distance of a single pair of stars near the ecliptic is to be observed for a period of three months or longer, the measures in the first and last twenty-five days of the period being used to determine the aberration, and those in the intermediate forty days to deduce the effect of temperature on the double mirror.

The question of the adjustment of the double mirror remains to be mentioned. This must be mounted so as to turn about the optical axis, and this axis should coincide nearly with the axis of figure. The effects of any movements of the double mirror will then be as follow:—

(1) In turning round the axis of figure the two images are displaced in opposite directions, but perpendicularly to the trace of the common plane of reflection.

(2) In turning round an axis in this plane and perpendicular to the axis of figure the two images move in the same direction perpendicularly to the trace of the plane of reflection.

(3) If the double mirror turns about an axis perpendicular to the plane of reflection, the two images move along the trace without changing their relative distance.

Reference has already been made to the applicability of M. Lœwy's new method to the determination of refraction at various altitudes. This was, in fact, the immediate object which M. Lœwy had in view when he devised the method, and his investigation of the conditions of the problem was communicated to the French Académie des Sciences early in 1886, the year before he published his memoir on aberration.

In his series of papers on the determination of refraction published in the *Comptes rendus*, vol. cii., M. Lœwy first gives a method for determining the constant of refraction, the law according to which refraction varies with the altitude being known. A pair of stars is observed when refraction has its maximum effect on their angular distance, and again when the effect of refraction is a minimum. For the maximum effect one of the stars must be on the horizon, and the other in the same

[1] The median is the line bisecting the angle between the directions of the two stars.

vertical circle with it, while for the minimum both stars must be at the same altitude. M. Lœwy then finds that the greatest variation of refraction will be obtained with an angle of 30° for the double mirror, but as with this there would be (for the latitude of Paris) a minimum interval of 6h. 35m. between the two epochs of observation, he prefers to take an angle of 45° for the double mirror, sacrificing only 15" in the effect of refraction, while reducing the interval between the observations to 4h. 44m. This is the minimum value of the interval found by selecting the pair of stars so that their common zenith distance at the second epoch is equal to the angle of the double mirror, or half the angular distance between the two stars.

The geometrical conditions thus found by M. Lœwy to give the maximum effect in the minimum interval of time between the observations may be somewhat modified in practice, provided the angular distance between the stars does not differ by more than a few minutes from twice the angle of the double mirror. M. Lœwy has thus been able to find some twenty pairs of bright stars suitable for the determination of refraction by this method. In its practical form the method consists in the measurement of the angular distance between a pair of stars 90° apart when one of the stars is near the horizon and the other near the zenith, and again when both the stars are at about the same altitude. It is not necessary that at the former epoch the low star should be very near the horizon, for, as M. Lœwy points out, observations may be advantageously continued till the altitude is nearly 20°, and thus the constant of refraction may be determined from observations which are practically unaffected by any uncertainty in the law of refraction.

It will readily be understood that the observation of the low star may be made either when it is rising or when it is setting. In the latter case the observation of the stars at equal altitude would precede that for which one of the stars is setting. By combining the observations of two pairs of stars chosen so that the first pair is rising when the effect of refraction on the second is a minimum, and that the first pair is at the minimum when the second pair is setting, the influence of any change in the angle of the double mirror will be eliminated by taking the mean of the two determinations, while the difference of these will give four times the change of angle in the interval, thus affording a precise determination of any such change, if it exists.

Various other methods are proposed by M. Lœwy for determining the refraction at any altitude without assuming its law of variation. These methods, however, appear to involve practical difficulties, as they either assume the absence of irregular variations in the refraction at an altitude of 10°, or require the construction of several double mirrors with different angles. They may be considered as supplementing the first method; and they are of interest as giving a direct measure of refraction independently of any theory.

The practical determination of the constants of aberration and refraction by the new method is being carried out by M. Lœwy and M. P. Puiseux with the equatorial *coudé* of the Paris Observatory, and the series of observations made during the past twelve months confirms in the most satisfactory manner the theoretical conclusions. M. Lœwy finds that the variations of the distances are really free from systematic errors, and he considers that the constant of refraction will be more accurately determined from a few nights' observations with his new method than from years of meridian observations.

In conclusion, I can only allude in the briefest terms to the other important researches for which astronomers are indebted to M. Lœwy. The following is a summary of the other new methods of instrumental research which M. Lœwy has devised in the last few years:—

(1) A method for determining the flexure of transit-circles at various zenith distances by means of an optical apparatus inserted in the central cube. This has been used to find the flexure of two transit-circles at the Paris Observatory, the absolute values of the flexure for the two ends of the telescope and for the axis being independently determined.

(2) A method for obtaining the latitude without making use of the declinations of fundamental stars.

(3) A general method for determining right ascensions without relying on assumed right ascensions of polar stars.

(4) A method for finding on each night the absolute declinations of stars without the necessity for observations of polar stars at upper and lower transit.

(5) Methods for determining directly the two co-ordinates of polar stars without a previous investigation of the instrumental errors.

All these methods except the first are based on the observation of close circumpolar stars in R.A. and N.P.D. out of the meridian at various points of the circles described by them. Conjugate observations either of a single star or of a pair of stars having the same N.P.D. are made with a transit-circle, having a field of view of 2°, at equal intervals (about two hours) before and after meridian passage or before and after passage over the hour-circle of 6h. east or west. The special methods of observation are developed in a series of communications to the French Académie des Sciences made in the years 1883 and 1885, and during the last two years M. Rénan has applied these new methods to a determination of the latitude of the Paris Observatory based on eighty very accurate results.

The account which I have given of M. Lœwy's inventions and researches is necessarily very imperfect, and I have had to pass over many points of interest in the application of his methods. But I trust that the summary I have made will at any rate suffice to show the very high importance of M. Lœwy's labours, and that they fully deserve the recognition which is to-day given to them, whether we have regard to the originality of the methods or to the value of the results which are to be obtained from them.

STRUCTURE, ORIGIN, AND DISTRIBUTION OF CORAL REEFS AND ISLANDS.[1]

THE picturesque beauty of the coral atoll, seated 'mid a waste of troubled waters, with its circlet of living green, its quiet, placid lagoon, and its marvellous submarine zoological gardens, has long been celebrated in the descriptions of voyagers to tropical seas. The attempt to arrive at a correct explanation of the general and characteristic form and features of these reefs and islands has, for an equally long period of time, exercised the ingenuity of thoughtfulmen.

Coral reefs are the most gigantic and remarkable organic accumulations on the face of the earth. They are met with in certain tropical regions, and are huge masses of carbonate of lime, secreted from ocean waters by myriads of marine organisms. While the great bulk of the reef consists of dead corals, skeletons, and shells, the outer surface is clothed with a living mantle of plants and animals. This is especially the case on the outer and seaward face of the reef, where there are, at all times, myriads upon myriads of outstretched and hungry mouths, and not the least interesting questions connected with a coral reef are those relating to how these hungry mouths are satisfied.

It is to the power of these organisms of secreting carbonate of lime from sea-water—building up and out generation after generation on their dead selves—that the coral reef owes its origin. So wonderful and unique is the result, that combination for a definite end has sometimes been attributed to these reef-builders.

There is, however, another process ever at work in the ocean, in a sense antagonistic to that of secretion of carbonate of lime by organisms, which has much to do in fashioning the more characteristic features of coral reefs. This is the solution of all dead carbonate of lime shells, skeletons, and calcareous *débris*, wherever these are exposed to the action of sea-water. As soon as life loses its hold on the coral structures, and wherever these dead carbonate of lime remains are unprotected by rapid accumulation or crystalline depositions, they are silently, surely, and steadily removed in solution. This appears to be one of the best established oceanographical facts, and any theories concerning the general economy of the ocean which fail to take account of this universal agency are most likely to be at fault. We know something about the rate of solution, probably more than we do about the rate of growth and secretion of carbonate of lime by the coral Polyps. It has been shown that the rate of solution varies with temperature, with pressure, and with the amount of carbonic acid present in the water. It is on the play of these two opposing forces—the one vital and the other chemical—and their varying activity in different regions and under different circumstances, that we rely for the explanation of many oceanographical phenomena, especially many of those connected with oceanic deposits and coral reefs. In some regions there may be more growth, secretion, and deposition of shell and coral materials than solution

[1] Lecture delivered by Dr. John Murray at the Royal Institution on Friday, March 16, 1888. Recently revised by the Author.

by sea-water, and then there results the formation of coral reefs and vast calcareous deposits at the bottom of the ocean. There may be an almost exact balance between these processes. And again, there may be more solution than secretion, as, for instance, in the red clay areas, which occupy the deepest parts of the ocean, and in some coral-reef lagoons.

What is the nature of the foundations of these coral islands, surrounded as they sometimes are by an ocean miles in depth? Why have some elongated reefs no lagoons? Why have most of the lagoons of the smaller atolls been filled up? Why is the circle of land or reef in the perfect atolls only, at most, a few hundred yards in diameter? What is the origin of the lagoon? What relation exists between the depth of the lagoon, its area, and the depth of the water beyond the outer reef? How has the dry land of these islands been formed, provided with a soil, a fauna and a flora? These appear to be the chief questions that demand an answer from any theory of coral island formation.

These coral formations are essentially structures belonging to the great oceans and ocean basins. They are dots of land within the oceanic areas that might be compared or contrasted with the small salt lakes which are scattered over the surface of the continental lands. A rapid survey of some of the more general phenomena of the great oceans may, then, lead to a better appreciation of the problems connected with coral reefs.

The great ocean basins occupy over two-thirds of the earth's surface, and have a mean depth of over two miles. The central portions of these basins, called the abysmal regions, occupy about one-half of the earth's surface, and have a mean depression below the general level of the continents of over three miles. The abysmal regions are vast undulating plains, sometimes rising to less than two miles from the surface of the sea, and again sinking to four and five miles beneath it. Volcanic cones rise singly or in clusters from these great submerged plains. When they shoot above the level of the sea they form single islands, like Ascension and St. Paul's Rocks, or groups, like the Azores, the Sandwich, the Fiji, and the Society Islands. As might have been expected, there are many more of these cones hidden beneath the waves than rise above them. When the *Challenger* sounded along the west coast of Africa, there was no suspicion that between her stations she was sailing over submerged cones. Since then, however, the soundings of telegraph ships have correctly mapped out no less than seven of these peaks between the latitude of Lisbon and the Island of Teneriffe. The depths on the summits of these vary from 12 to 500 fathoms. On one of them, at 400 fathoms, two species of coral (*Lophohelia prolifera* and *Amphihelia oculata*) were growing luxuriantly. Throughout the ocean basins about 300 such submarine cones, rising from great depths up to within depths of from 500 to 10 fathoms from the surface, are already known, or indicated by soundings.

All the physical agencies at work above the lower limit of wave action tend to wear away and level down these cones, and thus to form banks. Graham's Island, thrown up in the Mediterranean in 1831, was 200 feet in height and three miles in circumference, and was washed away in a year or two. The bank left on the spot, at first very shallow, has now 24 feet of water over it. Instances similar to this historical example must often have happened in the great ocean basins. Again, the same agencies produce wide banks around volcanic islands by washing away and spreading out the materials of the softer rocks. Such banks, with depths of less than 60 fathoms, are found extending many miles seawards around some volcanic islands.

On the other hand, all the deeply submerged summits are continually being built up to the lower limit of wave action by the accumulation of the remains of animals which live on them and by the fall of shells upon them from the surface waters. In the Solomon Islands, Dr. Brougham Guppy has shown that there are upraised coral islands with central volcanic cones covered with thick layers of marine deposits; Christmas Island, in the Indian Ocean, is another instance, and similar deposits must now be forming over hundreds of submerged mountains. In this way are foundations prepared for the true reef-building species, which only flourish in the shallower depths.

The bulk of the water of the ocean has a very low temperature; it is ice-cold at the bottom, even under the equator, but on the surface within the tropics there is a relatively thin film of warm water, with a temperature of from 70° to 84° F. This film of warm water is much deeper towards the western parts of the Atlantic and Pacific than it is in the eastern, the reason for this being that the trade winds, which blow continually from the east, carry all the warm surface water to the westward, and draw up cold water from beneath along the western shores of Africa and America to supply the place of that driven westward at the surface. Consequently, there is, at times, a very low temperature, and a great annual range of temperature, along these western shores. This is more clearly shown by the temperatures at 50 and 100 fathoms than by those at the surface. There are no coral reefs along the western shores of Africa and South America, a circumstance evidently connected with the low temperature, wide range, and, more directly, with the food supply, consequent on these conditions. It appears to be a confirmation of this view that, on the eastern shores of Africa, about Cape Guardafui, from off which the south-west monsoon blows for several months in the year, cold water is also drawn to the surface, and there, likewise, are no coral reefs, though they flourish to the north and south of this region.

Coral reefs flourish in mid-ocean and along the eastern shores of the continents, or wherever the coasts are bathed by the warmest and purest currents of water coming directly from the open sea. If we except Bermuda and one or two other outlying reefs, where the temperature may occasionally fall to 66° or 64° F., it may be said that reefs are never found where the surface temperature of the water, at any time of the year, sinks below 70° F., and where the annual range is greater than 12° F. In typical coral reef regions, however, the temperature is higher and the range much less.

The food supply of the coral reef is derived from pelagic oceanic organisms, which exist in the greatest variety and abundance in the surface and sub-surface waters of the ocean. These consist of myriads of Algæ, Rhizopods, Infusorians, Medusæ, Annelids, Molluscs, Crustaceans, Ascidians, and fishes. A very large number of these creatures, within the tropics, secrete carbonate of lime from the ocean to form their shells and skeletons, which, falling to the bottom after death, form the vast oceanic deposits known as Pteropod and Globigerina oozes. In falling to the bottom, they carry down some of the organic matter that composed their living bodies, and thus are the animals which live on the floor of the ocean chiefly supplied with food. Here it may be remarked, incidentally, that the abundance of life at depths of even over two miles is very great. Our small dredges sometimes bring up over sixty species and hundreds of specimens in one haul—of invertebrates and fishes, exclusive of the Protozoa. The pelagic organisms above mentioned oscillate from the surface down to about 80 or 100 fathoms, probably that stratum of the ocean affected by sunlight, and they apparently descend further in regions where the stratum of warm water has a greater depth. Many of the forms rise to the surface in the evening and during calms, and sink again in sunlight and during stormy weather. It is in the evening and when it is calm that this swarming life is most vividly forced on the attention by gorgeous phosphorescent displays. The lime-secreting organisms, like Coccospheres and Rhabdospheres, Foraminifera, Pteropods, and other Molluscs, are much more abundant, both in species and individuals, in the warmest and saltest waters than elsewhere. I have estimated, from tow-net experiments, that at least 16 tons of carbonate of lime, in the form of these shells, exist in a mass of the ocean, in coral-reef regions, one mile square by 100 fathoms in depth. If we take this estimate, which I consider much below the reality, and suppose one-sixteenth of these organisms to die and fall to the bottom each day, then they would take between 400 and 500 years to form a deposit one inch in thickness. I give this calculation more to indicate a method than to give even the roughest approximation to a rate of accumulation of deposits. The experiments were too few to warrant any definite deductions.

The great oceanic currents, moving westward at the rate of several miles an hour, bear these shoals of pelagic organisms on to the face of the reef, where millions of greedy mouths are ready and eager to receive them. The corals and other organisms situated on the outer and windward side of the reef receive the first and best supply; they are thus endowed with a greater amount of energy, and grow faster and more luxuriantly there than on other portions of the reef. The depth at which there is the most constant supply of this food is several fathoms beneath the surface, and there, too, the corals are found in most vigorous growth. It is only a relatively small quantity of this pelagic food that enters the lagoon, the corals that there struggle on in patches being largely supplied with the means of existence from the larvæ of reef-building animals.

So many observations were made during the *Challenger* Expedition on the pelagic fauna inside and outside reefs that

there is little, if any, doubt in my mind that the food supply is a most important factor in relation to the growth of corals in the different portions of a reef. Actual observations were made on the feeding of corals at a good many places, as well as numerous observations on the stomach contents. These observations have been confirmed by Alexander Agassiz.

It is as yet impossible to state in what form the lime, which is secreted as carbonate in such enormous quantities by marine organisms exists in the ocean.

Dana, in "Coral and Coral Islands," considers it "unnecessary to inquire whether the lime in sea-water exists as carbonate or sulphate, or whether chloride of calcium takes the place of these. The powers of life may take from the element present whatever results the function of the animal requires."

In connection with this question an interesting series of experiments are being conducted at the Scottish Marine Station, Granton, which go far to prove that the above hypothesis is correct.

The following table shows the average composition of sea-water salts, the acids and bases being combined in the way usually adopted by chemists—

Average Composition of Sea-Salt.

Chloride of sodium	77·758
Chloride of magnesium	10·878
Sulphate of magnesium	4·737
Sulphate of lime	3·600
Sulphate of potash	2·465
Bromide of magnesium	0·217
Carbonate of lime	0·345
	100·000

In the actual ocean water there are probably traces of every known element, and it is impossible to say what is the precise amount of the respective chlorides, sulphates, and carbonates present. Theoretically, every base may be combined with every acid, and the whole solution must be in a continual state of flux as to its internal composition. While the quantity of sea-salts in a given volume of water varies with position, yet it has been shown by hundreds of analyses that the actual ratio of acids and bases—that is, the ratio of the constituents of sea-salts—is constant in waters from all regions and depths, with one very significant exception—that of lime—which is present in slightly greater proportion in deep water.

The total amount of *calcium* in a cubic mile of sea-water is estimated at nearly 2,000,000 tons. The amount of the same element present in a cubic mile of river-water is nearly 150,000 tons. At the rate at which rivers carry down water from the land it is estimated that it would take 680,000 years to pour into the ocean an amount of calcium equal to that now held by the ocean in solution.

The amount of calcium existing in the 40,000,000 square miles of the typical calcareous deposits of the ocean exceeds, however, that at present held in solution if we merely take them to have an average thickness of 30 feet, and from this calculation we might say that, if the secretion and solution of lime in the other regions of the ocean be exactly balanced, and the calcium in the ocean remain always constant, those calcareous deposits of the thickness indicated would require between 600,000 and 700,000 years to accumulate. There is good evidence, however, that the rate of accumulation is much more rapid in some positions.

The lime thus carried down to the sea is originally derived from the decomposition of anhydrous minerals, and comes from the land in the form of carbonate, phosphate, and sulphate of lime—the carbonate being in the greatest abundance in river-water. On the other hand, the sulphate of lime very greatly predominates in sea-water, the carbonates being present in small quantity. We are not in a position to say whether or not the coral Polyps take the whole of the material for their skeletons from the carbonates, as is generally believed, or indeed to say what changes take place during the progress of secretion by organisms.

In the greatest depths of the Pacific coral seas there is striking evidence of the solvent power of ocean water. Our dredges bring up from a depth of three or four miles over a hundred ear-bones of whales and remnants of the dense Ziphioid beaks, but all the larger and more areolar bones of these immense animals have been almost entirely removed by solution. In a single haul there may also be many hundreds of sharks' teeth, some of them larger than the fossil *Carcharodon* teeth, but all that remains of them is the hard dentine. None of the numerous calcareous surface shells reach the bottom, although they are quite as abundant over the red clay areas as over those shallower areas, where they form Globigerina and Pteropod deposits. In consequence of the small amount of detrital material reaching these abysmal areas distant from continents, cosmic metallic spherules, manganese nodules, highly altered volcanic fragments, and zeolitic minerals, are there found in great numbers. Almost all these things are found occasionally in the other regions of the ocean's bed, but their presence is generally masked by the accumulation of other matters. In some regions Radiolarian and Diatom remains are found in the greatest depths, and they too are subject to the solvent power of sea-water, but to a much less extent than carbonate of lime shells.

As we ascend to shallower waters, a few fragments of the thicker-shelled specimens are met with at first; with lesser depths the carbonate of lime shells increase in number, until in the shallower deposits the remains of Pteropods, Heteropods, and the most delicate larval shells are present in the deposit at the bottom. This gradation in the appearance of the shells can be well seen in a series of soundings at different depths around a volcanic cone, such as has been described as forming the base of a coral atoll. There is no known way of accounting for this vertical distribution of these dead shells except by admitting that they have been dissolved away in sinking through the deeper strata of water, or shortly after reaching the bottom; indeed, an examination of the shells themselves almost shows the process in operation. It is rare to find any trace of fish-bones in deposits other than the otoliths.

These considerations, as well as numerous experiments in the laboratory, show that everywhere in the ocean dead or amorphous carbonate of lime structures quickly disappear wherever they are exposed to the action of sea-water, and in investigating the evolution of the general features of coral reefs it is as necessary to take cognizance of this fact as of the secretion of carbonate of lime by organisms. At the same time, too much stress cannot be laid upon the fact that carbonate of lime, although markedly soluble in sea-water in the amorphous form in which it exists in connection with (organic) life, becomes practically insoluble when after the death of the secreting animal it assumes the crystalline state.

In a paper read before the Royal Society of Edinburgh, embodying some of the results of his investigations on the solubility of carbonate of lime under different forms in sea-water, Mr. Irvine remarks, "It is due to this molecular change that coral deposits, shells, and calcareous plants are able to accumulate in the ocean, ultimately to form beds of limestone rocks."

The first stage, then, in the history of a coral island is the preparation of a suitable foundation on the submerged volcanic cones, or along the shores of a volcanic island, or the borders of a continent. In the case of the atoll the cone may have been reduced below the level of the sea by the waves and atmospheric influences, or built up to the lower limit of breaker action by the vast accumulation of organisms on its summit.

A time comes, however, should the peak be situated in a region where the temperature is sufficiently high, and the surface currents contain a suitable quality of food, that the reef-builders fix themselves on the bank. The massive structure which they secrete from ocean water enables them to build up and maintain their position in the very face of ocean currents, of breakers, of the overwhelming and outrageous sea.[1]

"Coral" with the sailor or marine surveyor is usually any carbonate of lime shell or skeleton or their broken-down parts. "Coral" is used by the naturalist in a much more restricted sense: he limits the term to animals classed as Madrepores, Hydrocorallines, and Alcyonarians. The animals belonging to the first two of these orders comprise those included under the vague term of reef corals. Besides these, however, very many other classes of animals contribute to the building up of coral

[1] Dr. Brougham Guppy says, "History can afford us no clue to the first appearance or the age of reefs; yet in the myths of the Pacific Islanders we find that the savage inhabitants of these regions regard the history of a coral atoll as commencing with the submerged shoal, which through the agency of God-like heroes is brought up by their fish-hooks to the surface." —Paper, Vict. Inst.

reefs and islands—such are Foraminifera, Sponges, Polyzoa, Annelids, Echinoderms, and Calcareous Algæ. The relative proportions of these different organisms in a reef vary with the region, with the depth, and with the temperature, but members of what are known under the term of reef corals appear always to predominate.

The animals of the true reef-building species resemble the common sea-anemones in structure and size; the individual Polyps may vary from the eighth of an inch in diameter to over a foot. Some of the structures built by colonies may exceed 20 feet in diameter.

There may be great variety in the appearance of submerged reefs as they rise from banks of a different nature, form, and extent, as, indeed, was pointed out long ago by Chamisso. There may be differences due also to the kinds and abundance of deep-sea animals living on such banks, as well as differences due to currents, temperature, and other meteorological conditions.

From the very first the plantations situated on the outer edge will have the advantage, from the more abundant supply of food and the absence of sand in the water, which last more or less injuriously affects those placed towards the interior. Chamisso attributed the existence of the lagoon to the more vigorous growth of the peripherally situated corals of a reef, as compared with those placed towards the middle, and in this he was to a large extent right, but the symmetrical form of the completed atoll is chiefly due to the solution of the dead carbonate of lime structures. The Great Chagos Bank illustrates the irregular way in which such a large bank of coral plantations approaches the surface. When these, however, reach the surface, they assume slowly a more regular outline, those on the outer edge coalesce, and ultimately form a complete ring of coral reef, and the lagoon becomes gradually cleared of its coral patches or islands, for, as the atoll becomes more perfect, the conditions of life within the lagoon become less and less favourable, and a larger quantity of dead coral is removed in solution.

The coral atoll varies greatly in size and form: it is usually more or less circular, horse-shoe shaped, and may be one or over fifty miles in diameter. The breakers spend their fury on the outer edge, and produce what is known as the broad shore platform; but within, trees descend to the very shore of the lagoon, where there is quiet water, and a ship may often enter on the lee side of the atoll and find safe anchorage.

In this connection it is important to bear in mind the relation which exists between the periphery and the superficial area of the lagoon in atolls of different sizes. If the coral plantations which rise from the top of a submerged mountain have an area of one square mile, then on reaching the surface of the waves there will be a shallow depression in the centre owing to the more rapid growth of the outer edge. Such an atoll will have, if it be a square, four miles of outer reef for the supply of coral sand and other *débris*, and these being washed and blown into the one square mile of shallow lagoon it is likely to become filled up, the result being a small island with dry lagoon, in which may be found deposits of sulphate of lime, magnesian and phosphatic rocks, and guano—all these testifying to the great age of the island and absence of subsidence in the region. It is only atolls with a diameter of less than two miles that thus become filled up. In other and larger plantations, rising from a more extensive bank, the conditions are very different. In this larger atoll—say four miles square—there is now only one mile of outer reef to each square mile of lagoon, instead of four miles of outer reef to the one square mile of lagoon in the smaller atoll. Only one-fourth of the detrital matter and food enters the larger lagoon, from the outside, per square mile of lagoon, and hence there is proportionately less living coral, the solvent agencies predominate, and the lagoon is widened and deepened. Growing seawards on the outer face and dissolving away in the lagoon, the whole expands after the manner of a fairy ring, and the ribbon of reef or land can never in consequence increase beyond a half or three-quarters of a mile in width, it being usually much less. I have recently made a very careful comparison of the latest Admiralty Survey of the lagoon of Diego Garcia with the one made many years ago, and the result appears to me to indicate that the area of the lagoon has considerably increased in the interval, and the average depth is a little greater than formerly, although shallower in some places.

Atolls may occur far away from any other land, but it more frequently happens that they are arranged in linear groups, in this respect resembling volcanic islands. Extensive banks may be crowded with small atolls, like the Northern Maldives; or a bank may be occupied by one great and perfect atoll twenty to forty miles in diameter, like some of the Southern Maldives and the Paumotus. In some instances the large atolls appear to have resulted from the growth and coalescence of the smaller marginal atolls; especially does this seem to have been the case with the large Southern Maldives.

The outer slopes vary greatly in different reefs, and in different parts of the same reef. When there is deep water beyond, the reef very often extends out with a gentle slope to a depth of 25 to 40 fathoms, and is studded with living coral, the bosses and knobs becoming larger in the deeper water farthest from the reef, where there are great overhanging cliffs, which eventually fall away by their own weight, and form a talus on which the reef may proceed further outwards. Occasionally there is a very steep descent almost at once from the outer edge. Thus, the deeper the water beyond, the more slowly will the reef extend seawards. In reefs with a very gentle slope outside, the corals are frequently overhanging at depths of 6 or 7 fathoms, for in these instances the lower part of the sea-face of the reef is rendered unsuitable for vigorous growth, in consequence of the sand which is carried in by waves coming over the comparatively shallow depths outside; in these cases, lines of growing corals, or a submerged barrier, are sometimes met with in deep water some distance seawards from the edge of the reef.

As has been stated, the lagoon in many of the smallest atolls has been filled up, but this never appears to happen in atolls with a diameter of over two miles unless there be distinct evidence of upheaval. In perfectly-formed atolls—that is, those in which the reefs are nearly continuous throughout—the deepest water is found towards the centre of the lagoon, and there is a relation between this depth and the depth of water beyond the outside reefs. In North and South Minerva reefs, in the South Pacific, where the outside depths are very great, there are depths down to 17 fathoms in the lagoons, which are apparently clear of coral heads. Here we may suppose that the central parts of the lagoon have for a long time been exposed to the solvent action of sea-water, owing to the slow lateral growth of the reef as a whole. In the same regions the Elizabeth and Middleton reefs, which are about the same size, have only 4 or 5 fathoms within the lagoons, and the depths outside the reefs are, at the distance of a mile, mostly within the 100-fathom line, and sometimes less than 50 fathoms. There are also many coral heads within the lagoons. Here we may suppose the atolls to be more recent, and to have extended more rapidly than in the case of the Minerva reefs. If the depths beyond the reefs be taken into consideration, then there is usually a direct relation between the depth of the lagoon and its diameter. The greatest depths, even in the largest atolls, do not exceed 50, or at most 60, fathoms; they are usually much less. In atolls which are deeply submerged, or have not yet reached the surface, which have wide and deep openings into lagoon-like spaces, this relation may not exist. In these instances the secretion and deposition of carbonate of lime may be in excess of solution in all parts of the lagoon. It is only when the atoll reaches the surface, becomes more perfect, and its lagoon waters consequently less favourable to growth, that the solution of the dead corals and calcareous *débris* exceeds any secretion and deposition that may take place throughout the whole extent of the lagoon; it is then widened and deepened, and formed into a more or less perfect cup-like depression, unless the lagoon be of small size and is filled up.

The whole of a coral reef is permeated with sea-water like a sponge; as this water is but slowly changed in the interior parts, it becomes saturated, and a deposition of crystalline carbonate of lime frequently takes place in the interstices of the corals and coral *débris*. In consequence of the solution of coral *débris* and the re-deposited lime occupying less space, large cavities are formed, and this process often results in local depressions in some islands, as, for instance, in Bermuda. At many points on a reef where evaporation takes place there is a deposition of amorphous carbonate of lime cementing the whole reef materials into a compact conglomerate-like rock.

The fragments of the various organisms broken off from the outer edge during gales or storms are piled up on the upper surface of the reef, and eventually ground into sand, the result being the formation of a sandy cay or shoal at some distance back from the outer edge of the reef—the first stage in the formation of dry land.

The fragments of pumice thrown up into the ocean during far-distant submarine eruptions, or washed down from volcanic

lands, are at all times to be found floating about on the surface of the sea, and these, being cast up on the newly-formed islet, produce, by their disintegration, the clayey materials for the formation of a soil—the red earth of coral islands. Just within the shore platform these pumice fragments are found in a fresh condition, but as the lagoon is approached they disappear, the soil becomes deeper, and the most luxuriant vegetation and largest trees are found close to the edge of the inner waters. The land is seldom continuous around the atoll; it occurs usually in patches. The water passes over the shallow spaces between the islets and through the deeper lagoon entrances, these last being kept open by the strong sand-bearing currents which pass at each tide.

The few species of plants and animals which inhabit these coral islands have been drifted to the new island like the pumice, or carried, many of them maybe, by birds; lastly, savage and civilized man finds there a home.

There is no essential difference between the reefs forming fringing and barrier reefs, and those which are known as atolls. In the former case, the corals have commenced to grow close to the shore, and as they grow outward, a small boat-passage, and then a ship-channel, is carved out between the reef and the shore by tidal scour and the solvent action of the water on the dead parts of the reef: thus, the fringing reef may be converted into a barrier reef; or the barrier may be formed directly by the upward growth of the corals at some distance from the shore. In some instances the corals find a suitable foundation on the banks that surround islands and front continental lands, it may be, at a great distance from the coast, and when they reach the surface they form a distant barrier, which proceeds seawards, ultimately on a talus made up of materials torn from its seaward face.

If the foregoing considerations be just and tenable, then it would appear that all the characteristic features of coral reefs can be produced, alike in stationary areas or in areas of slow elevation and subsidence, by processes continually at work in the ocean at the present time. Slow elevation or subsidence would only modify in a minor way a typical coral atoll or barrier reef, but subsidence in past times cannot be regarded as the cause of the leading characteristics of coral reefs. There are abundant evidences of elevation in coral-reef regions in recent times, but no direct evidence of subsidence. If it has been shown that atoll and barrier reefs can be formed without subsidence, then it is most unlikely that their presence in any way indicates regions of the earth's surface where there have been wide, general, and slow depressions.

According to Mr. Darwin's theory, which has been almost universally accepted during the past half-century, the corals commence to grow close to the shore of an island or continent: as the land slowly sinks, the corals meanwhile grow upwards to the surface of the sea, and a water space—the lagoon channel—is formed between the shore of the island and the encircling reef, the fringing being thus converted into a barrier reef. Eventually, the central island sinks altogether from sight, and the barrier reef is converted into an atoll, the lagoon marking the place where the volcanic or other land once existed. Encircling reefs and atolls are represented as becoming smaller and smaller as the sinking goes on, and the final stage of the atoll is a small coral islet, less than two miles in diameter, with the lagoon filled up and covered with deposits of sea-salts and guano.

It is at once evident that the views now advocated are in almost all respects the reverse of those demanded by Mr. Darwin's theory.

The recent deep-sea investigations do not appear in any way to support the view that large or small islands once filled the spaces now occupied by the lagoon waters, and that the reefs show approximately the position of the shores of a subsided island. The structure of the upraised coral islands, so far as yet examined, appears to lend no support to the Darwinian theory of formation. When we remember that the great growing surface of existing reefs is the seaward face from the sea surface down to 20 or 40 fathoms, that large quantities of coral *débris* must be annually removed from lagoons in suspension and solution, that reefs expand laterally and remain always but a few hundred yards in width, that the lagoons of finished atolls are deepest in the centre, and are relatively shallow compared with the depth of the outer reefs, then it seems impossible, with our present knowledge, to admit that atolls or barrier reefs have ever been developed after the manner indicated by Mr. Darwin' simple and beautiful theory of coral reefs.

DARWIN VERSUS LAMARCK.[1]

AFTER a brief sketch of the life of Lamarck (1744–1829), his theory was stated in his own words as follows:—

"(1) In every animal which has not arrived at maturity, the increased and continued employment of any organ strengthens that organ gradually, develops it, enlarges it, and gives it a power proportional to the duration of its employment: on the other hand, the continued disuse of any organ gradually weakens it, deteriorates it, progressively diminishes its faculties, and finally causes it to disappear.

"(2) Every feature which, under natural conditions, individuals have gained or lost by the action of circumstances to which their race has been for some time exposed—as, for instance, the results of excessive use or disuse of an organ—is preserved in reproduction and transmitted to the offspring, provided that the acquired changes were present in both parents."

The small changes thus produced and transmitted from generation to generation are increased in successive generations by the action of the same causes which originated them, and thus in long periods of time the form and structure of the descendants of an ancestral organism may be completely changed as compared with the form and structure of the ancestor.

Given sufficient time, these small changes can have produced man and the higher animals from simple primitive protoplasmic animalcules.

Prof. Lankester then pointed out the truth of the first law of Lamarck, but mentioned the preliminary objections to Lamarck's theory, which had prevented its acceptance by the naturalists of the first half of this century. He then briefly epitomized Darwin's theory as follows:—

(1) All plants and animals produce offspring which resemble their parents on the whole (heredity); these offspring, however, exhibit also new and individual features differing from those of their parents (congenital variations).

(2) In Nature there is a severe struggle for existence. Only one pair out of the many thousands often produced by a pair of plants or animals survive to maturity, and in their turn produce offspring.

(3) The survivors are those whose congenital variations have enabled them to gain advantage over their fellows.

(4) The surviving forms *may* be almost exactly like their parents, but often a departure from the parental form must be an advantage, however small. Such departure, or variation, when IN-BORN OR CONGENITAL, not only enables its possessor to survive and produce offspring, but is handed on by heredity to that offspring.

(5) A successful congenital variation is intensified in the new generation bred from parents in both of which it had congenitally appeared.

(6) By this process of natural selection of advantageous congenital variations, operating in countless millions of successive generations, the transformation of simple into more elaborate forms of life has been effected.

The real difference between Lamarck's and Darwin's theories was then explained. Congenital variation is an admitted and demonstrable fact; transmission of congenital variations is also an admitted and demonstrable fact. Change of structure acquired during life—as stated by Lamarck—is also a fact, though very limited. But the transmission of these latter changes to offspring is NOT PROVED EXPERIMENTALLY; all experiment tends to prove that they cannot be transmitted. Semper's book on this subject was cited as a failure in the attempt to prove such transmission.

The causes of congenital variations were next discussed, and the "stirring up" of the germ-plasma by the process of fertilization was pointed to as the chief.

Very minute congenital variations can be useful, and, therefore, selected; but congenital variations are not necessarily minute.

The subject of correlated variations was next mentioned, and their great importance pointed out. A mechanical model was used to explain this matter: it represented an antelope in which when the neck is made to elongate the legs simultaneously lengthen, whilst the horns disappear and the tail shortens.

The lecturer then gave examples of the successful explanation

[1] Abstract of a Lecture delivered at the London Institution, Finsbury Circus, on February 14, 1889, by Prof. Ray Lankester, LL.D, F.R.S.

of cases by Darwinism where Lamarckism fails. Mimicry and protective colouring, adaptation of flowers to insect visitors, instincts of neuter insects, and Lamarck's chosen case, the giraffe, were among these.

It was then pointed out that breeders have never produced new varieties by transmission of acquired characters (Lamarckian), but always by transmission of congenital characters (Darwinian).

Whilst all this tends to the complete rejection of Lamarck's theory, it is true that Darwin himself admitted Lamarckism as an explanation of some rudimentary organs (disuse), and of some instincts (transmission of acquired habit).

On the other hand, neo-Darwinians reject Lamarckism altogether, because (1) the fundamental fact of transmission of a change of structure or habit acquired during the life of an individual by the action of external agencies is not only not proved but is contrary to experience; (2) such transmission is highly improbable in view of the structure and origin of the reproductive germs; (3) even if admitted as possible, Lamarckism is not needed in order to explain the facts of the structure and habits of existing plants and animals, in addition to Darwinism. Pure Darwinism is sufficient.

Finally, the lecturer dealt with some cases advanced by Lamarckians as favourable to their views, and gave their Darwinian explanation.

Among these were rudimentary organs, where the fully-developed organ would not be injurious, *e.g.* the intrinsic muscles of the human ear. These were explained by panmixia and parsimony of growth.

Blind animals in caves and in the deep sea, *e.g.* blind cray-fish, Thaumastocheles, and blind fishes, were shown to be best explained by the natural selection of congenital blindness. Amongst a whole brood of animals swept by a flood into a cavern, or by a current into deep water, those with perfect eyes would escape by following the light, whilst those with congenitally defective eyes would remain and reproduce their defect in their offspring, and in each succeeding generation the same process of natural selection would be continued.

Wingless insects and birds were similarly explained.

Instincts, *e.g.* "shamming dead," nest-building, choice of food, were briefly considered, and shown to be explicable by Darwinism and not by Lamarckism.

In fact, it was declared that, in proportion as our knowledge of any class of such facts is extensive and thorough, the Darwinian explanation is found to be correct and the Lamarckian inadequate and inapplicable.

A consideration of the mental evolution of man, according to neo-Darwinism was promised as the subject of a future lecture. It was briefly stated that the results of education and circumstances, good or bad, cannot be transmitted, whilst hereditary qualities, good or bad, cannot be eliminated, except by selection in breeding.

The transmission of acquired experience does not take place by heredity, but (among civilized societies) by the agency of tradition and books.

In civilized societies the injurious effects of unlimited neglect of selective breeding is largely neutralized by panmixia, giving an average race, neither wholly good nor wholly bad.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Botanic Garden Syndicate, unlike some others at Cambridge, have been able to erect their new plant-houses within one pound of the estimate, £3000. The work has been satisfactorily done by Messrs. Boyd, of Paisley. Solid foundations have been laid, so that when required new wood-work may be built on the same walls. The new houses include a warm orchid-house, warm fern-house, stove, palm-house, aquarium, and stove-pit. A laboratory, for investigations required to be conducted near the plant-houses, has been built; it contains two large working-rooms and a dark chamber. The collections removed to the new houses are now in capital condition. The hardy cactuses, probably unsurpassed, have been removed to the border in front of the new stove. A new bed has been made for the choicer hardy Ericaceæ. Great progress has been made in naming and labelling. Among plants of scientific interest that have flowered in the gardens is *Pilocarpus pennatifolius*, which yields pilocarpine, *Erythroxylon Coca, Narcissus Broussoneti* (the corona a mere rim), and many others. Among the most interesting plants received have been *Gerbera Jamesoni*, a fine Composite from the Cape, *Isonandra Gutta* (yielding gutta-percha), *Washingtonia robusta*, a choice new palm, *Stachys tuberifera*, a new vegetable (the crosnes of the Paris markets), and numerous hardy bamboos.

The regulations altering the arrangement of papers in the Natural Sciences Tripos have been confirmed, making the papers special ones in subjects, instead of general ones covering all the subjects.

The following have been appointed members of the Boards of Electors to Professorships named: Moral Philosophy, Principal Caird; Chemistry, Prof. A. W. Williamson; Botany, Sir Joseph Hooker; Geology, Prof. A. H. Green; Jacksonian of Natural Philosophy, Prof. A. W. Williamson; Mineralogy, Prof. H. N. Story-Maskelyne; Political Economy, Right Hon. L. H. Courtney; Zoology, W. H. Flower, C.B.; Experimental Physics, Sir W. R. Grove; Mechanism and Applied Mechanics, Sir F. J. Bramwell, F.R.S.; Physiology, Prof. Humphry; Logic, Prof. Bain.

Mr. A. E. Shipley has been approved as a teacher of Comparative Anatomy for the purpose of medical study.

SCIENTIFIC SERIALS.

The American Journal of Science, February.—Points in the geological history of the Islands Maui and Oahu, Hawaii, by James D. Dana. The subjects illustrated by the present state of these islands are: the conditions of extinct volcanoes in different stages of degradation; the origin of long lines of precipice cutting deeply through the mountains; the extent and condition of one of the largest of craters at the period of extinction, and the relation of cinder and tufa cones to the parent volcano. The accompanying plates, reduced from the recent large Government maps, show the present general features of both islands. Incidental reference is made to the late controversy on Darwin's theory of coral islands, the author declaring emphatically that no facts have hitherto been published by Mr. Murray or Mr. Guppy that prove the theory false, or set aside the arguments in its favour. Some of the facts are more in favour than opposed to it, while none do more than offer a possible alternative.—An experiment bearing upon the question of the direction and velocity of the electric current, by Edward L. Nichols and William S. Franklin. The authors, who had already independently developed a method similar to that lately described by Foeppl (*Annalen der Physik und Chemie*), here repeat his experiment with an apparatus capable of indicating the direction and velocity of the current, supposing it to have direction, even though that velocity were very great indeed. They show that they would have been able to detect a change of deflection due to the motion of the coil, even though the velocity of the current had been considerably in excess of one thousand million metres per second.—On the occurrence of monazite as an accessory element in rocks, by Orville A. Derby. The researches of Mr. John Gordon and Prof. Gorceix have placed beyond doubt the wide distribution of monazite in the sea and river sands of Brazil, but under circumstances that give no clue to its origin. The petrographic analyses here described have resulted in the discovery that gneiss, granite, and syenite yield, besides zircon, a certain quantity of microscopic crystals of a heavy yellow mineral apparently identical with the Bahia monazite. Recently, also, Mr. Gordon has obtained residues of zircon and monazite from the river sands at Buenos Ayres, and from gneiss and granite decomposed *in situ* at Cordoba in the Argentine Republic.—On the use of steam in spectrum analysis, by John Trowbridge and W. C. Sabine. These experiments show that a remarkable degree of economy in time and in waste of apparatus results from the use of a jet of steam in spectrum analysis, when the spark method of obtaining the spectra of metals is employed.—A comparison of the electric theory of light and Sir William Thomson's theory of a quasi-labile ether, by J. Willard Gibbs. A comparison is here instituted between the electric theory of light and the new theory of an elastic ether expounded by Sir William Thomson in the *Philosophical Magazine* for November 1888. The result of this inquiry seems to be that both theories in their extreme cases give identical results. The greater or less degree of elegance, or completeness, or perspicuity, with which these laws may be developed by different physicists should weigh nothing in favour of either

theory. The elastic theory, however, is regarded as somewhat less convenient as a working hypothesis than the electric.—In this number appears Part 1 of an exhaustive monograph, with numerous illustrations, on the geology of the volcanic island of Fernando de Noronha, South-West Atlantic, by John C. Branner.

The last volume (xviii.) of the *Memoirs of the Kazan Society of Naturalists* contains an elaborate inquiry into the distribution of solanin (an alkaloid discovered by Desfosses in many *Solanaceæ*) in plants, by E. Wotschall; short reports on geological exploration in the Governments of Vyatka and Ufa, by A. Netschaeff and A. Lavrsky; and a description of the flora of the neighbourhood of Ufa, by A. Gordyaghin.

SOCIETIES AND ACADEMIES.

London.

Royal Society, February 7.—"The Principles of Training Rivers through Tidal Estuaries, as illustrated by Investigations into the Methods of improving the Navigation Channels of the Estuary of the Seine." By Leveson Francis Vernon-Harcourt, M.A., M.Inst.C.E.

After stating the principles upon which the training of the non-tidal portions of rivers are carried out, the undefined and unsatisfactory condition of the principles followed in training rivers through wide tidal estuaries, and the discordant views of engineers on the subject, were pointed out. The absence of definite principles, and the divergence of opinion amongst engineers, have received a remarkable illustration in the great variety of schemes proposed for extending the training walls in the Seine estuary beyond Berville, where the works were stopped, in 1870, owing to the unexpected changes the works had already produced. It occurred to the author in August 1886, that if it should be possible to reproduce, in a working model, the original state of the Seine estuary before the training works were commenced, and next the present state of the Seine, as modified by these works, could be obtained, then the successive introduction in the model of the several schemes, proposed for the extension of the training walls, might furnish results indicating approximately in miniature the changes which the works would actually produce if carried out in the estuary, and also afford a basis for the establishment of general principles for training rivers through wide estuaries. A model, accordingly, was made of the tidal Seine, to the scale of 1/40,000 horizontal, and 1/400 vertical; the bed was formed of fine sand, so that it could be moulded by the current; the fresh-water discharge was produced, at the upper end, by the flow of water from a small cistern; and the tidal ebb and flow were effected by the tipping of a tray, placed at a suitable angle at the lower end, representing the open sea. The model was first worked in November 1886, and the experiments were continued at intervals up to 1889. Silver sand was first used for forming the bed of the miniature estuary; and some of the phenomena of the actual estuary, such as the *bore*, the "*verhaulc*" or reverse current, and the shifting channels, were reproduced in the model; but when the training walls were introduced into the model, on the lines of the existing training walls, it was found that the silver sand could not be adequately carried in suspension by the small currents in the model to reproduce the accretion which has occurred in the estuary behind and beyond the training walls. A variety of fine powders, of low specific gravity, were consequently experimented on in the model, but they mostly proved too sticky, or pasty, or otherwise unsuitable. At last a fine sand from Chobham Common, belonging to the Bagshot beds, containing an admixture of peat, offered better results, and was employed for the subsequent experiments.

After working the model for some time with a bed formed of this Bagshot sand, the channels assumed a form very closely resembling in general outline the chart of the Seine of 1834. This result, by reproducing a former condition of the estuary, confirms the previous results obtained by Prof. Osborne Reynolds with a model of the Upper Mersey estuary, showing that it is quite practicable to reproduce in a model the main tidal channels in an estuary.

The second stage of the investigation involved the quite novel condition of introducing training walls in a model, and producing the resulting accretion. This most essential stage was the subject of a long series of experiments, but was at last satisfactorily accomplished with Bagshot sand. The existing training walls were inserted in the model, and the resulting deepening of the trained channel and the accretion outside and beyond were reproduced in the model, and also the shifting channel between the termination of the training walls and the sea.

The third stage of the investigation was then entered upon, consisting in the successive introduction in the model of the lines of the five principal schemes at present advocated, observing the changes they respectively produced in the model of the estuary, and recording them in the form of charts of the estuary, which are appended as plates to the paper. A final experiment was also made with an arrangement of training walls forming as gradually expanding a channel as practicable, without restricting the width of the outlet. The lines designed for the extension of the training walls in each scheme are briefly described in the paper, as well as indicated in the charts, and also the channels and accretion which they each produced.

The probability of the results obtained really representing in miniature the results which corresponding works in the estuary of the Seine would actually produce was then considered; for if the effects of any training works could be foreshadowed by experiments in a model, the value of such experiments, in guiding engineers towards the selection of the most suitable design, could not be over-estimated. Though the effects of winds and waves, and the actual rate of accretion, cannot be reproduced in a model, it is evident, from the first stage of the investigation, that the main forces at work, in the comparative shelter of an estuary, are the tidal ebb and flow and the fresh-water discharge, which are the forces which can be produced in a model. Moreover, the correspondence of the second stage of the investigation with the existing state of the Seine estuary confirms the accordance between the results in the model and the condition of the estuary. The extension of training walls decreases the influence of winds and waves; and therefore the results of the third stage of the investigation are more likely to correspond with the changes which such works would actually produce in the estuary, than those of the first and second stages. Also the results obtained in the model with the two earlier schemes are precisely those which the author predicted would occur, before the experiments were commenced, if the schemes were actually carried out in the estuary.

The paper concludes with a classification of the experiments, with the view of deducing general principles for guidance in training rivers through tidal estuaries. The three classes are, (1) outlet of estuary considerably restricted, and channel trained inside towards outlet; (2) channel trained in sinuous line, expanding towards outlet, but kept somewhat narrow at changes of curvature; (3) channel trained in as direct a course as practicable, and expanding regularly to outlet.

The experiments of the first class exhibited a deep outlet, and a fairly continuous channel inside where the training works were prolonged to the outlet. The channel, however, was irregular in depth near the outlet; and a bar appeared in front of the outlet outside. The breakwater, also, extending across part of the original outlet, occasioned deposits both inside and outside the estuary, by producing slack water in the sheltered recesses.

The second class of trained channel was designed to profit by the well-known scour at the concave face of bends in non-tidal rivers, and to continue the depth thus obtained by restricting the width between the bends. Experiment, however, did not bear out the advantages of this system, probably owing to the variable direction of the flood tide at different heights of tide, its being checked in its progress by the winding course, and not acting in unison with the ebb, from the difference in its direction and the width of the trained channel near the outlet. The third class of trained channel afforded a wide channel, tolerably uniform in depth, in the experiments; the flood tide was less impeded in its progress than with the other forms of training walls, and appeared to act more in concert with the ebb.

The experiments accordingly indicate that the only satisfactory principle for training rivers through wide estuaries with silt-bearing currents is to give the trained channel a gradually expanding form, with as direct a course as practicable to the outlet. The rate of increase in width between the training walls must be determined by the special conditions of the estuary.

February 14.—"On a Series of Salts of a Base containing Chromium and Urea," No. 2. By W. J. Sell and Prof. W. J. Lewis.

The paper is a continuation of that published by one of the authors (Proc. Roy. Soc., vol. xxxiii. p. 267). It is here shown

that the chief product of the reaction of chromyl dichloride on urea is the dichlortetrachlorochromate of a base containing the elements of urea with chromium to which the formula $\left\{ (CON_2H_4)_{12}Cr_2 \right\}\begin{matrix} 4CrO_3Cl \\ Cl_2 \end{matrix}$ is assigned. This compound crystallizes from hydrochloric acid in brown-yellow crusts, which are immediately decomposed by water with formation of the dichlordichromate and hydrochloric acid. Among a large number of other new salts described, of which the normal bromide, $(CON_2H_4)_{12}Cr_2Br_6 6H_2O$, and iodide, $(CON_2H_4)_{12}Cr_2I_6$, may be taken as typical, the base also forms a perbromide, $(CON_2H_4)_{12}Cr_2Br_6 6Br_2$, and a periodide of similar composition, behaving in this respect like the organic bases. These substances, as indeed all the salts hitherto obtained, crystallize with great facility, and are as a rule sparingly soluble.

Anthropological Institute, February 12.—Dr. John Beddoe, F.R.S., President, in the chair.—Dr. Beddoe read a paper on human remains discovered by General Pitt-Rivers at Woodcuts, Rotherley, and Winkelbury Camp.—Mr. Bernard Hollander read a paper on centres of ideation in the brain. The object of this paper was to furnish the basis of a scientific phrenology. The author took it for granted: (1) that all mind manifestation is dependent on brain matter; (2) that the various elements of the mind have distinct seats in the brain, which, however, have not been as yet determined; (3) that the recent researches by physiological experimenters and pathological investigators, which have resulted in defining distinct regions for motion and sensation, established the physiological correlative of psychological actions. By applying galvanic currents to definite portions of the brain, or by destroying certain areas, physiological experimenters caused movements of certain limbs and muscles. In itself the distribution of motor areas in the brain would be of little value to the psychologist, except that it proves to him the plurality of functions of the brain. When, however, we observe that the movements caused by excitation form the physical parallel of a mental action, we may arrive at the psychological function of a certain portion of brain by reducing the various faculties of the mind to their elements, and watching their physical expression. To arrive at the demonstration of centres of ideation: (1) we must observe the physical expressions of our thoughts and feelings; (2) we must take the limbs and muscles, which are affected by definite emotions, and see on what occasions they are made to move by central excitation. Thus we find that in a definite part of the frontal convolution (Ferrier's centre No. 7) the galvanic current had the effect of elevating the cheeks and angles of the mouth with closure of the eyes. On no other region could the same be effected. Darwin points out ("Expression of the Emotions," p. 202) that under the emotion of joy the mouth is acted on exclusively by the great zygomatic muscles, which serve to draw the corners backwards and upwards. The upper and lower orbicular muscles are at the same time more or less contracted. Duchenne and Sir Chas. Bell are of the same opinion, and Sir Crichton Browne, speaking of the general paralysis of the insane, says that in this malady there is invariably optimism, delusions as to wealth, rank, &c., and insane joyousness, while its very earliest physical symptom is trembling at the corners of the mouth. The effect produced by the galvanic current on Ferrier's centre No. 7 is thus shown to be the physical expression of the emotion of joy. Combe located there his "organ of cheerfulness" which he afterwards called "Hope"; and there is no doubt some relation between the effect of Ferrier's experiment and the result of Combe's observation. Prof. Sigmund Exner says the centres for the facial movements extend from the gyrus centralis anterior to the latter halves of the lower frontal convolutions, an area which corresponds with Gall's "centre for mimicry" (afterwards named "Imitation.") Most marked, however, is the harmony between the results of modern experiments and the observations made by the early phrenologists when we arrive at the demonstration of the "gustatory centre." Ferrier's experiments on the lower extremity of the temporosphenoidal convolution caused movements of the lips, tongue, and cheeks—indications of gustatory sensation. Looking up the *Edinburgh Phrenological Journal* (vol. x. p. 249), we find that many men claimed the discovery (in 1824) of the organ for gustatory sensation, as afterwards called "Gustativeness" or "Alimentiveness," and that they located this centre in exactly the same region. As this organ is difficult to be observed on account of the zygomatic arch and the temporal muscle, phrenology was much abused at the time. Prof. Ferrier's experiments on his centre No. 11, on the lower extremity of the ascending parietal convolution, resulted in retraction of the angle of the mouth. The action is that of the platysma myoides muscle, which, as Sir Chas. Bell ("Anatomy of Expression," p. 168) states, is strongly contracted under the influence of fear, and which he calls the muscle of fright. Phrenologists (Gall and Spurzheim) located in this region their organ of "Cautiousness," which they found largely developed in persons known for their timidity. Prof. Ferrier's centre No. 7 is said to cause "raising of the shoulders with extension of the arms," a movement which Darwin and Mantegazza refer to the expression of patience, submission, and the absence of any intention to resist. Gall's organ of "Veneration," which corresponds with this centre, is said to produce an instinctive feeling of respect, and when defective in children, Combe says, it has the effect of making them regardless of authority, prone to rebellion, and little attentive to command. Though the work, as described, is far from complete, it may have the effect of causing Gall's theories to be re-examined, and of pointing out a sure method for the demonstration of centres of ideation.

Mathematical Society, February 14.—J. J. Walker, F.R.S., President, in the chair.—Mr. H. F. Baker was admitted into the Society.—The following communications were made:—On the diophantine equation $y^2 + \left(\frac{dy}{dx}\right)^2 =$ square, Prof. Cayley, F.R.S.—Sur la transformation des équations algébriques, Signor Brioschi.—On projective cyclic concomitants or surface differential invariants, E. B. Elliott.—On secondary invariants, Prof. L. J. Rogers.—Remarks upon algebraical symmetry, with particular reference to the theory of operations and the theory of distributions, Major Macmahon.

Royal Meteorological Society, February 20.—Dr. W. Marcet, F.R.S., President, in the chair.—The following papers were read:—Report on the helm wind inquiry, by Mr. W. Marriott. The helm wind is peculiar to the Cross Fell Range of mountains in Cumberland, which runs from north-north-west to south-south-east. This range is high and continuous, and is not cut through by any valley. Cross Fell is 2900 feet above sea-level. From the top of the mountains to the plain on the west there is an abrupt fall of from 1000 to 1500 feet in about a mile and a half. At times when the wind is from some easterly point the helm forms over this district; the chief features of the phenomenon being the following: a heavy bank of cloud rests along the Cross Fell Range—at times reaching some distance down the western slopes, and at others hovering just above the summit; while at a distance of two or three miles from the foot of the Fell a slender roll of dark cloud appears in mid-air and parallel with the helm cloud; this is the helm bar. The space between the helm cloud and the bar is usually quite clear, while to the westward the sky is at times completely covered with cloud. The bar does not appear to extend further west than about the River Eden. A cold wind rushes down the sides of the Fell, and blow, violently till it reaches a spot nearly underneath the helm bars when it suddenly ceases. The observations that have been made in the district during the past three or four years show that the helm wind is not such a rare occurrence as it was popularly supposed to be, the bar having been observed on forty-one occasions in 1885, sixty-three in 1886, and nineteen in 1887. The phenomenon takes place usually when the sky to the eastward is covered with cloud.—An atmospheric sketch, by Mr. F. A. Velschow.—The drought in New South Wales in 1883–84, and rainfall at Corella, 1879–88, by the Ven. Archdeacon Wynne.

Royal Microscopical Society, February 13.—Annual Meeting.—Dr. C. T. Hudson in the chair.—The Report of the Council was read, showing an increase in the number of Fellows, and in the revenue of the Society. This will probably be the last annual meeting in the present library, which is required by King's College, and the Society will have to seek a new habitation.—Dr. Hudson delivered his annual address, taking as his subject, "Rotifers and their Distribution."

Paris.

Academy of Sciences, February 18.—M. Des Cloizeaux, President, in the chair.—On the vaccinal properties of pathogenic microbes transformed to simple saprogenic microbes destitute of all virulent properties, by M. A. Chauveau. These researches have been undertaken for the purpose of estimating

the value of certain facts supposed to throw some light on the natural history of micro-organisms in general, with special reference to the question of specific transformation. The main conclusion is that the charbon microbe entirely deprived of its virulence has not become the simple saprogenic microbe of ordinary fermentations set up in inorganic centres, for it has still preserved one of the most essential attributes that indicate the infectious nature of the pathogenic microbe; hence it has not undergone specific transformation. Such at least is the present inference, without prejudice to the question of possible ulterior metamorphoses of which *Bacillus anthracis* may be capable under the action of compressed oxygen or any other means. In a future communication it will be shown that at this stage the microbe has not even been deprived of the faculty of reverting to its virulent state.—On Egyptian blue, by M. F. Fouqué. The author has undertaken a fresh study of this pigment, which was discovered by Vestorius, of Alexandria, but which ceased to be made after the fall of the Western Empire. He finds its formula to be $CaO,CuO,4SiO_2$, consisting of 63·7 parts of silica, 14·3 of lime, 21·3 of copper oxide, with a trace of iron; specific gravity 3·04.—On two fossil Echinodermata from Thersakhan in Turkestan, by M. G. Cotteau. These specimens from the banks of the Sumbar, an affluent of the Attrek, are identical with the *Coraster vilanovæ* which abounds in the Upper Chalk of Alicante, Spain. Their presence in Turkestan at such a distance from the Pyrenees shows that at one time the Cretaceous seas occupied vast regions stretching eastwards to Central Asia and India.—Summary of the solar observations made at the Royal Observatory of the Collegio Romano during the second half of the year 1888, by M. P. Tacchini. Compared with the corresponding period for 1887 and 1886, the solar spots show a further decline in 1888, with a maximum of days without any spots. The protuberances have also decreased, but more irregularly, and at a less rapid rate.—On shooting-stars, by M. E. Minary. It is argued that the incandescence of these bodies cannot be explained by the transformation of motion into heat. The gases being perfectly elastic bodies, and in the upper atmospheric regions in an extremely rarefied state, heat cannot be produced by the shock of bodies endowed with great velocity and impinging on perfectly elastic molecules capable of receiving the motion and acquiring the velocity of those bodies; in this case the movement is communicated, not dissipated or transformed to heat. Had such transformation taken place, the velocity of the bodies on their trajectory would be progressively retarded, while the incandescence would be proportionately increased. But observation shows only luminous flashes, and more or less uniform velocities of translation at least for all the bodies that are not combustible. The reading of the paper was followed by some observations by M. Cornu, who remarked that the illumination of the trajectory of the shooting-stars might be attributed to a development or a discharge of static electricity without any considerable rise of temperature; as implied by the incandescence of detached particles of meteorites. This would agree with the spectral observations made on the shooting-stars, and would lend support to the view that certain cosmic phenomena, such as auroras, the zodiacal light, comets, solar protuberances, &c., are electric manifestations analogous to those that are so easily generated in rarefied gases.—On a general law relative to the effects of reversible transformations, by M. Gouy. It has been noticed that the effects produced by mechanical actions are often opposed to those actions (law of Lenz, thermic effects). Here M. Gouy establishes a general law, of which these facts form a particular instance, and which is applicable not only to direct mechanical actions, but also to a large number of reversible transformations.—Experimental studies on the dynamic and static elasticity of metallic wires, by M. E. Mercadier. As a complement to various researches in acoustics and thermodynamics, the author here determines the velocity of sound in metallic wires, first by directly registering their longitudinal vibrations, and then by deducing the velocity from the measurement of elastic expansions. His researches extend to copper, steel, platinum, aluminium, silver, and gold wire, varying in diameter from 0·5 to 1 millimetre.—On the rotatory power of crystallized chlorate of soda, by M. Ch. Eug. Guye. The results of these experiments agree fairly well with those obtained by M. Schuke for the visible parts of the spectrum. They may easily be reduced to a uniform temperature by employing the coefficient given by that physicist. These studies will be continued for the purpose of ascertaining whether the same coefficient is equally applicable to the ultra-violet radiations.—Tests for the mercaptans, by M. G. Denigès. Isatine, already used in sulphuric solution as a test for thiophene, is here shown to be also an excellent test for mercaptan.—On the origin of the eruptive rocks, by M. A. de Lapparent. From the constitution of the acid rocks—that is, those charged with silica—a fresh argument is drawn in support of the theory respecting the primordial fluidity of the globe.—Papers are contributed by M. M. Meslans, on the preparation and properties of the fluorides of propyl and isopropyl; by M. A. Lacroix, on the petrography of gneiss occurring in Ceylon and in Salem (Madras); and by MM. G. Weiss and A. Erckmann, on the optical properties of natural and false amber.

TOLLENS'S "CARBOHYDRATES."

Kurzes Handbuch der Kohlenhydrate. By B. Tollens. (Breslau: Maruschke and Berendt, 1888.)

THIS admirable *précis* of the chemistry of the carbohydrates is a model work of its kind. It is not merely a lucid account of this well-marked group of carbon compounds, but has the rare merit of preserving its facts and conclusions in their original guise—that is, as the offspring of research. Too often, the authors of treatises on experimental science, more especially of the genus text-book, are compelled to present their subject in such a way as to produce the impression that phenomena follow from laws, rather than that laws have followed from the phenomena which they generalize. This is no doubt justifiable, and in the end perhaps not seriously harmful, since the student is soon brought by his laboratory work to an appreciation of the perspective of his science, and to the correction of any superstitions which may have been engendered in his mind as to its origin and up-building. In the book before us, on the other hand, every fact is stamped and recorded as the contribution of a worker. A specialist, such as the author, engaged in active research in the field which he pauses, as it were, to describe, must write from the point of view of the worker; and hence it is that in the 330 short pages into which his account is condensed, we have over 1300 references to original memoirs. The impression produced, moreover, is that he has submitted this huge mass of experimental evidence to a searching examination, of which the matter of the book is the valid survival. It is to be hoped that the author's example will be generally followed. It is becoming less and less possible to keep pace with research in the many special branches into which chemistry is diverging. But if specialists will, as the author has done, unburden themselves to an imaginary interviewer, the task, which is laid upon us all, of keeping up with the progress of discovery and research will be both sweetened and lightened.

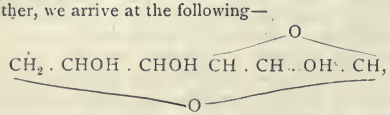
In proceeding to notice more particularly the contents of the work, we are struck, first, with its method of classification. The treatise is divided into two parts, the first dealing with the carbohydrates proper, together with such other comparatively inert compounds, *e.g.* arabinose, as stand in close connection with them; the second is an account of the derivative acids and their lactones ("saccharines").

The first section sets forth the general or typical properties and characteristics of the group, with an account of their origin in the plant, the evidence as to their molecular weight and constitution, their synthetical formation in the laboratory (phenose, acrose), their isolation in the pure state, their optical properties, and the various methods adopted for the determination of specific rotation. Then follows in outline the scheme of classification. The various groups under which the compounds are ranged are: (1) monosaccharides, or glucoses, $C_6H_{10}O_5$ (dextrose, lævulose, &c.); (2) disaccharides, or saccharoses, $C_{12}H_{22}O_{11}$ (cane-sugar, maltose, &c.); (3) polysaccharides—(*a*) crystalline (raffinose, $C_{36}H_{64}O_{32} \cdot 10H_2O$, and lactosin, $C_{36}H_{62}O_{31}$); (*b*) non-crystalline or *saccharocolloids*, &c., $C_6H_{10}O_5 \pm MH_2O$ (starch, inulin, gums, celluloses, pectone substances); (4) the somewhat miscellaneous group of substances which, although lacking some one or more of the group characteristics, are yet closely related to the carbohydrates—(*a*) in which $H : O = 2 : 1$ (arabinose, cerasinose, inosite, formose); (*b*) in which $H : O > 2 : 1$ (quercite, pinite, mannite).

Having thus forecast the order of treatment, the author plunges at once into the work of particular description. Beginning with dextrose, we have at the outset (*a*) a terse but minute account of the laboratory method of isolation from saccharose, also of the method of manufacture from starch; (*b*) certain physical properties of the anhydride and monohydrate, with solubilities and a table of specific gravities of aqueous solutions; (*c*) behaviour towards polarized light,—after a brief discussion of the variations between the numbers of different observers and their cause, we have the author's final selection of the formulæ, (1) for the anhydride $(\alpha)_D = 52{\cdot}5 + 0{\cdot}018796\,P + 0{\cdot}00051683\,P_2$, and (2) for the monohydrate $(\alpha)_D = 47{\cdot}73 + 0{\cdot}015534\,P + 0{\cdot}0003883\,P_2$, P being the percentage of substance in solution; (*d*) the results of heating at various temperatures; (*e*) actions of acids; (*f*) actions of alkalies; (*g*) action of nascent hydrogen (conversion into mannite); (*h*) action of the halogens and various forms of oxygen; (*i*) action of oxidizing (metallic) oxides; and (*k*) its several fermentations. Then follows a detailed account of the derivative compounds of dextrose: (A) with bases; (B) with negative radicles; (C) ethereal compounds; (D) hydrazine derivatives; (E) compounds with aromatic amines; (F) with metallic salts; (G) with hydrocyanic acid (conversion into normal heptoic acid). The author then gives a detailed account of analytical methods, *i.e.* (i.) identification by qualitative reaction; (ii.) estimation by polarization of the various oxidation methods (Cu, Hg, and Ag salts), and by fermentation. We have reproduced these heads, under which the chemistry of dextrose is treated, as characteristic of the method of the book. The typical saccharose, cane-sugar, is dealt with in even greater detail, the author giving a complete though brief account of the process of preparation from beet, with illustrated descriptions of the manufacturing plant, as also of the polarization instruments commonly employed for sugar estimation, viz. the Soleil-Ventzke-Scheibler, and that of Schmidt and Häusch.

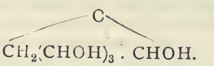
Of the amorphous polysaccharides or saccharocolloids, starch is treated at considerable length. The views of physiologists as to its origin in the plant are briefly discussed. Its resolutions by the various hydrolytic reagents are dealt with in detail, and due prominence is given to the results of the researches of O'Sullivan and of Brown and Heron. Special details are given of the methods of estimation of starch in farinaceous raw materials, with a description of the Lintner-Soxhlet apparatus for carrying out the acid hydrolysis. As the starch group is characterized by resolution into dextrose, so the inulin group, next described, appear to be poly-derivatives of lævulose. A third is composed of substances yielding galactose as a product of resolution (lævulan, galactan, Carragheen mucilage), while a fourth comprises such

gums and mucilages as yield various glucoses, and sometimes also arabinine, as products of hydrolytic resolution (gum-arabic, cerasin, bassorin, "wood gum"). Ascending in the scale of molecular complexity, the celluloses are next described; and lastly, in separate sub-sections, lignin, cork, and pectic derivatives. We have been interested in comparing the author's account of the latter group with those given under "Celluloses" in the new edition of Watts's "Dictionary." There is a close agreement in general method of treatment; and it is satisfactory to find that the problem of the constitution of the celluloses is being worked on such lines as would be laid down from a study of the general view of the carbohydrates which Prof. Tollens has given us. Neither of these acounts of cellulose suggests any probable constitutional formula for the unit group of which the celluloses may be regarded as poly-derivatives; but, putting the views of both authors together, we arrive at the following—

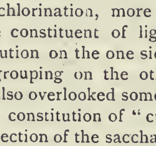


which we think will at least be found of service as a working hypothesis. In the section "Lignin," Prof. Tollens has overlooked some of the researches of recent years, which have, as the result of investigations of its hydrolysis and chlorination, more definitely identified the non-cellulose constituent of lignified tissue with a furfuralic constitution on the one side, and the tendency to an aromatic grouping on the other. In the section "Cork," he has also overlooked some of Fremy's interesting work on the constitution of "cuticular" substances The concluding section of the saccharocolloids comprises the pectic group of plant constituents, which are briefly but fully described.

The fourth section opens with an account of *arabinose*, which the author represents by the constitutional formula—



Formose, or polymerized formaldehyde, is not regarded as a true glucose. Carius's *phenose* is described; the evidence as to its composition, however, is very slender. The writer has, moreover, devoted some time to a repetition of Carius's research, but failed to obtain any product such as that described. *Inosite* is represented on the basis of Maquenne's researches, by the symmetrical formula—



Dambonite and *bornesite*, which are found in caoutchouc-yielding juices, are described as the mono- and di-methyl ethers of inosite, respectively.

The fifth section comprises the hexahydric alcohol mannite and its isomerides, dulcite, sorbite, and perseite, of which the typical mannite is fully described.

The second part of the work gives a detailed account of "substances closely related to the carbohydrates, and obtained for the most part from them, which are either acids or acid-anhydrides (lactones), and the molecule of which contains 6 C-atoms": (*a*) saccharinic acid, $C_6H_{12}O_6$, and its isomerides, iso- and *meta*-saccharinic acids, their lactone-anhydrides, $C_6H_{10}O_5$, "*saccharines*," and their oxy-derivatives, *saccharones*, $C_6H_8O_6$; (*b*) gluconic acid, $C_6H_{12}O_7$, and its isomerides, galactonic and arabinose carbonic and mannitic acids; saccharic acid, $C_6H_{10}O_8$, and its isomerides, mucic, iso-, meta-, and para-saccharic acids, with their lactonic and other derivatives.

Such is a brief account of the contents of the book before us. The main purpose is necessarily the theoretical treatment of the subject—from the point of view, that is, of pure chemistry; at the same time due prominence is given to technical considerations, and the physiological aspects of the subject are by no means excluded.

We do not believe that we are yet within measurable distance of a knowledge of the actual molecular constitution of the carbohydrates. We do not even think that the evidence for the C_6 formulæ of the simplest members is at all conclusive. One of the assumed criteria of this point—the calculation of molecular weight from the lowering of the freezing-point of solvents by the presence of compounds in solution, as proposed by Raoult—is not mentioned by Prof. Tollens. At a recent meeting of the Chemical Society, Messrs. Brown and Morris communicated the results of an investigation of the freezing-point of solutions of the simpler carbohydrates, which appear to confirm the generally accepted views. Nevertheless, it would be premature to pronounce at all positively, either as to this particular criterion, or as to the evidence generally on these points.

The chemistry of the carbohydrates brings us into contact with the syntheses and transformations of the organic world. The plant is, and will remain through all time, the chemist's ideal. Every contribution to the chemistry of the carbohydrates is a step towards a comprehension of the chemistry of elaboration. The number of workers in the field is relatively small, but will increase as the methods of investigation are rendered more precise. It is from this point of view that we commend this little work to the notice of all who have either a special or general interest in plant-chemistry.

BRITISH MOSSES.

British Mosses. By F. E. Tripp. 2 Vols. New Edition. (London: George Bell and Sons, 1888.)

THE fact that a new edition of this work has been called for shows that these elegant plants have a wide-spread circle of admirers, and that there are many seekers after a knowledge of their structure.

The introduction occupies thirty-eight pages. In Sect. 1, on the homes of mosses, we have a highly poetical description of the third day of Creation, and production of vegetation according to Genesis. This is followed by the natural distribution and habits of the mosses; and by charming word-pictures of woods and moorlands the authoress compels her readers to accompany her and see for themselves the beauties that await observation on every side and at every season.

Sect. 2, the characteristics of mosses, is written in

somewhat the same poetic strain, and glances at the leading aspects of mosses in natural scenery. Sect. 3, structure of mosses, gives a clear and succinct outline of the various organs of these plants, and their functions. Sects. 4 and 5, collecting and examining mosses, and uses of mosses, are the best in the book, and show the devotion of the writer to the study of this branch of botany. Then follows a synopsis of genera after Schimper's "Syn. Musc. Eur.," and at p. 45 we arrive at the description of species and plates, to which the remainder of the work is devoted.

The descriptions are all on one uniform plan, very short and under five heads—colour, stems, leaves, capsule, locality. The text is therefore somewhat monotonous and dry, while the essential points characteristic of the species are not always brought out; *e.g.* the Bryinæ are "Plants cellular, germinating from spores, with stems and leaves; fruit a capsule," which applies equally well to the Hepaticæ. With species this want of definiteness in description is apt to lead altogether astray. In other instances an erroneous term is introduced; thus *Trichostomum nitidum* is stated to have leaves "hairy at apex," *T. litorale* leaves "with short hair-points," whereas both have solid conical points, formed by the nerve.

The cell-structure of the leaves is a most important character, and is requisite both in descriptions and illustrations, but is not treated sufficiently in either. The 37 plates represent the plants of the natural size, and are very well coloured, so that the larger species may be readily recognized; but the leaves are not sufficiently magnified nor their structure sufficiently defined to render them sure guides, for the smaller species are too much alike, and the smallest of all, represented on Plate 5, it would puzzle any bryologist to discriminate.

Although for these reasons the work is not so helpful to the student as it might be, it forms an elegant table book. The paper is excellent, and the clear symmetric printing could hardly be surpassed.

OUR BOOK SHELF.

Catalogue of the Marsupialia and Monotremata in the Collection of the British Museum (Natural History). By Oldfield Thomas. (London: Printed by order of the Trustees, 1888.)

THIS is one of the new series of Zoological Catalogues of the British Museum, which, from their containing descriptions of all the known species of the group catalogued, form handy and excellent hand-books for the student, and serve for much more than records of the treasures of our British Museum.

This volume contains the descriptions of 151 species of Marsupials and 3 of Monotremes, in addition to descriptions of 12 well-marked varieties of the former and 2 of the latter order. Of this large total of 168, only 20 are not represented in the British Museum collection. The specimens amount to 1304 in all, of which 173 are preserved in spirits.

This is a very marked increase above the number in the list published in 1843, in which but 94 species were enumerated. Apart from the number of species represented in the collection, the value of these is greatly increased when they are "type" forms. In such forms, the British Museum is extremely rich, possessing 74, followed by the Paris Museum with 21, and then, at a long distance, by the Museums of Sydney and Leyden, with 8 each. In this Catalogue, probably for the first time, a double synopsis of each genus and species is given, in order to enable the student to identify a specimen either from its external characters, or from its skull alone. In order to make these latter synopses useful, explanations of the nomenclature and of the measurements are given.

The synonymy of the genera and species is worked out in very great detail, and in the case of the Monotremes we have in addition references to the literature bearing on the anatomy, embryology, &c., of the forms belonging to the order.

Although most of the species of Marsupials have been named within the last hundred years, and the greater number of them have names of quite recent date, yet the hasty descriptions of some authors have added much to the list of synonyms. In addition to the ordinary synonymy, Mr. Thomas has in most instances given references to the more important papers on the anatomy of the forms. These references make this Catalogue useful to the comparative anatomist as well as to the zoologist. To make such a list perfect would require much space, but, so far as we can judge, all the more important papers have been referred to; under *Phascolarctus cinereus*, we would add one on its anatomy by Prof. Macalister, in the *Ann. and Mag. Nat. Hist.*, 1872, vol. x., and one on the occurrence of a premaxilla-frontal suture in the skull, by Prof. Mackintosh (Proc. Roy. Irish Acad., n. s., vol. iii.).

We hope the day is not far distant when all the mammals in the British Museum collection will be catalogued in an equally accurate and effective manner.

Report of the Proceedings of the United States Expedition to Lady Franklin Bay, Grinnell Land. By Adolphus W. Greely. Vol. I. (Washington: Government Printing Office, 1888.)

EVERYONE knows, at least in its main outlines, the story of the Polar Expedition commanded by Lieut. Greely. Three years ago (NATURE, vol. xxxiii. p. 481) we reviewed the work in which he presented an interesting popular account of his experiences. The present volume contains the official Report, dated Washington, June 30, 1885, which Lieut. Greely addressed to the Chief Signal Officer of the United States army; and a singularly fascinating Report it is—all the more fascinating as no attempt is made to set forth the facts in a lively or picturesque style. The writer is so completely occupied with the events he records that he seems to have neither time nor inclination for any thought about the manner in which they should be presented. As appendices to the Report an immense number of documents relating to the Expedition are printed; and many of these are of considerable value, not only supporting the statements of the Report, but adding details which give freshness to the central narrative. The volume is enriched by an abundant supply of excellent full-page illustrations, illustrations grouped in plates, illustrations in the text, and maps and charts.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Origin of Coral Islands.

MR. MURRAY's concise explanation of the formation of coral reefs and islands presents advantages in more than one respect. It demands no *a priori* assumptions, but begins and ends with that which can be observed, while Darwin's theory requires the preliminary concession of subsidence, which never has been and never

perhaps can be observed. It must appear ungracious to question a theory that accords so completely with the natural history of coral islands, but even this theory requires a geological concession, and that is stability. Coral islands, it may be supposed, after all only differ from other oceanic islands in being crusted over with coral, so that we cannot see their original state, and the question is whether we can grant such long periods of stability to them, from our experience of other oceanic islands, which are free from coral and can therefore be observed. Nearly all oceanic islands are volcanic, and it is probable that their elevation coincides more or less with the period of volcanic activity somewhere along their line. It is obvious that coral islands are not formed during this phase, because no theory would then hold good; the peaks would grow through and carry up the coral, which might leave only such small traces of its existence as we find in a single spot in Madeira. It would not be unreasonable to suppose that if the expansive and elevating force were withdrawn the peaks would slowly subside, and that if there are some lines of elevation, there must be others of subsidence, unless the earth is as a whole growing in bulk. Darwin claims the existence of areas of subsidence, and that these are eminently favourable to coral growth, and it is quite apparent that if the Island of Madeira were to sink, as it has undoubtedly risen, its last appearance in a coral sea would be as an atoll. We shall never see the interior structure of a stationary or subsiding coral island, and can only look for a re-elevated example with a crust that has been protected from solution whilst dead and submerged, and yet not sufficiently so to mask the core.

In submitting geological considerations I am not questioning any of Mr. Murray's observations, which are in every way admirable, though it does appear to me doubtful whether atolls could increase outwards in deep water on their own talus, in face of the dissolution of dead coral that is claimed to take place in the interior of the lagoons, and yet more so in deeper water.

J. STARKIE GARDNER.

The Sun's Corona, 1889.

A GENERAL statement of the successes of the Western Eclipse Expeditions on January 1 has already appeared in NATURE. More photographs of the corona were taken than ever before—many of them indifferent and worthless, but an unusually large number of great excellence. The best that I have so far seen were taken with 5-inch telescopes, by Mr. W. H. Pickering at Willow, and by Captain R. S. Floyd at Lakeport, both in California. The latter's lens was newly made by Clark, on the Stokes-Pickering plan, convertible from optical to photographic use by reversing the crown lens.

Until the photographs can be well collated, there is little use in presenting them; and the difficulties arising in this work are by no means easy to meet.

With the drawings, however, the case is different. These were made in great abundance, and I have received sufficient responses to my printed instructions to afford very satisfactory conclusions as to the appearance of the corona. The state of the sky was practically everywhere favourable throughout California, Nevada, Idaho, Wyoming, Montana, Dakota, and Manitoba.

The instructions for sketching the corona were printed in three sections: (1) drawings of the corona as a whole; (2) drawings with small telescopes of the filaments about the solar poles; (3) sketches of the outlying streamers along the ecliptic. These latter were made with the assistance of an occulting disk, set up at such distance from the eye of the observer that it would subtend an angle of 65′. It was supposed that disks of this size, being much larger than those used on any previous occasion, would hide very nearly all the inner corona, and leave the eye free to follow the faint outer filaments to their farthest limit. The magnitude and brilliancy of the inner corona, however, were such as to convince me that the disks might better have been one-fourth larger.

From the best of all the drawings now available, of the three classes, Mrs. Todd has prepared the accompanying sketch of the corona. This was done without knowledge of the details shown on any of the photographs, and it may be taken as an index of the sort of results which may be derived from the co-operative plan of figuring the optical corona. It is also instructive in studying the differences between the optical and the photographic corona.

DAVID P. TODD.

Amherst College Observatory, February 22.

[No sketch was received with this letter.—ED.]

The Meteoric Theory of Nebulæ, &c.

THERE would appear to be a difficulty in the theory of the meteoric constitution of nebulæ,[1] &c., which, as far as I am aware, has not been mentioned.

It is, namely, the fact that some gas—probably part of it permanent—exists in the nebula along with the moving masses in translatory motion. Making allowance for the relatively small effect of gravity on the gas, due to the diffuse distribution of the matter, and consequently having regard to the probable tenuity of the gas; it has nevertheless, I find, been estimated by Joule ("Scientific Papers," vol. i. p. 539) that meteors are first observed at a height of 116 miles in the earth's atmosphere. He estimates that 0·0003 of a grain of air is contained in a column of air one mile long, and one square foot in cross section at that height. This, I find by calculation, amounts to 1/1000 millionth of an atmosphere in round numbers as to density.

So that if in some nebulæ the gas had something like this small density, the bodies, or masses moving in translatory motion according to the kinetic theory, would (if their velocity were at all comparable to that of those colliding in the earth's atmosphere) behave as meteors, or inflame; and so apparently be rapidly converted into gas. Even if they did not inflame; no doubt the heat consequent on friction would be considerable. It might be suggested, perhaps, that the mass of these bodies in some nebulæ may be so great that they do not lose their translatory motion rapidly, even if they leave a luminous track. In any case it is evident that this stage of evolution is not a lasting one, and, to my mind, it seems that it is less permanent than is perhaps generally supposed.

I find that Mr. G. H. Darwin, in his paper in the Philosophical Transactions, 1889, above alluded to, suggests the hypothesis that the "metallic rain" generated by the condensation of the incandescent vapour of iron could "fuse with old meteorites whose surfaces are molten." It seems to me that the rate of translatory motion, calculated by him at $5\frac{1}{2}$ kilometres per second, is scarcely allowed for here. How, it may be asked, could such "metallic rain" fuse on bodies colliding against it at this velocity? Some are moving at a less velocity, no doubt; but some are moving at a greater.

The temperature equivalent to this value for translatory motion ($5\frac{1}{2}$ kilometres per second) is, I find, 36,000° C. (about); *i.e.* this would be the temperature if the translatory motion alone were entirely converted into heat. Clausius has calculated, I believe, that in a gas the ratio of the whole energy (which includes translational and vibrational energy of molecules) is to the vibrational energy alone as the specific heat at constant pressure is to that at constant volume.[2] If this be the case, a very large proportion of the translatory motion is resolved into internal motion—that motion which emits the waves of heat analyzed in the gas. Must not the same be true of meteoric masses: or is not the principle (ratio) independent of the *scale*, or number of molecules clustered about a centre, and moving as one lump in the motion of translation? In some complex gases, at least fifty to sixty molecules may be clustered about a centre to form a lump. Then if more (as in a meteorite) are so clustered, it appears that the same must hold true, as regards subdivision of the energy between translatory motion and vibratory motion (heat). If so, by the great temperature equivalent of the translatory motion (viz. 36,000° C. above estimated), the meteorite would rapidly be dissociated into separate molecules by the subdivision of the energy according to the above principle—just as the more firmly united constituents of the lumps (*i.e.* compound molecules) of gases would be dissociated, even if moving at but a fraction of the above translatory velocity.

Is it supposed perhaps that the length of path between encounters (giving time to cool?) in meteorites constituting nebulæ, prevents this? This point is not apparently gone into in Mr. Darwin's paper. But if the meteoric mass has time (nearly) to cool down, or lose, by radiation into stellar space, the heat generated at each successive collision, then it would seem that the translatory motion would be somewhat rapidly lost by con-

[1] I allude specially to Mr. G. H. Darwin's paper, "On the Mechanical Constitution of a Swarm of Meteorites," of which an abstract appeared in NATURE of November 22 and 29, 1888 (pp. 81 and 105). The paper is contained in full in the Philosophical Transactions, vol. clxxx., 1889.

[2] It may be curious to observe that, if a meteoric swarm whose mass equalled that of the sun, were contained within an impenetrable envelope, whose radius equalled the radius of Uranus's orbit (nearly), the mean density of the meteoric swarm would be one five-millionth of an atmosphere only; which represents a fair "vacuum" of a Sprengel pump. This degree of distribution of matter may be represented by a centimetre cube of iron placed at the corner of a cube 139 metres in the side.

version into heat (wasted in space); and this, again, is an indication of the relatively small permanence in such a system, before pointed out as a probable fact. If there is not much free gas in a nebula, the heat radiated by the meteoric masses into space will be great, because unobstructed by the gas. If, on the other hand, there is much free gas in the nebula, it will fritter the translatory motion down by friction into heat. A translatory motion whose temperature equivalent (36,000° C.) is from ten to twenty times more than sufficient to volatilize the moving masses, if utilized, could scarcely exist for a lengthened epoch, or this would seem to be an unnatural state of things.

If the meteoric masses had a mean length of path at all comparable in relative scale to that of a gas at normal density; such as, for instance, if the mean path were (merely for illustration) 1000 times the diameter of the meteorite; then it is evident that the whole system—by a translatory motion of $5\frac{1}{2}$ kilometres per second—would be resolved into gas in a few minutes or even seconds of time. The question then becomes, as it seems, How far does lengthening the mean path diminish the tendency to resolution into vapour by allowing time to cool between the encounters? or some mechanical relations might possibly be demonstrated here from elements[1] or physical data determinable apparently. S. TOLVER PRESTON.

Paris, February.

Upper Wind Currents over the North Atlantic Doldrums.

THE following observations were taken on board the steamship *Araucania* on her voyage from Liverpool to Valparaiso in December last:—

From the Cape Verde Islands down to 9° N. lat. the surface wind was steadily north-east, but the low clouds came as persistently from south-east, and the middle or high layers from south-west.

About 5° N. the wind worked gradually through east to south-east, and we experienced no calm doldrum, nor even a belt of variable winds. From here to the equator the surface wind remained south-east, while the low clouds came from between south and south-east, but the middle and high layers still passed from south-west.

From the line till about 10° S., while the surface wind continued to blow from south-east, the high cirrus moved from the north-west.

The circulation of the atmosphere, indicated by these observations, is very different from that described by myself in your columns on two former occasions. On one, while traversing the same track as now, only in the month of July 1885; and on another while going from Cape Verde to Cape Town in December of the same year, I found the highest current over the doldrums coming from the east. Now there was no doldrum at all, and though there were 200 miles of latitude between the place where the last south-west highest current and the first north-west highest current were observed, it seems somewhat improbable that there was a narrow belt of high-level east winds between these two currents from some point of west.

It may be noted that cirrus came from the south-west for about 300 miles of southing over the south-east trade, and that a low current from south-east blew over both trades from 6° S. to 13° N. RALPH ABERCROMBY.

Straits of Magellan, January 15.

The Giant Earthworm of Gippsland.

IN the last issue of NATURE (p. 394) I observe in an article upon *Megascolides australis* that a supposition is expressed that very large earthworms will be found to occur in South America as well as in other continents. It may be of a little interest to mention that I found near the town of Manaos, in Amazonia, in the year 1874, an earthworm that measured 30 inches in length by $\frac{3}{4}$ inch in greatest breadth. When found, in the early morning, it was quite fresh, though newly dead, being somewhat crushed near one end, probably by some passer-by in the darkness. Unfortunately the worm spoiled in the rum in which I attempted to preserve it. JAMES W. H. TRAIL.

Weight and Mass.

PROF. GREENHILL seems to have overlooked the fact that my letter in NATURE of February 7 (p. 342) related entirely to procedure in teaching. I merely stated that as the result of experience I have found it absolutely necessary to use terms strictly in the senses assigned to them by definition, and not to use the same term in two senses. I find that it conduces to clearness and accuracy to use the word "pound," for example, only in the sense of a certain quantity of matter, and to use the phrase "weight of a pound" when speaking of the force of gravity on that quantity of matter.

With the ordinary expressions used by engineers when addressing engineers or other persons who, presumably, are able to distinguish between the different senses in which the same term or phrase is used, I have no quarrel whatever, and must decline Prof. Greenhill's invitation to express an opinion as to the accuracy of the phrases which he quotes from NATURE.

University College, Bangor, February 25. A. GRAY.

The Formation of Ice.

IN connection with the discussion on the formation of ice in crystals, it might be worth while to record that on December 6, 1861, in a slight frost, I saw some in the process of formation in a trough of water. There were three thin pieces of ice in it, two irregular, but the third a beautiful star, 4 or 5 inches in diameter, having six feather-like rays which were branched twice or thrice, in all cases at an angle of 60°. Also, two days before, when the water in the trough was frozen over, I observed in it six-rayed stars several inches in diameter very slightly raised above the rest of the surface. T. W. BACKHOUSE.

Sunderland, March 2.

ROTIFERA AND THEIR DISTRIBUTION.[1]

IT is no longer possible, I think, for your President to give, as the substance of his address, a summary of the most important improvements of the microscope, and of the most remarkable results of microscopical research, which have been recorded in the preceding twelve months.

All this is now so fully and so admirably done in your own journal, by your energetic Secretary and his able colleagues, that your Presidents will most probably, in future years, have to follow the excellent precedent set by Dr. Dallinger, and choose for the subject of their address some topic directly springing from their own special studies. For, on an occasion like this, each President would wish to give the Society the best he can, and it is clear that this best must be sought for among matters of which he has a special knowledge.

Unfortunately, an accident, which befell me early last year, not only robbed me of the pleasure of being present at several of your monthly meetings, but also produced consequences that compelled me to put my microscope aside; and, as I had not long before finished my share of the "Rotifera," I feared at first that I had lost the power of pursuing any new investigations, just at the very time when I had published the results of all my old ones.

There is, however, still a portion of my subject with which I am familiar, and which, I believe, has not as yet been touched upon by anyone; and I venture to

[1] It is said that "The total energy of agitation in an isothermal adiabatic sphere is half the potential energy lost in the concentration from a condition of infinite dispersion" (NATURE, Nov. 29, 1888, p. 107). This is apparently the analogue of the ratio of Clausius, somewhat differently expressed, viz. the ratio between the two parts of the energy, translational and vibrational (internal motion), applicable to a rigid body, and calculated at $\frac{2}{3}$ *a priori* by Maxwell. I would venture one remark here. It appears evident that if the mean thermal equivalent of *half* the potential energy lost were all accumulated in the meteorites, they would be volatilized. If, on the other hand, part of this thermal equivalent were dissipated in space by radiation, the meteorites could not possess their natural equivalent of thermal energy due to the translatory motion, and consequently it would seem that in the continued effort towards the equalization of these two forms of energy (translatory and thermal), the translatory motion would with tolerable rapidity degrade down to a value which could no longer support the weight of the superincumbent material. This would be another argument for the small degree of permanence of such a system.

[1] Address delivered at the Annual Meeting of the Royal Microscopical Society, by Dr. C. T. Hudson, President, on February 13, 1889.

hope that I may make it interesting to you. It relates to what may be called the foreign Rotifera; that is to say, to those Rotifera which have not as yet been found in our islands. One would naturally like to know what proportion these foreign species bear to the British; whether there are any families or genera entirely absent from the British fauna; whether there appears to be any law of distribution among the Rotifera; and how far it is possible to account for the existence of the same species in places which are thousands of miles apart. But many of the numerous memoirs, from which information on these points is to be derived, are only to be found, scattered widely, in various European periodicals; and so are difficult to be procured; while, of those that have been published separately, the best are rare.

Under these circumstances I thought it not improbable, that the members of our Society might be glad to know, that the task of studying and condensing these memoirs had been, in the main, accomplished; and that I am able now to present them with some of the results.

In the first place, I made a list of all the known species, and marked against each the various localities in which it has been found. It was curious to see, as the table grew, how certain well-known Rotifera were picked out by their rapidly advancing scores, till at last about fifty typical Rotifera were separated from the rest; while, of these, a smaller group enjoyed the further distinction of having a very wide range, not only in latitude and longitude, but also in altitude.

The same table showed at a glance that Great Britain decidedly outstripped all other countries in the number of its recorded species, having quite two-thirds of the whole. Nor was this all, for the Rotifera seemed, like trade, to follow the flag, and to haunt the British colonies just as if they were British ships.

The reason, for this curious pre-eminence of British Rotifera, is clearly seen when we notice how those species are distributed, which have as yet been found in one country only. There are about 240 such species, and of these no fewer than 173 (that is to say, more than two-thirds) are peculiar to Great Britain. It is, of course, obvious that this apparent selection of Great Britain as the fatherland of the Rotifera is simply due to the greater energy, industry, and skill with which the search for new species has been pursued in this country. It is, however, very remarkable that the naturalists of Great Britain should, in late years, have added to the Rotiferous fauna two and a half times as many species as the naturalists of all other countries put together have done; and this highly honourable result is mainly due to members of your own Society, and especially to my deeply-lamented colleague and dear friend, the late Mr. Philip Henry Gosse, F.R.S.

After I had seen how greatly the value of the recorded distribution of the Rotifera was affected by what I may term the "personal equation," I at first feared that I should obtain little else from my tables than a well-merited tribute to the energy of British naturalists. Further inspection, however, showed other points that are well worth your notice.

In the first place, my lists showed that Germany, Switzerland, and Hungary come next in order to Great Britain, in the total number of species that each records; and I have only to mention the names of Ehrenberg, Leydig, Cohn, Grenacher, Zacharias, Eckstein, Plate, Imhof, Perty, Bartsch, Vejdovsky, Zelinka, not to say many others, to make it obvious that the result is due, not to the real distribution of the species in these countries, but to the comparative skill and industry of their naturalists.

Next, my table shows clearly that in all cases a considerable number, and in some the great majority, of the above-named fifty typical Rotifera, range throughout Britain, France, North and South Germany, Denmark, Switzerland, Hungary, and Russia; so that we may reasonably conclude that a considerable proportion of the 450 known species would probably be found in almost any part of Europe, if they were diligently searched for. Here, for instance, is a list of thirty well-known Rotifera, all of different genera, and all recorded in at least five of the above eight European countries:—

Floscularia ornata	Diglena catellina
Stephanoceros Eichornii	Mastigocerca carinata
Melicerta ringens	Rattulus lunaris
Limnias ceratophylli	Dinocharis pocillum
Lacinularia socialis	Scaridium longicaudum
Philodina roseola	Salpina mucronata
Rotifer vulgaris	Euchlanis dilatata
Actinurus neptunius	Cathypna luna
Asplanchna helvetica	Monostyla cornuta
Triarthra mystacina	Colurus uncinatus
Hydatina senta	Metopidia lepadella
Notommata aurita	Pterodina patina
Proales decipiens	Brachionus urceolaris
Furcularia forficula	Anuræa aculeata
Eosphora aurita	Notholca striata.

Besides, many of the Rotifera are very tolerant of climate, and appear to be able to live anywhere that they can get food. For instance, *Rotifer vulgaris* is to be found all over Europe, and at all heights; thriving under moss, near the top of the Sidelhorn, and on the Tibia, at an altitude of 9000 feet above the sea. It has been met with also in Nubia, on the slopes of the Altai Mountains in Siberia, in Ceylon at the top of Adam's Peak, in Jamaica, and in the Pampas of La Plata. *Brachionus pala* has nearly as great a range; for it has been found in many parts of Europe, in Egypt, at the Cape of Good Hope, in Siberia, Ceylon, Jamaica, and New Zealand. Besides these, *Diglena catellina*, *Hydatina senta*, *Actinurus neptunius*, and a few others, have all been met with in different quarters of the globe. But the distribution of the Rotifera presents us with other facts quite as curious as these. For not only are European species to be found ranging over Asia and Africa, but America, and even Australia and New Zealand, in spite of their ocean belts, possess the same familiar creatures; and, moreover, seem to have hardly any peculiar to themselves. Here, for example, is a list of Rotifera that have been found in Sydney by Mr. Whitelegge, and in Queensland by Mr. Gunson Thorpe:—

Floscularia ornata	Conochilus volvox
,, campanulata	,, bullata (*n. sp.*), *T.*
,, cornuta	Asplanchna Brightwellii
,, Millsii	,, ebbesbornii
,, coronetta (*var.*), *W.*	Cephalosiphon limnias
Melicerta ringens	Actinurus neptunius
,, conifera	Rattulus tigris
Œcistes crystallinus	Notommata centrura
,, janus	Euchlanis triquetra
Limnias ceratophylli	Dinocharis pocillum
,, annulatus	,, triremis (*n. sp.*), *W.*
,, cornuella	Brachionus militaris
Lacinularia socialis	Anuræa cochlearis
,, pedunculata (*n. sp.*), *W.*	Pedalion mirum.

Mr. Thorpe has also found what seems to be a swimming Floscule, with a forked foot and a dorsal eye; as well as a new *Noteus* or *Brachionus*, with a strangely unsymmetrical lorica, bearing ten spines in front, and three behind. Who would ever have imagined that, in a sea-girt continent, at the opposite side of the globe—in a land whose fauna and flora are so strange as those of Australia—we should find that twenty-four out of thirty recorded species were British; and that, of the remaining six, one (*Floscularia Millsii*) had a habitat in the United States?

The United States, too, Jamaica, and Ceylon all reproduce the same phenomenon, though on a reduced scale; so that the question at once arises, How could these

minute creatures, who are inhabitants of lakes, ponds, ditches, and sea-shore pools, contrive to spread themselves so widely over the earth? Take, for instance, the case of *Asplanchna ebbesbornii*, which till quite lately had but one known habitat, viz. a small duck-pond in a vicarage garden in Wiltshire. The very same animal has been found by Mr. Whitelegge in the botanical gardens at Sydney, New South Wales. No doubt, in time, it will be found elsewhere also; but how, or when, did it pass from the one spot to the other?

Again, there is the strange Floscule, *F. Millsii*, a Rotiferon apparently linking together the genera *Floscularia* and *Stephanoceros*, and which has been found almost simultaneously by Mr. Whitelegge at Sydney, and Dr. Kellicott at Ontario. The possibility of its journeying between two such points seems quite as hopeless as that of *Ashplanchna ebbesbornii's* passing from New South Wales to Wiltshire.

And such cases are numerous. How did *Hydatina senta* and *Brachionus pala* get to New Zealand? or *Notops brachionus* and *Rotifer vulgaris* to the top of Adam's Peak, and the Pampas of La Plata? Again, there is *Pedalion mirum*: since I first found it, in a pond at the top of Nightingale Valley, at Clifton, it has been met with in four or five other places in England, including a warm water-lily tank at Eaton Hall; but, till quite lately, in no other country. Now I have just received a letter from Mr. Gunson Thorpe, telling me that he has found it swarming in a pool on a rocky headland in Queensland.

You have, no doubt, long ere this anticipated the solution of the puzzle, and see clearly enough that living creatures, to whom a yard of sea-water is as impassable a barrier as a thousand miles of ocean, could only have reached or left Australia, New Zealand, Jamaica, Ceylon, &c., in the egg; not the soft, delicately shelled, and quickly hatching summer egg, but the ephippial egg, which is protected by a much harder and thicker covering, which is constructed so as to bear without injury a long absence from the water, and which hatches, so far as is known, some months after it has been laid.

But this explanation still requires to be explained. The case of the free-swimming Rotifera is simple enough. They are most of them to be found, at some time or another, in small shallow pools, and their eggs either fall to the bottom of the water, or are attached to the small confervoid growth on the stones in it. Such pools frequently dry up, leaving the ephippial eggs to wait for the rainy warm weather of next year. Then comes boisterous weather, and the dusty surface of the exposed bottom of the pool is swept by a wind, which raises the dust high into the air, ephippial eggs and all. For these latter are minute things; few exceeding one three-hundredth of an inch in length, and many even half that size. Once raised in the air, I see no reason why they should not be driven by aërial currents, unharmed, half round the globe, falling occasionally in places where water, temperature, and food are alike suitable.

The dust of the eruption at Krakatão, which gave us such wonderful sunsets and green moons in 1883, travelled from the Sunda Isles to England in three months; and so the ephippial eggs of *Asplanchna ebbesbornii*, and other Rotifera, may have traversed the distance from England to Australia, and yet have been capable of hatching at the end of the journey.

It may perhaps seem a fanciful notion to account for the stocking of the ponds at Sydney by eggs carried thousands of miles in the air, but several well-known facts warrant the hypothesis. The tops of our houses, the heights of the Alps, the slopes of the Siberian mountain ranges, are haunts of the Philodines, which, being an exceptionally hardy race, have accommodated themselves to living in damp mosses at the edge of a glacier, or in a gutter which now holds a mere handful of stagnant water, now is a racing current, and now a dusty leaden basin, glowing under a blazing sun. No doubt eggs of all sorts of species fall on the same spots, but only to perish under trials that none but a Philodine could survive.

How various are the species whose eggs are thus wafted up by the air has been well shown by Mr. J. E. Lord, who has given a list of no fewer than forty-five species (contained in twenty-nine genera) that he found, in the course of twelve months, in the same garden pond. It was, however, admirably situated for catching whatever there was to be caught, for it lay in a flat plot of ground, where there was an entire absence of trees and shade, so that its surface was fully exposed to every wind that blew.

The eggs, of course, must often fall on unsuitable places, and be carried past suitable ones, and this accounts for the capricious appearances of Rotifera in some well-watched ponds, and for the frequent disappointments of the naturalists who visit it. To this aërial carriage of the eggs is also due the otherwise perplexing fact that, when any rare Rotiferon is found in one spot, it is frequently found at the same time in closely neighbouring ponds and ditches, even in such an unlikely hole as the print of a cow's foot filled with rain, but not at all in more promising places at some distance off.

Admitting, then, this fitful shower of eggs as proven, we at once see another way in which they may readily travel to distant lands. For it is quite possible that now and then they may fall on the cargo of an outgoing ship. Here they might lie safely in cracks and creases till, the journey being over, the knocking apart of packing-cases and the shaking of wrappers would set them afloat again, to drop down, it may be, into the Botanical Gardens of Sydney, the shore-pools of Ceylon, or the ponds of Jamaica. In fact, these Rotifera would have really done what I have already pointed out that they seemed to do—they would have followed the flag.

The eggs of the tube-makers, however, and of such Rotifera as live only in the clear waters of lakes and deep ponds, present a greater difficulty, for their eggs either lie within their tubes, or are attached to growing weeds, or fall down to a bottom which lies covered all the year round with several feet of water. The wind and sun here cannot be the only means of dispersion. Aquatic birds, and dogs, are probably assisting agents. The birds, as they swim among the water-plants, must frequently set free the eggs from the tubes of the Rhizota, as well as those which adhere to Confervæ, Potomagetons, and water-lilies, and so get them attached to their feathers. Then away they fly, carrying the eggs to some far distant lake, or shaking them off into the air with the flapping of their wings.

In confirmation of this idea, I may mention that the well-known naturalist, Mr. John Hood, of Dundee, who has added so many remarkable species of Rhizota to our Rotiferous fauna, informs me that the Scotch lakes most prolific in new and rare species are those which are visited annually by wild fowl from the North. Prof. Leidy also informs me that his collector, Mr. Seal, noticed sand-pipers haunting the duck-pond where he found an *Asplanchna* very similar to *ebbesbornii*, and that he thought that "these birds were especially instrumental in distributing the lower forms of aquatic life." I may also add that on one occasion I found in a temporary rain puddle, barely a yard across, a living ciliated ovum of *Plumatella repens*. Of course the puddle itself contained no adult forms, and the ovum must have been brought by some bird the distance of at least half a mile. The twin polypes were already partially developed inside the ovum, and it is curious that so delicate a thing should have borne this transport safely.

Dogs probably play a humbler part in the dispersion of the Rotifera; but they cannot help taking some part in it, by intercepting, as they swim, eggs that are slowly sinking

to the bottom, or by brushing off, on to their coats, eggs which have been already caught by the weeds; for the ephippial eggs are frequently armed with hooks or spines, which make them adhere easily to a pond-weed or to a hairy coat, and yet would not prevent a dog's vigorous shake, after his bath, from sending them flying into the air, or on to the dust, where sun and wind would do the rest.

Perhaps one of the most curious illustrations of this aërial conveyance of Rotiferous eggs is the account of *Callidina symbiotica*, which we owe to Dr. Carl Zelinka. It was in the depth of last winter that I read his interesting memoir, concerning a new *Callidina* that he had discovered inhabiting the little green cups on the under surfaces of the leaves of a scale-moss (*Frulliana dilatata*). As I knew that this plant grew on the elms of our Clifton promenade, I started off at once, on the rather forlorn hope of finding some living specimens of the new Rotiferon. When I arrived at the promenade I passed patch after patch of the scale-moss, hoping in vain to find something more promising than the withered liver-coloured stuff which alone was to be seen on the tree-trunks. At last I gave up further search, and pulling off a scrap of what looked like old ragged carpet, I carried it home. There I put a bit of it into a watch-glass, covered it with water, and gently teased it out with needles, till I found an under frond that had some pretension to being green. This I transferred to a glass cell, and placed it under the microscope with the cups turned towards me; and it was with no little pleasure that, in about a quarter of an hour, I saw first one *Callidina*, and then another, stretch its proboscis out of a cup, unfurl its wheels, and begin to feed.

No wonder that these *Philodinadæ* are to be found everywhere when they can bear to be frozen alive in the cell of a plant, or wasted by a midsummer sun in a leaden gutter!

Some chance breeze must have first wafted a *Callidina's* egg on to the scale-moss, just after a shower, when the whole plant was wet, and the little green cups were filled with water. The young *Callidina*, when hatched, could not have desired a better home. The rainfall, on an elm, flows down its furrowed bark in tracks as constant as those of a river and its tributaries; and the growth of the *Jungermann* follows these tracks. Every shower fills the spaces between its flat layers of overlapping leaves with water; and the lower layers, sheltered by the upper, retain for a long time water enough for the *Callidina* to creep about or swim in. And when, at last, the sun and air have dried up the water, the creature retreats into its green cup, which presents so small an aperture to the air, and is so fenced round with thick juicy cells, that the contained water is almost certain to hold out till the next shower. If it does not, the *Callidina* is still content; it becomes conscious of the coming crisis, draws in its head and foot, rounds its trunk into a ball, secretes round itself a gelatinous covering, and waits for better times.

But the Rotifera owe their wide dispersion not only to the ease with which their eggs are blown from one place to another, but also to their powers of endurance, and to their marvellous capacity for adapting themselves to new surroundings. A Philodine may say with Howell, "I came tumbling out into the world a true cosmopolite." I have already noticed how the *Philodinadæ* will endure such extremities of heat, cold, and dryness as Nature inflicts on them; but she does not put their full powers to the test, for, when time is given to them to don their protective coats, they can bear a heat gradually advancing to 200° F., or a fifty days' exposure to a dryness produced over sulphuric acid in the receiver of a good air-pump. Ehrenberg tells us that, whereas he killed *Volvox globator* with one electric shock, it took two of the same intensity to kill *Hydatina senta*; and that *Rotifer vulgaris* will swallow laudanum and yet "be lively," adding that a solution of cantharides seemed "to give it new life." The same irrepressible creature will flourish in water containing a perceptible quantity of sulphuric acid, while *Asplanchna priodonta* will swim about actively for twenty-four hours in a weak solution of salicylic acid, and *Synchæta pectinata* will do the same in chromic acid. The great majority of the fresh-water species die when dropped into sea-water, but some will bear sudden immersion in a mixture of one part sea-water to two fresh. We should not be surprised, therefore, to find not only that there are thirty-four known marine species of Rotifera, but that seventeen of these species are to be met with alike in salt-water and in fresh.

The following is the list of Rotifera found in salt or brackish water; those marked with a star are also the inhabitants of fresh-water:—

Floscularia campanulata*	Colurus amblytelus
Melicerta tubicolaria*	,, caudatus*
Rotifer citrinus*	,, dactylotus
Synchæta baltica	,, pedatus
,, tremula (?)*	,, uncinatus*
Pleurotrocha leptura (?)*	Mytilia tavina
Notommata naias*	Pterodina clypeata
Proales decipiens*	Brachionus Bakeri*
Furcularia forficula*	,, Mülleri
,, gracilis*	Notholca striata*
,, Reinhardti	,, spinifera
Diglena catellina*	,, inermis
,, grandis*	,, scapha*
Distemma raptor	,, thalassia
,, marinum	Anuræa valga*
Rattulus calyptus	,, biremis
Monostyla quadridentata	Hexarthra polyptera.

Although this is doubtless a very imperfect list, still it is sufficient to show how these fresh-water animals are slowly spreading into the tide-pools on the sea-shore. Some may have commenced their change of habitat in the field drains which are periodically invaded by the brackish waters of a tidal river. It was precisely in such a locality that I first found *Brachionus Mülleri*, in water only faintly salt, and at a height of 30 feet above the Severn. Ditches of this kind are to be found all down the Avon; from the highest point, that the tide reaches, to its mouth. As they approach the Severn their water becomes more and more brackish, and the preponderance of marine species in them more pronounced; so that it is easy to see how the descendants of a fresh-water Rotiferon, passing slowly down the river-side from ditch to ditch, may in course of many generations come to endure the sea itself.

In other cases the air-borne eggs may have dropped into the pools, of every degree of brackishness, which usually skirt the shores of our river estuaries. It is in such places, on the Scottish shore, that Mr. John Hood has found so many new marine species, and where no doubt so many more are yet to be found.

But the most noteworthy point about the above list is that the number of distinct genera is so great. One would rather have expected to find but four or five genera hardy enough to endure salt water; and yet here are no fewer than nineteen genera for the thirty-four known marine species; and of these latter, seventeen species are yet in the transitional state, inhabiting alike salt waters and fresh. Still more curious is it to find that all the four orders are represented; and that *Rhizota*, *Bdelloida*, and *Scirtopoda* have each furnished a contingent to the marine forms, as well as the more frequent *Ploima*. It is, of course, rather startling to hear that *Melicerta* and *Floscularia* are to be found inhabiting sea-water; but I know of no reason why any doubt should be thrown on Dr. Weisse's record of having so found them on the sea-shore at Hapsal.

The capacity of the Rotifera for adapting themselves to new surroundings is shown by a mere enumeration of the

strange places in which they are found. For these fresh-water creatures, the common inhabitants of lakes and ponds, are to be found in brackish ditches, sea-pools, the mud of ponds, the dust of gutters, in tufts of moss, on the blades of wet grass, in the rolled-up leaves and in the cups of liver-worts, in the cells of *Volvox*, the stems and sporangia of *Vaucheria*, in vegetable infusions; on the backs of *Entomostraca*, on their abdominal plates, on their branchial feet; on fresh-water fleas, wood-lice, shrimps, and worms; in the viscera of slugs, earth-worms, and Naiades; and in the body-cavities of *Synaptæ*.

But the great variability of every part of the external and internal structure of the Rotifera points to their fitness for playing the parts of cosmopolites. See how in *Floscularia* and *Stephanoceros* the head and its appendages are so developed that they dwarf all the rest; how in *Apsilus* the trunk predominates; while in *Actinurus* both head and trunk become appendages of a huge foot. The corona diminishes continually from the large complex organs of *Melicerta*, *Hydatina*, and *Brachionus*, down to the furred face of *Adineta* and the tuft of *Seison*, and vanishes altogether in *Acyclus*. The antennæ can be traced from long infolding or telescopic tubes, furnished with setiferous pistons, special muscles, and nerves, through a succession of shorter and simpler structures, till they become mere pimples or even setiferous pits in the body surface. The skin is hardened into a perfect lorica in *Brachionus*, is partially hardened in *Dapidia*, is merely tough in *Mastigocerca*, and is soft and quite unarmed in *Notommata*. The appendages of the body in Pedalion rise almost to the dignity of crustaceous limbs, for they have joints, and are worked by opposing pairs of muscles, passing across their cavities from point to point. In *Asplanchna* these appendages become stumpy projections, and the muscles, though still passing freely across the body-cavity, are reduced to threads. In *Triarthra* the appendages become chitinous spines; and at last, when we reach *Adineta*, *Taphrocampa*, and *Albertia*, we find that we have passed from a Rotiferon closely resembling a Nauplius-larva to one that is a simple worm.

The internal structure is just as plastic. The characteristic trophi exhibit a series of striking changes as we pass from one genus to another. In one direction the change is due to the degradation of the mallei, in the other to that of the incus; and in both this degradation is pushed so far, that the changing parts may be said almost to disappear. For in *Brachionus* and *Euchlanis* the mallei are well developed; in *Furcularia*, mere needle-shaped curved rods: in *Asplanchna*, so evanescent that it is hardly possible to find them in an animal killed by pressure.

By another set of changes, the rami are in their turn reduced almost to evanescence; becoming feeble loops in *Stephanoceros*, and in *Floscularia* two membranes attached to the unci.

Changes, great in degree, if not in variety, occur also in the excreto-respiratory system. For the contractile vesicle, which fills quite half the body-cavity in some *Asplanchnæ*, dwindles down in various species till it seems to vanish in *Pterodina* and *Pedalion*; while in one abnormal form, *Trochosphæra*, the connection between the lateral canals and the contractile vesicle is snapped, and the latter becomes an appendage of the cloaca only.

The nervous system, wherever it has been made out, is indeed always on the same plan; but its central organ, the nervous ganglion, is, in *Copeus* and *Euchlanis*, a great cylindrical sac stretching from the head below the mastax; while in *Floscularia* it shrinks into a small star-shaped body between the eyes and the organ of taste.

The alimentary and reproductive systems are those which vary the least; but even here the difference, in proportionate size, is very great between the stomachs of *Sacculus* and *Synchæta*, and also between the ovaries of *Asplanchnopus myrmeleo* and *Asplanchna priodonta*.

But not only do most of the external parts and internal organs vary in turn almost to vanishing, but these variations are not in any way simultaneous. The result is, that we find an organ, of a form characteristic of one family or genus, occurring in a species that belongs to another. Thus, for instance, the trophi of the *Melicertadæ* appear in *Pompholyx*, one of the *Triarthradæ*. Nay, more; it is easy to point out Rotifera that bear some striking characteristics of two or three other genera, or even of two or three other families. *Microdon clavus*, for example, has the central mouth and double ciliary wreaths of one of the *Rhizota*, the eye of a *Notommata*, the trophi of a *Diglena*, and the foot of a *Monostyla*. Again, *Pterodina patina* has the corona of *Philodina*, the lorica and transversely wrinkled retractile foot of *Brachionus*, the foot-ending of a young Rhizotan, and the mastax of the *Melicertadæ*. Then there is Mr. Thorpe's new Australian Floscule, which swims freely like one of the *Ploïma*, has the buccal cup and wreath of *Floscularia*, the dorsal eye of *Notommata*, and the body and forked foot of *Proales*.

To sum up, we may say that in the female Rotifera, the corona, head, foot, toes, appendages of the trunk, antennæ, eyes, and contractile vesicle vary down to almost absolute extinction; while, if we include the male in our survey, we must add that even the whole of the alimentary tract may disappear also. Moreover, the characteristics of the various groups interlace in so many ways that no organ—nor, indeed, any combination of two or three organs—can be relied upon to determine with certainty an animal's true position.

Two conclusions are, in consequence, irresistibly forced on us: the first, that the Rotifera, from *Pedalion* to *Albertia*, are related by descent; the second, that their curious habitats, wide dispersion and great variations in their structure are due to causes that have been at work for a very long period of time.

One other fact has also been made clear in this review—namely, that the British Rotifera give a very fair idea of the whole class. No doubt there are many foreign species, and some of these are very remarkable, and of great interest; but the greater number fall readily enough into the divisions that contain our own species.

And indeed it is a fortunate thing that we can here, at our own doors, study so many typical forms from life. For what books or drawings can give us the delight which we derive from observing the animals themselves?

To gaze into that wonderful world which lies in a drop of water, crossed by some atoms of green weed; to see transparent living mechanism at work, and to gain some idea of its modes of action; to watch a tiny speck that can sail through the prick of a needle's point; to see its crystal armour flashing with ever-varying tint, its head glorious with the halo of its quivering cilia; to see it gliding through the emerald stems, hunting for its food, snatching at its prey, fleeing from its enemy, chasing its mate (the fiercest of our passions blazing in an invisible speck); to see it whirling in a mad dance to the sound of its own music, the music of its happiness, the exquisite happiness of living,—can anyone, who has once enjoyed this sight, ever turn from it to mere books and drawings, without the sense that he has left all Fairyland behind him?

THE DARKNESS OF LONDON AIR.

A GREAT deal has been written at various times upon the subject of London fogs.

The constitution of these London fogs has been carefully gone into by several well-known men of science, from time to time; and the results obtained are of very great interest, as they prove, amongst other things, that during the winter London air has an unusually large amount of

carbonic acid in it. Dr. W. J. Russell found from experiments made in the City of London a few years ago, that on one day the carbonic acid had increased to 14·1 parts in 10,000 of air—that is, there was more than three and a half times the average amount present.

The question will naturally be asked, whether we cannot check this increase of carbonic acid in London air; and, in reply, it may be said that we can; partly by stopping the enormous volumes of sooty smoke belched out daily from hundreds of thousands of chimneys in the metropolis; and, partly, by having more open spaces, &c.

It is well known that the crowding of many people and animal life of all sorts, upon a small area of land, increases the production of carbonic acid, whether it be from respiration or from coal-burning; and it is almost indisputable that the latter produces the well-known black fogs and yellow fogs.

That these black fogs and yellow fogs—to which London and other large towns are liable in the winter—have a most injurious effect upon human beings and all animal life, and vegetation also, cannot be doubted, since we see the death-rate largely increased during the prevalence of black fogs; and of late years the more delicate plants, and indeed the strong ones, both at the Botanical Gardens, Regent's Park, and at Kew, have suffered much from the same cause.

Two things are to be briefly shown in this paper: (1) the general thickness and density of the atmosphere over London during the winter; and (2) the amount of artificial light used during the prevalence of black or dark yellow fogs in various parts of London.

SKETCH MAP OF A PORTION OF LONDON:—MEASURING POINTS SHOWN BY BLACK DOTS.

In connection with this subject various observations were taken in London during the winter of 1887–88, and the results are given below.

Before proceeding further, we may note that London was very free from fogs during the winter of 1887–88—a fact which was probably, to a certain extent, due to the light rainfall, and the unusual dryness, in consequence, of the great plain or valley of the Thames. This was the case not only in London, but in Manchester, Leeds, Liverpool, and elsewhere.

(1) As regards the general thickness and density of London air. The sketch plan of a portion of London will show that Primrose Hill—which is about 219 feet above the sea-level—was the point selected for (let us say) measuring from.

Three lines, which embraced the measuring points fixed upon, were taken over London, these lines being respectively the south-west line to St. Mary Abbot's Church, Kensington; the south line to the Clock Tower, Houses of Parliament; the south-east line to St. Paul's Cathedral. One more line was taken towards the country: this we will call the north line to St. John's Church, Hampstead. Intermediate measuring points were taken on all these lines, church spires or towers, &c., being selected as the most conspicuous objects that could be seen from Primrose Hill.

The distance of all these intermediate measuring points

from Primrose Hill, and their names, are given in Table I. The *total* number of times that each of the chosen points was seen during the five months selected is also given.

It will be observed that during the 152 days which make up the five months selected, Christ Church, Lancaster Gate, and St. Mary Abbot's Church, Kensington, on the south-west line; the Clock Tower, Houses of Parliament, on the south line, and the Scotch Church, Regent's Square; and St. Paul's Cathedral, on the south-east line, were *never once* seen.

When it is known that on any ordinary fine day during the late spring, summer, and early autumn, you can see right across London, on any one of the selected lines, it will be easy to realize how thick the air over London is during the winter.

It may be noted that when you could see as far as St. John's Church, Hampstead, it would, as a rule, have been possible to see much further, but since there was no point beyond Hampstead which could be taken as a measuring point, it was impossible to record the distance.

(2) As regards the amount of artificial light used in various parts of London owing to the prevalence of dark fog. The observations given below were made, with the assistance of various friends, during the winter of 1887-88, and give the approximate result in hours.

TABLE I.—*The distances given in this Table are all measured approximately from Primrose Hill.*

Notting Hill Gate, W.	19	0	15	0	2¼	36¼
Homerton, E. ...	34¼	24¼	38¼	4¾	11½	113

The manner in which the observations (given in Table II.) were made will be seen in detail from Table III., which was kept by Mr. E. Liddell at the College, Homerton, E.

This table is given because Homerton suffered more from darkness than any other part of London, owing, it cannot be doubted, to the large number of factories in the neighbourhood. It will be seen later on in this paper that Leeds suffered more from darkness than the other provincial towns selected, and this was due probably to a great extent to the same cause.

From Table II. it will be seen that January was the worst month for dark fogs, the average for each of the districts given being 27 hours of darkness per month.

London is not much worse than our large provincial towns in respect to dark fogs. Table IV. gives the results of observations made in several towns.

It will be seen from Table IV., that dark fog was general in the tabulated towns during the month of January. It is said that Manchester, of late years, has been unusually free from dark fogs, owing to the fact that a very large number of mills have been moved out, so as to escape the heavy town rates, &c. The ordinary white fog has also been reduced, probably through thousands of acres of the wet morass lands on the west side of Manchester having been well drained recently. This being

[1] On thirty-six days this point could not be seen.

the case, something might be done to improve the drainage of the marshes to the east of London.

Presuming that dark fogs are principally due to smoke, —and Sir Douglas Galton, in a paper read at the Parkes Museum in 1887, on "The Cause and Prevention of Smoke," declared that black (or dark) fog was *entirely* the result of smoke, while Dr. Marcet attributes the density of London fog *mainly* to smoke—it is clear that we want legislation to intervene, and to extend the Metropolitan Acts of Parliament, viz. those of 1853 and 1856, and instead of allowing these Acts to deal only *partially* with factory smoke, to cause them to be applied to every house in London.

TABLE III.—*Fog Observations from November* 1, 1887, *to March* 31, 1888.

NOTE.—Two spaces will be found below for every day during the five months. When, owing to the prevalence of fog, artificial light is used on a particular day, put a × in the *first* space assigned to that particular day; and in the *second* space put the quarters of an hour or number of whole hours and quarters during which light is used.

Manchester ...	16	20	37	0	3	76

[1] Fog not dense on March 23, but very dark.
[2] Darkness, rather than fog, from 2.45 to 3.40.
[3] Fog and darkness.

It is not necessary to quote any figures here, to prove how the death-rate in London rapidly increases during the prevalence of smoke fogs, as everyone knows it too well. But we may give an extract from the *Gas World* to show the enormous and quite unnecessary cost of these smoke fogs.

The *Gas World* says that, "during the foggy days which were experienced between the 16th and 24th of November 1887, the Gas Light and Coke Company sent out to its customers in London no less than 710,251,000 cubic feet of gas; that to manufacture this quantity 71,000 tons of coal must have been carbonized, and that the total value of the gas, without the consideration of the by-products, is £106,000. During the nine days, therefore, the public paid the Gas Light and Coke Company no less than £490 per hour for *artificial light*."

This calculation, it should be observed, does not include the amount supplied by other Gas Companies in London during the same short period of fog.

W. HARGREAVES RAFFLES.

ELECTRICAL STRESS.[1]

THE subject of the discourse was brought before the members of the Royal Institution some years ago by Mr. Gordon. In the interval a considerable amount of work has been done upon it, both in England and Germany, and many experiments have been devised to illustrate it. Some of the more striking of these, though of great interest to the student, are rarely or never shown in courses of experimental lectures. The lecturer and Mr. C. V. Boys, F.R.S., last year devised a set of apparatus which has made the optical demonstration of electrical stress comparatively easy, and most of the results obtained by Kerr and Quincke can now be demonstrated to audiences of a considerable size. Before discussing this portion of his subject the lecturer introduced it by an explanation of principles on which the experiments are founded.

Magnetic lines of force can easily be mapped out by iron filings, but the exhibition of electrical lines of force in a liquid is a more complex matter. In the first place, if two oppositely electrified bodies are introduced into a liquid which is a fairly good non-conductor, convective conduction is set up. Streams of electrified liquid pass from the one to the other. The highly refracting liquid phenyl thiocarbamide appears to be specially suitable for experiments on this subject. If an electrified point is brought over the surface a dimple is formed which becomes deeper as the point approaches it. At the instant at which the needle touches the liquid the dimple disappears, but a bubble of air from the lower end frequently remains imprisoned in the vortex caused by the downward rush of the electrified liquid from the point. It oscillates a short distance below the point, and indicates clearly the rapid motions which are produced in the fluid in its neighbourhood. When the needle is withdrawn a small column of liquid adheres to it. This effect is, however, seen to greater advantage if a small sphere about 5 mm. in diameter is used instead of the needle-point. When this is withdrawn a column of liquid about 5 mm. high and 2 mm. in diameter is formed between the sphere and the surface. A similar experiment was made by Faraday on a much

[1] Abstract of a Lecture delivered at the Royal Institution on February 15, by Prof. A. W. Rücker, F.R.S.

larger scale with oil of turpentine, and he detected the existence of currents, which are in accord with the view that the unelectrified liquid flows up the exterior of the cylinder, becomes electrified by contact, and is repelled down its axis. In view of this explanation, and the movements assumed can be clearly seen in the phenyl thiocarbamide, the performance of the experiment on a small scale is not without interest. The possibility of the formation of such violent up-and-down currents in so small a space must depend upon a very nice adjustment between the properties of the liquid and the forces in play. It is obvious that such movements of the liquid must be a disturbing element in any attempt to make the lines of electric force visible.

Again, if a solid powder be suspended in a liquid into which electrified solids are introduced, it tends to accumulate round one of the poles. This subject has been investigated by W. Holtz. Sometimes the powder appears to move in a direction opposed to that in which the liquid is streaming. Sometimes two powders will travel towards different poles.

If powdered antimony sulphide be placed in ether, it settles at the bottom of the liquid, and if either two wires insulated with glass up to their points, or two vertical plates be used as electrodes, on exciting them slightly the solid particles arrange themselves along the lines of force. If the electrification be increased, they cluster round the positive pole. On suddenly reversing the electrification by means of a commutator, they stream along lines of force to the pole from which they were previously repelled. Other methods of obtaining the lines of force have been devised. They can, for instance, be shown by crystals of sulphate of quinine immersed in turpentine.

The tendency of the lines of force to separate one from the other was illustrated by Quincke's experiment. A bubble of air is formed in bisulphide of carbon between two horizontal plates. It is in connection with a small manometer, and when the plates are oppositely excited, the electrical pressure acting at right angles to the lines of force, being greater in the liquid than in air, compels the bubble to contract.

Kerr's experiments depend upon the fact that, since the electrical stress is a tension along the lines of force, and a pressure at right angles to them, a substance in which such a stress is produced assumes a semicrystalline condition in the sense that its properties along, and perpendicular to, the lines of force are different. Light is therefore transmitted with different velocities according as the direction of vibrations coincides with, or is perpendicular to, these lines; and the familar phenomena of the passage of polarized light through crystals may be imitated by an electrically stressed liquid.

The bisulphide of carbon used must be dry, and, to make the phenomena clearly visible, it is necessary that the light should travel through a considerable thickness. Thus, to represent the stress between two spheres, elongated parallel cylinders should be used, the axes of which are parallel to the course of the rays of light. These appear on the screen as two dark circles. Between crossed Nicols, the planes of polarization of which are inclined at 45° to the horizontal, the field is dark until the cylinders are electrified, when light is restored in the space between them.

If parallel plates with carefully rounded edges, and about 2 millimetres apart, are used, the colours of Newton's rings appear in turn, the red of the third order being sometimes reached. If one plate is convex towards the other, the colours of the higher orders appear in the middle, and travel outwards as the stress is increased. The experiments may be varied by using two concentric cylinders, or two sheets of metal bent twice at right angles to represent a section through a Leyden jar. In the first case a black cross is formed; and in the second, black brushes unite the lower angles of the images of the edges of the plates. By the interposition of a piece of selenite, which shows the blue of the second order, two of the quadrants contained between the arms of the cross become green, and the others red. In like manner the horizontal and vertical spaces between the inner and outer coatings of the "jar" become differently coloured.

There are several phenomena connected with the stress in insulators which present considerable difficulties. Thus in a solid it is found impossible to restore the light between crossed Nicols by a uniform electrical field. That the non-uniformity of the field has nothing to do with the phenomenon in liquids, though at first disputed, is now generally admitted. It may be readily proved by means of a Franklin's pane, of which half is pierced into windows. The glow is much weakened by thus removing part of the uniform field, though it is thus made much less uniform.

Again, though most dielectrics when placed in an electric field expand, the fatty oils contract. Prof. J. J. Thomson has recently pointed out that this indicates that another set of strains are superposed upon those assumed in the ordinary explanations of these phenomena, and by which they may be neutralized or overcome.

In experiments with carbon bisulphide it is necessary to take every precaution against fire. For this purpose the cell which contains the liquid should be immersed in a larger cell, so that if—as sometimes happens—the passage of a spark cracks the glass the liquid may flow into a confined space. This should stand in a tray with turned-up edges, and an extinguisher of tin plate should be at hand to place over the whole apparatus. No Leyden jars should be included in the electrical circuit. The difficulties which formerly arose in the exhibition of experiments in statical electricity owing to the presence of moisture in the air of a lecture-room are now immensely reduced by the Wimshurst machine, which works with unfailing certainty under adverse conditions. A new and very beautiful machine was kindly lent by Mr. Wimshurst for the purposes of the lecture.

NEW BUILDINGS AT CAMBRIDGE FOR PHYSIOLOGY AND ANATOMY.

THE energy and success of the Cambridge teachers of science are once more demonstrated by the proposal to build new laboratories, with a large lecture-room, for anatomy and physiology, and a museum and dissecting-room for human anatomy, on a scale commensurate with the importance of the medical and biological school. The present physiological laboratories, which ten years ago were a great advance upon the mere make-shift arrangements that had previously done duty, are now disagreeably overcrowded. At present, Prof. Foster's elementary class is attended by between 190 and 200 students; and the several advanced classes have from twenty to thirty-five students. In the laboratory there are now only places for ninety students of histology; but accommodation has been provided for about seventy more in a temporary building attached to the museum. Inasmuch as the students of the elementary class must all go through the histological course, lasting throughout three terms, it is evident that they can be accommodated only by relays, and that in order to accommodate the advanced students, who have no proper places of their own, much crowding must take place, whereas the advanced students' work-places ought not to be disturbed, as these students need opportunities for continuous work. For chemical physiology there are only eight places available, and there is one fairly large room for physical physiology; there is no adequate lecture-room.

The proposed buildings have once been deferred, plans having been prepared in 1884; but it is hoped that the

delay may have led to the presentation of a better and more complete plan. The details of the scheme would be too long for us to give; but the result will be to provide an excellent new building extending for 190 feet along Corn Exchange Street, in continuation of the east front of the present buildings for physiology and comparative anatomy, and occupying the whole distance between them and the Corn Exchange. Besides rooms for teachers and demonstrators, aquaria, and preparation-rooms, there will be a new class-room in which 140 additional students for histology can be accommodated. There will be a demonstration-room in which about fifty students at a time can be shown experiments which now have to be omitted owing to the want of such a room. By rearrangement of rooms additional accommodation will be given to chemical physiology and to research, while rooms will be available for advanced students to work without interruption from the elementary classes.

The new lecture-room will be in the middle block, between the anatomical and physiological buildings; internally it is to measure 40 by 45 feet, by 25 feet high to the wall-plate, above which will be an open queen-post trussed roof, with sky-lights in the sides. There will also be a large window in the east gable. This lecture-room will accommodate 240 students, for more than which number it is not yet considered necessary to provide; although if the school continues to expand till it reaches the dimensions of the Edinburgh School, which is not impossible, a still larger lecture-room will ultimately be required. But the present proposal will give a room far superior to the room now in use, both for anatomy and physiology.

The northern block, for human anatomy, has about 70 feet of frontage, and contains, in addition to offices, Professor's and articulating-rooms, &c., a museum 40 feet by 60, lighted by windows in three walls, and 17 feet high, admitting of the construction of a gallery. Above the museum is a dissecting-room of rather larger area, well lighted.

The estimated cost is, for physiology, £4755; lecture-room, £3338; human anatomy, £5872: total, £13,965. The report and plans are to be discussed on Saturday next, and we hope they will be promptly carried out, as the anatomical buildings at present in use are painfully inadequate, and physiology is also urgently in need of better accommodation.

NOTES.

THE subject of the Croonian Lecture to be delivered before the Royal Society during the present year will be "Preventive Inoculation." The lecture will be delivered by M. Roux, and will be founded on observations made in the Pasteur Institute. It is hoped that M. Pasteur will be present at the lecture.

MR. EADWARD MUYBRIDGE, of Philadelphia, who by arrangement with the Managers of the Royal Institution had agreed to give a discourse after Easter on "The Science of Animal Locomotion in its Relation to Design in Art" (illustrated by the zoopraxiscope), a subject of great novelty and interest, has kindly consented to deliver it on Friday evening, the 22nd instant, Dr. Edgar Crookshank being compelled, through illness, to defer his discourse on "Microbes," which was to have been delivered on that evening.

To meet the expressed wish of the members, the Council of the Mineralogical Society has resolved that two additional general meetings shall be held in London during the current year; the first has been fixed for Tuesday, March 12, and the other for Tuesday, June 25. The general meetings still to be held in London during the year will thus be on the following Tuesdays: March 12, May 7, June 25, November 5 (anniversary). The meetings will be held on the premises of the Geological Society, Burlington House, Piccadilly, at 8 p.m.

ON Monday, March 11, Mr. William Jago will begin, at the City and Guilds of London Institute, a course of ten lectures on "Bread-making." The lectures will be delivered on Monday and Thursday evenings at 7.30. The special object of the course is to give, in the simplest possible manner, instruction to practical working bakers as to the nature of the changes which occur during the manufacture of bread.

IN spite of the enthusiasm evoked in Norway by the success of the Nansen Expedition, the national subscription opened to defray the cost has been but poorly responded to. In consequence, Herr Gamél, of Copenhagen, whose munificence enabled the Expedition to start at all, has offered to contribute the balance wanting.

WE regret to have to record the death of the Rev. John George Wood, author of "Common Objects of the Sea-shore" and many other popular works on natural history. He died on Sunday, while on a visit to Coventry, from an attack of peritonitis. Mr. Wood was in his sixty-second year.

THE death is announced of Dr. Johannes Brock, lately Professor of Zoology at Dorpat University. He was well known by his scientific journey to the Indian Archipelago, undertaken with the pecuniary help of the Berlin Academy. He died at Göttingen, where he had been appointed Professor of Natural Science.

DR. J. SOYKA, Professor at the German University at Prague, and formerly at the University of Munich, shot himself during a fit of melancholia, on February 23. He was the author of works on Bacteria.

LAST week, in answer to a question put by Mr. Mundella, with regard to the aid to be granted by the Government to provincial Colleges, the Chancellor of the Exchequer made the following statement:—"A vote for provincial Colleges has been put down in the Estimates for 1889–90. The Government have found considerable difficulty in deciding what Colleges should be entitled to share in it, and in what proportions and on what conditions it should be distributed between them. They have accordingly appointed a small Committee to make particular inquiries and advise them on these points. The Committee will sit at an early date, and its deliberations are not likely to be prolonged. Upon receiving its report the Government will settle the scheme of distribution. The sum voted will, of course, be available for the Colleges which are entitled to share in it during the coming financial year."

THE Owens College is one of the Manchester institutions which benefit by the will of the late Mr. John Rylands. He has bequeathed to it £10,000.

SOME time ago the Coast Fishing Section of the German Fisheries Society established a zoological station at Ditzum, on the Dollart, where researches on the fauna of the German Ocean were carried on during the summer months. The Society are now making arrangements to keep the station open during the whole year.

A BIOLOGICAL STATION, chiefly for the promotion of the fisheries, is to be established in Denmark, at a cost of £2000, with a yearly subsidy of £480.

THE Fisheries Exhibition which has just been opened in St. Petersburg is the first Exhibition of this kind that has been held there. It will remain open till the end of April.

ON February 20, about 10 p.m., a remarkably brilliant meteor was seen in and around Stavanger, on the west coast of Norway. It radiated in the south-east, and, going in a westerly direction, burst about 35° above the horizon, without any detonation, but leaving a long trail behind. Its light was a dazzling white.

On January 22, about 2 a.m., an earthquake shock was felt at Hönefos, in Central Norway. This was followed by another, and by a few more at intervals, but faint in character.

A number of houses were destroyed by the earthquake that occurred at Fleurier, in the Jura Mountains, on February 13 last.

In the *American Meteorological Journal* for December last, General Greely, Chief Signal Officer, contributes an interesting article on "Average Velocities of Low-area Storms and Upper Air Currents in the United States." The author shows that the decrease in velocity of the former is regular and unbroken from February to June, and that the increase is nearly as regular to February again. He expresses the important opinion that the average movement of low-area storms in the United States bears a definite relation to the velocity of upper air currents; and in support of this, a chart is given showing a remarkable accord between the mean hourly velocity of low-area storms and the mean velocity of the upper air currents from 1881–87. Prof. M. W. Harrington contributes a useful article in the shape of a translation of a simple demonstration of the deflection of horizontal motion due to the earth's rotation, from Dr. Günther's "Lehrbuch der Geophysik," without the use of higher mathematics. In the January number, Mr. A. L. Rotch gives a very complete account of the organization of the meteorological service in France since the first establishment of weather telegraphs by Leverrier at the Paris Observatory in 1856, together with descriptions of the instruments and methods now employed. Since 1887 the meteorological service has been separated from the astronomical work, and has been under the able direction of Prof. E. Mascart. The observing-station of the Central Office is the Parc St. Maur Observatory, nearly ten miles south-east of Paris.

In the latest Report of the Bombay Chamber of Commerce, it is stated that it was decided by the Government last May to abolish the office of Meteorological Reporter of Western India, and substitute for it that of Reporter at a reduced salary, who would work under and through the Meteorological Office at Simla. The Chamber, thinking that this alteration would be detrimental to the shipping in the port by stopping the system of storm-warnings that had been carried on for some years, petitioned the Government against the proposed change, and advocated the establishment of additional coast and inland signal stations to aid in the daily forecasts. The Chamber also pointed out in its petition that its members have, for a number of years, printed bi-weekly weather reports, which were indispensable in the absence of a Government daily weather chart and report. The Superintendent of the Meteorological Department of the Government of India was sent to Bombay to make inquiries, but his visit only resulted in the closing of the office in the month of August. Since that time the head of the Telegraph Department has superintended the forecasts. The scheme now about to be tried is that, in consideration of a small monthly payment by the Chamber of Commerce and the Port Trust, a daily telegraphic weather report chart and storm warnings and a bi-weekly crop report will be supplied to each member of the Chamber.

Mr. R. Andree has lately been collecting information as to the use of signals by primitive peoples, and the facts he has brought together—summarized in *Science*—are interesting and suggestive. American Indians use rising smoke to give signals to distant friends. A small fire is started, and, as soon as it burns fairly well, grass and leaves are heaped on the top of it. Thus a large column of steam and smoke rises. By covering the fire with a blanket, the Indians interrupt the rising of the smoke at regular intervals, and the successive clouds are used for conveying messages. Recently, attention has been called to the elaborate system of drum-signals used by the Cameroon negroes, by means of which long messages are sent from village to village. Explorations in the Congo basin have shown that this system prevails throughout Central Africa. The Bakuba use large wooden drums, on which different tones are produced by two drum-sticks. Sometimes the natives "converse" in this way for hours; and, from the energy displayed by the drummers, and the rapidity of the successive blows, it seemed that the conversation was very animated. The Galla south of Abyssinia have drums stationed at certain points of the roads leading to the neighbouring States. Special watchmen are appointed, who have to beat the drum on the approach of enemies. Cecchi, who observed this custom, designates it as a "system of telegraphs." The same use of drums is found in New Guinea. From the rhythm and rapidity of the blows, the natives know at once whether an attack, a death, or a festival is announced. The same tribes use columns of smoke or (at night) fires to convey messages to distant friends. The latter are also used in Australia. Columns of smoke of different forms are used for signals by the inhabitants of Cape York and the neighbouring island. In Victoria, hollow trees are filled with fresh leaves, which are lighted. The signals thus made are understood by friends. In Eastern Australia, the movements of a traveller were made known by columns of smoke, and so was the discovery of a whale in Portland Bay.

A very important series of vapour-density determinations have been made by M. Alphonse Combes, which appear to decide the much-discussed question of the valency of aluminium. It will be remembered that a few months ago, as noticed in these columns (vol. xxxviii. p. 624), Profs. Nilson and Pettersson, of Stockholm, published the results of a most conclusive series of experiments upon chromic chloride, showing that at the lowest available temperature the density of the chloride corresponds so closely to the formula $CrCl_3$, as to preclude the possibility of the existence of molecules of Cr_2Cl_6 in the gaseous state. This decisive result in the case of chromium, following as it did after the experiments of Prof. Victor Meyer and Dr. Grünewald upon ferric chloride, which also resulted in showing that the formula $FeCl_3$ represented the only stable molecular condition, appeared to indicate that the metals of this group are really triads, and that the double formulæ Cr_2Cl_6 and Fe_2Cl_6 must be abandoned. This conclusion was further strengthened by the fact that still earlier determinations of the vapour-densities of the chlorides of indium and gallium by Prof. Meyer, Profs. Nilson and Pettersson, and M. Friedel, had yielded conclusive results, pointing to the formulæ $InCl_3$ and $GaCl_3$. In the case of aluminium, however, the evidence has been by no means so decisive. As shown by Dr. Young, in an admirable *résumé* of all the experimental data bearing upon this question in Nature (vol. xxxix. p. 198), determinations of the vapour-density of aluminium chloride by Profs. Nilson and Pettersson showed that from 440° C. the density gradually diminished, until at about 800° it arrived at the value corresponding to $AlCl_3$, and then remained constant for about 200°, until, in fact, it began to break up with liberation of free chlorine. On the other hand, Messrs. Friedel and Crafts, in a beautifully graduated series of experiments, found that at 218°, 31° above the boiling point, the density corresponded almost exactly to the formula Al_2Cl_6, and remained practically constant to 400°. More recently, Messrs. Roux and Louïse have found that, at temperatures near their boiling-points, methide and ethide of aluminium possess densities corresponding to the formulæ $Al_2(CH_3)_6$ and $Al_2(C_2H_5)_6$; these values, however, do not remain constant for any sufficient interval of temperature, and so are by no means conclusive. At this interesting moment M. Combes brings forward his experiments upon a new compound, acetyl acetonate of aluminium, $[Al(C_5H_7O_2)_3]_n$, a

substance readily obtained perfectly pure as a white crystalline solid, melting at 193°–194°, and vaporizing unchanged at 314°–315°. Two consecutive density determinations by Victor Meyer's method in an atmosphere of nitrogen and at the temperature of boiling mercury, which is only 45° above the boiling-point of the substance, yielded numbers corresponding to the molecular weights 325·5 and 324·2. The molecular weight of $Al(C_5H_7O_2)_3$ is 324·5; so that, even at this comparatively low temperature, just as in the case of chromium chloride, the triad is the only possible formula. There was no trace of decomposition, the pure white crystals being found re-formed and chemically unchanged after the experiment. From this result it appears pretty conclusive that aluminium does behave like chromium, iron, indium, and gallium, and that, although in the case of the chloride, molecules of the composition Al_2Cl_6 may for a brief space exist, yet the most stable molecules of aluminium compounds in general are those in which the metal plays the part of a triad.

IN some notes on a voyage to the Greenland Sea in 1888, published in the *Zoologist* for March, Mr. Robert Gray gives some curious particulars with regard to the contents of the stomachs of several hooded seals, *Cystophora cristata*, shot on July 9. While most were empty, one was packed full with a bluish mud or ooze, in which were embedded the crystalline lenses of two eyes belonging probably to some small species of fish, and the remains of one Crustacean common at the surface (*Themisto*). The stomachs of three other seals contained mud alone. "With regard to the presence of mud in these animals' stomachs," says Mr. Gray, "while considering the depth of the water too great (in this instance 200 fathoms; in another, 1100) to permit the bottom being reached, the only explanation I am able to offer is that the substance must be swallowed in small quantities by the seals along with their ordinary food (Crustaceans living at the surface), and that, owing to its indigestible nature, it accumulates in course of time in the stomach. These seals are occasionally observed disappearing under the ice, for the purpose, I believe, of feeding on the immense number of Crustaceans which are known to accumulate there. Many of the ice-fields bear on their surface, immediately under a superficial coating of snow, cargoes of mud (apparently of an alluvial origin). During the process of melting, the mud may accumulate on submerged tongues or ledges of the ice, and thus become the retreat of numbers of Crustaceans, which, as they are devoured by the seals, are swallowed along with a small quantity of the mud. Some such explanation must, I think, be conceived."

A PAPER on the occurrence of Pallas's sand-grouse (*Syrrhaptes paradoxus*) in Ireland was read some time ago before the Royal Dublin Society, by Dr. Robert Scharff, and has now been printed. The immigrations of the bird began in Ireland at the end of May and lasted to the middle of July, when they ceased until the end of November. It is difficult to say, with any degree of accuracy, how many specimens found their way to Ireland; but Dr. Scharff thinks that in the various flocks which were seen there may have been about one hundred birds. A far larger number, however, may not have been observed. "Following their instinctive desire to explore the extreme west," says Dr. Scharff, "hundreds may have perished in the waves of the Atlantic, thus putting a stop to their enterprising spirit."

AN interesting paper on the Coreans was read lately by Mrs. E. R. Scidmore, an American lady who, in 1887, visited, as a guest, Judge Denny, the foreign adviser to the King of Corea. Wisps of straw and bits of cloth hang at the doorways to keep off evil spirits; and these, according to Mrs. Scidmore, are the only signs of worship seen about Seoul. The Coreans have the worship of ancestors, as the Chinese; and a trace of the old dragon-worship must order their toleration of snakes, as it is impossible to get a Corean servant to kill the snakes that drop from the mud roof and slip out of the flues of the kaugs that warm the floors of the houses. Until the arrival of the American physicians, the king and queen had an army of necromancers and wizards in attendance upon them, and a form of Shamanism was practised upon the sick. They were consulted also in matters of State policy.

A SUPPLEMENT to the first volume of the *Internationales Archiv für Ethnographie* has been issued. It consists of a careful and interesting monograph, by Dr. Otto Stoll, on the ethnology of the Indian tribes of Guatemala. He has much that is valuable and interesting to say about the social organization of these tribes, their religious ideas and customs, and their skill in various industrial arts. Two admirably coloured plates accompany the essay, and three illustrations are given in the text.

THE January and February numbers of *Mathesis*, a Belgian mathematical journal, have just been issued as a single number of seventy pages, which are wholly taken up with a French translation of the "supplementary chapter" of Dr. Casey's "Sequel to Euclid" (pp. 165–248, fifth edition). With the double part the editors present a copy of M. Vigarié's useful "Premier Inventaire de la Géométrie du Triangle," to which we lately drew attention.

THE proprietors of the Castle Mail steamers have issued a guide "to the land of gold and diamonds, and the places touched at by their various steamers." The book is called "South Africa, and how to reach it by the Castle Line." The author is Mr. Edward P. Mathers.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus* ♀) from India, presented by Miss L. C. Hart; a Grey Ichneumon (*Herpestes griseus*) from India, presented by Mrs. Margaret Allison; an American Black Bear (*Ursus americanus* ♂) from North America, presented by Messrs. Hugh Williams and Basevi, Lieutenants R.N.; a Common Fox (*Canis vulpes*), British, presented by the Lord Tredegar; a Short-eared Owl (*Asio brachyotus*), captured at sea, presented by Mr. R. Phillips; a Common Blue Bird (*Sialia wilsoni*) from North America, presented by Commander W. M. Latham, R.N.; an Axolotl (*Siredon mexicanus*) from Mexico, presented by Mr. E. Evelyn Barron; nine Moorish Geckos (*Tarentola mauritanica*) from the South of France, presented by Masters F. and O. Warburg; a Manatee (*Manatus australis*) from Guiana, deposited; two Tui Parrakeets (*Brotogerys tui*) from Brazil, four White-breasted Gallinules (*Gallinula phœnicura*) from India, purchased; an Unarmed Trionyx (*Trionyx muticus*) from North America, received in exchange.

OUR ASTRONOMICAL COLUMN.

SOLAR ACTIVITY IN 1888.—The behaviour of the various orders of solar phenomena, spots, faculæ, and prominences, during the past year has shown most conclusively that the minimum must now be very near at hand, and it may with confidence be expected to fall either towards the end of the current year or else early in 1890. The spots especially have shown unmistakable signs that the trough of the eleven-year curve is nearly reached, for they have been few in number, small in size, and low in latitude, and there have frequently been considerable intervals in which no spots have been seen at all. The remarkable depression of October 31 to December 9, 1886 (see NATURE, vol. xxxv. p. 445) has in some respects indeed not been equalled during 1888, but there has been no such long period of unbroken quiescence since the minimum of 1879 as that recorded in last October, when in the three weeks October 4–24 not a single spot was seen, whilst there were but three days showing spots in the thirty-seven from September 29 to November 5. Other spotless or nearly spotless periods in 1888 were January 23–30, February 4–17, March 1–8, March 24–31, April 6–15, April 30 to May 10,

May 24 to June 8, June 30 to July 12, July 18 to August 7, and December 22–31. And not only were there these long and numerous breaks in the spot manifestations, but when spots were seen they were almost always small in size and few in number. On not a single day in the year did the total spotted area amount to $\frac{1}{1200}$ of the surface of the visible hemisphere; on only eight days did it exceed $\frac{1}{2000}$. The mean daily spotted area for the year amounted only to about 9 parts in 100,000, or almost precisely the same as in 1877. In January there was a feeble but fairly sustained display of activity up to the 22nd; there was a similar but less lasting manifestation at the end of February, and again about the middle of March. April was very quiet, but May 11–23 yielded a fair show of spots, May 14 giving the largest area of the year. August 28 to September 9 was also a fairly active time; but the most prolific month as to entire spotted area, though not as to number of spots, was November, following immediately after the longest period of entire quiescence. The last ten days of last year, and the first two months of the present, have been exceedingly barren.

A rough tendency has manifested itself in the past as in previous years, for quiet intervals to follow each other at the distance of half a synodic rotation of the sun, indicating a preference of the spots for a few favoured longitudes. In latitude, the spots have continued to be more numerous in the southern hemisphere—a condition of things that has prevailed, on the whole, ever since the dying away of the great spot of November 1882. Generally speaking, the spots have lain close to the equator, not often rising above 5° or 6° of latitude in the northern hemisphere, and 9° or 10° in the southern; but the same curious pulsation shown in the great eleven-year cycle has been also visible in these minor oscillations, and whenever there has been anything like an outburst, there has also been an effort to ascend to higher latitudes. Thus, the greatest display in the northern hemisphere, that of November, lay in lat. + 11°; whilst a part of the outbreak in the southern hemisphere in September reached lat. − 16°.

The monthly numbers for spots and faculæ given by Prof. Tacchini, in the *Comptes rendus*, vol. cvi. No. 18, vol. cvii. No. 6, and vol. cviii. No. 7, are as follows, and may be compared with those given for previous years in NATURE, vol. xxxiii. p. 398, vol. xxxv. p. 445, and vol. xxxvii. p. 423:—

	Relative frequency of days without spots.	Sun-spots. Relative frequency.	Relative size.	Mean daily number of groups.	Faculæ. Relative size.
January	0·21	2·70	11·17	1·30	14·13
February	0·74	2·30	5·91	0·48	11·09
March	0·61	1·70	6·22	0·48	14·57
April	0·39	1·65	4·31	0·89	13·65
May	0·54	2·50	18·77	0·46	7·20
June	0·42	3·71	4·18	0·79	17·52
July	0·68	1·10	3·45	0·42	15·81
August	0·46	1·86	13·71	0·68	14·29
September	0·04	4·80	40·12	1·68	27·80
October	0·80	0·68	1·12	0·08	5·72
November	0·41	3·12	21·88	0·77	9·12
December	0·44	2·44	10·64	0·56	10·22

The foregoing table shows that the faculæ have not by any means varied simultaneously with the spots, and that their diminution as compared with 1886 and 1887 has been but slight. They showed, however, a very noticeable development during the secondary maximum of September, whilst the prominences, on the other hand, fell off considerably both in September and November, but attained their greatest development during the year about March and April, when the spot activity was decidedly feeble. This diversity of behaviour shows that the connection between the spots and hydrogen prominences is less intimate than it has sometimes been stated to be. Nevertheless, the prominences also afford very distinct evidence of a continued decline, as the following figures, given by the Rev. S. J. Perry in the *Observatory* for March, will show:—

	Mean height of chromosphere. ″	Mean height of prominences. ″	Mean extent of prominence arc. ° ′
1886	8·05	24·78	13 36
1887	8·13	23·86	9 29
1888	8·06	20·96	6 46

The highest individual prominences recorded by Prof. Tacchini were 2′ in height, and were seen on January 10 and February 7.

The magnetic variation has also shown a decline during the year in fairly faithful parallelism to the sun-spots; indeed, the accordance has, according to Dr. R. Wolf, been closer in 1888 than in 1887. The following are the numbers he gives in the *Comptes rendus*, vol. cviii. No. 2:—

1888.	Wolf's relative numbers (Zurich). r.	Δr.	Variation in magnetic declination (Milan). v. ′	Δv. ′
January	13·0	− 0·1	3·03	−0·68
February	7·0	− 8·7	3·02	−0·67
March	6·3	+ 3·6	7·11	+0·12
April	3·9	− 3·6	8·27	−1·06
May	7·8	− 9·4	8·48	−0·82
June	6·5	− 9·8	9·27	−0·28
July	1·9	−24·3	8·58	−1·67
August	1·9	−19·2	9·17	+0·10
September	7·8	+ 0·9	7·31	+1·23
October	2·0	− 3·5	6·32	+0·29
November	12·9	+ 8·4	2·18	−0·89
December	9·9	−10·6	1·76	−0·47
Mean	6·7	− 6·4	6·21	−0·40

The formula $v = 5'·62 + 0·045r$, which Dr. Wolf has established for Milan, would give $v = 5'·92$ if $r = 6·7$, whilst the observed value of v was $6'·21$, a difference of $0'·29$. The difference between the observed and computed values was $0'·40$ for 1887.

COMET 1889 *a*.—This object, discovered by Mr. Brooks on January 14, appears to be lost. Prof. Holden, writing on January 30 to the editor of the *Astronomische Nachrichten*, states that both Mr. Barnard and Prof. Swift had carefully searched for it with the Lick instruments, but without success.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 *MARCH* 10–16.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on March 10

Sun rises, 6h. 26m.; souths, 12h. 10m. 21·6s.; sets, 17h. 54m.: right asc. on meridian, 23h. 23·8m.; decl. 3° 54′ S. Sidereal Time at Sunset, 5h. 8m.

Moon (at First Quarter on March 9, 18h.) rises, 10h. 41m.; souths, 18h. 53m.; sets, 3h. 9m.*: right asc. on meridian, 6h. 7·2m.; decl. 21° 54′ N.

GEOGRAPHICAL NOTES.

M. ROLLAND, a French naturalist, charged with an official mission to Madagascar, has sent in his Report to the Minister of Public Instruction. M. Rolland sums up his geographical observations by remarking that, notwithstanding its apparently simple contour, the topography of Madagascar is exceedingly complex. Behind the line of lagoons which border the coast, and which, except that the water is salt, remind one of the *étangs* of Languedoc, the hills begin to rise, and increase in height towards the interior. Behind these, again, the mountains rise by stages to a height of over 6500 feet. The surface is cut up by innumerable ravines, at the bottom of which are torrents, which rush on their way towards the Indian Ocean. This chain forms the backbone of the island, and consists mainly of Primary and crystalline rocks. When it is crossed, the Mozambique Channel is reached. The two slopes, east and west, are very unequal in extent. The former, which M. Rolland has explored to a considerable extent, occupies more than one-third of the total area of Madagascar. A broad valley, that of the Mangoro, runs north and south, parallel to the great central chain and the coast. Unfortunately, the Mangoro is not navigable, even for canoes. The two other most important rivers are the Manangoro and the Mangataka; and these three rivers, with innumerable streams, render this part of the island one of the best-watered regions on the globe. The climate varies considerably from one zone to another. On the east coast the temperature oscillates between 13° and 30° C.; on the west coast, it never descends below 17°; in Imerina province it ranges from 5° to 25°. M. Rolland refers in some detail to the well-known characteristics of the fauna of Madagascar, and to the abundance of mineral treasures, especially iron, copper, and lead; but, he states, the natives carefully conceal the localities of the beds.

LIEUT. VANS AGNEW has undertaken a journey to the Upper Salween and South-Eastern Tibet, with the object of attempting the solution of the problem of the course of the Lu River—whether to the Irawadi or the Salween—propounded by General J. T. Walker in his paper read to the Royal Geographical Society on April 25, 1887. The Council of the Society have sanctioned a contribution of £100 towards the expenses of the expedition. Lieut Vans Agnew leaves India for the Salween in the course of the present month.

AT the February meeting of the Berlin Geographical Society Dr. A. Schenck read a report on his recent journey in Nama Land and Herero Land, South-West Africa. He showed that the whole country between Walfisch Bay and the Orange River is—in consequence of the purely mechanical decomposition of the prevailing granitic rock, which is taking place under the great daily variations of temperature, causing in many places the disintegrated surfaces to be eaten away in the form of a crust—covered over with a sea of sand and granitic shingle, from which the highest elevations stand out like islands. The country is not suited for agricultural colonies. The coast and the interior stand in contrast with regard to the season of rainfall. While on the coast the rain falls mostly in winter, the rainfall in the interior occurs only in summer, and nearly always in the form of thunder-showers, which, as Dr. Schenck believes, are caused by the condensation of the moisture-laden air, which is brought to this part by the warm, humid, north-east winds from the more equatorial regions of Africa, through coming into contact with the cool south-west winds blowing from the coast to the interior. As to the configuration of Great Nama Land, Dr. Schenck gives the following notes. After the hilly coast-region between Angra Pequena and Aos is passed, a broad valley-like depression is reached, filled up with drift-sand. East of the depression the country ascends and forms a stony, desolate plain, out of which rise isolated peaks or longer mountain-chains running in a north and south direction. The whole of this district, as far as Aos, forms a connected mountain system composed of ancient rocks, granite, and gneiss, which has been buried by the sand from which the higher parts stand out. Beyond Aos the traveller enters upon the steppe region, which is divided into detached plateau districts. Beyond Aos and the river-bed of the Goägib, on which the station of Bethanien is situated, the Huib plateau stretches away to the north, as far as the region of Khuias, and to the south to a point a few miles north of the Orange. A long series of table-mountains, resembling in form truncated cones, mark the western escarpment of this plateau; the former are composed of granite and gneiss, and are covered with limestone and sandstone, horizontally laid down. East of Bethanien, and corresponding with the line of a long geological fault, is the escarpment of another plateau; it is about 5000 feet in height. It descends to the Great Fish River on the east; on the other side of the river, the plateau character of the country is continued to the Karas Plateau, which extends into the brush steppe of the Kalahari. Further details concerning this interesting region will be found in the March number of the Proceedings of the Royal Geographical Society.

THE FORCES OF ELECTRIC OSCILLATIONS TREATED ACCORDING TO MAXWELL'S THEORY. BY DR. H. HERTZ.[1]

II.

Note by the Translator.

IT is to be noted that Hertz follows the French system of wave-lengths and periods. Had I noticed this before the diagrams went to the engraver, I would have altered it, and interpreted his T as ½T, &c., throughout. As it is, I have left them everywhere as in the original. My elaborate attempt to evade a literal translation of *Doppelpunkt* was quite unnecessary. Prof. Karl Pearson has sent me a reference to Maxwell's definition of "double-point" in vol. i. Art. 129, first edition of "Electricity and Magnetism."—O. J. L.

In order now to ascertain the distribution of force for the remaining parts of space we may use graphic representation, constructing for definite times the lines of electric force, viz. the curves Q = const., for equi-distant values of Q.

Since Q itself is the product of two factors, of which one depends only on r, the other only on θ, the construction of these curves presents no great difficulty.

We decompose every value of Q for which we want the curve into two factors in different ways; we determine the angle θ for which $\sin^2 \theta$ is equal to the one factor, and by means of an auxiliary curve that value of ρ for which the function of ρ contained in Q is equal to the other factor; we thus get as many points as we please of the curve. When one attempts to carry out the construction one perceives many small processes which it would be prolix to detail here. We will content ourselves with examining the results of such construction, as exhibited in Figs. 1, 2, 3, 4.

These figures represent the distribution of force at the times $t = 0$, $\frac{1}{4}T$, $\frac{1}{2}T$, $\frac{3}{4}T$; and also, by suitable inversion of the arrows, for all future times which are similar multiples of $\frac{1}{4}T$. At the origin is shown, in the correct aspect and about of the right proportional size, the arrangement by which in our earlier experiments the oscillations were excited.

The lines of force are not indicated right up to the picture because our formulæ regard the oscillators as infinitely short, so in the neighbourhood of a finite oscillator they are insufficient.

Let us begin a study of the figures with Fig. 1. Here, when $t = 0$ the radiation is in the condition of its strongest development, but the poles of the straight oscillator are not electrically charged—no lines of force start thence. Such lines of force begin, however, now from the time $t = 0$ to start out from the poles; they are inclosed in a sphere which expresses the value $Q = 0$. In Fig. 1 this sphere is indeed still vanishingly small, but it enlarges itself quickly, and by the $t = \frac{1}{4}T$ it fills already the space R_1 (Fig. 2). The distribution of lines of force inside the sphere is approximately of the same kind as correspond to a static electric charge on the pole. The speed with which the spherical surface $Q = 0$ spreads out from the origin is at first much greater than $\frac{1}{A}$ [or "v"]; in fact, the latter velocity would only correspond to

[1] Translated and communicated by Dr. Oliver Lodge. Continued from p. 404.

the distance given in the figure as $\frac{1}{4}\lambda$ for the time $\frac{1}{4}$T. At infinitesimal distance from the origin the velocity of outspreading is indeed infinite.

This phenomenon it is which we represented in the old mode of expression by saying that along with the inductive action travelling with the velocity of light there was superposed an electrostatic force travelling with infinite speed.

We properly express this phenomenon in terms of our present theory when we remark that fundamentally the self-forming waves do not arise solely from processes occurring at the origin, but are influenced by the condition of the whole surrounding medium, which latter, according to Maxwell's theory, is the true seat of the energy. However this may be, the surface Q = 0 expands with a velocity which gradually reduces to $\frac{1}{A}$, and by the time $t = \frac{1}{4}$T it fills the space R_2 (Fig. 3). By this time the electrostatic charging of the pole is at its greatest development; the number of lines of force which start thence attains its maximum value.

With further increase of time no fresh lines of force protrude from the poles; rather, those already produced begin to withdraw back into the conductor, there to vanish as lines of electric force, their energy, however, being converted into magnetic energy.

Hence occurs a singular behaviour which in Fig. 4 ($t = \frac{3}{8}$T) is plainly to be recognized, at least in its beginning. The lines which have furthest removed themselves from the origin get

Fig. 1.

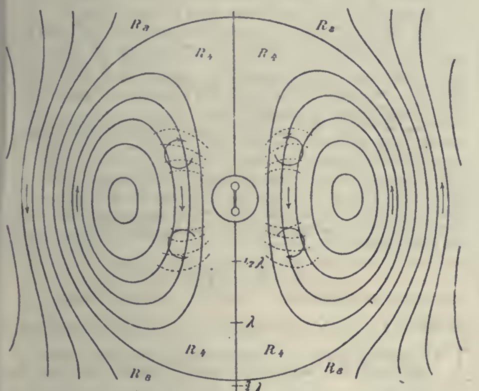

Fig. 2.

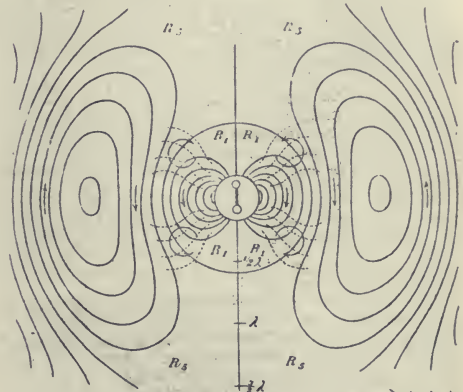

Fig. 4.

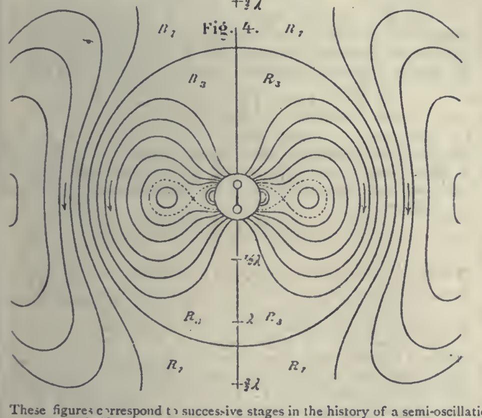

Fig. 3.

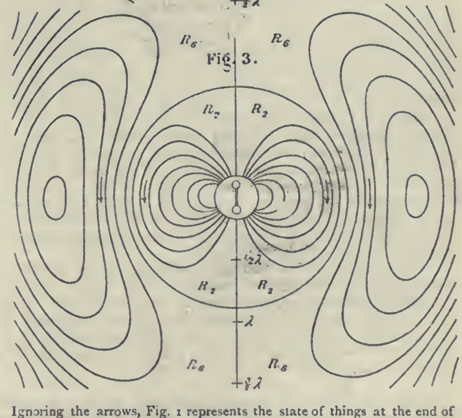


These figures correspond to successive stages in the history of a semi-oscillation. Ignoring the arrows, Fig. 1 represents the state of things at the end of every half-period; Fig. 3 at the end of every quarter-period; Figs. 2 and 4 represent one-eighth and three-eighths of a complete oscillation respectively. I do not feel clear about the correctness of the straight arrows in Fig. 1.

drawn together by the stress with a lateral inflexion; this inflexion approaches nearer and nearer to the axis of z; and then a self-closed portion detaches itself from each of the outer lines of force, which automatically spread out into space, while the residue sink back into the conductor.

The number of receding lines is just as great as the number of originally expanding lines; their energy, however, is necessarily diminished by the energy of the detached portion. This loss of energy corresponds to the radiation into space. In consequence of it the oscillation must soon come to rest unless some impressed forces restore the energy lost to the source. Meanwhile we have regarded the oscillations as undamped, and thus implicitly understood the existence of such forces.

In Fig. 1, to which we can now return for the time t = T, since we can imagine the arrows inverted, the detached portions of the lines of force fill the space R_4, while the lines starting from the poles have completely vanished. But new lines of force break out from the pole, and compress the lines whose early history we have followed into the space R_5 (Fig. 2).

It needs no further explanation now to follow these lines into the spaces R_6, R_7, and R_8. More and more they transform themselves into a pure transverse wave motion, and lose themselves as such in the distance. One would get the best picture of the play of force if one made a series of drawings for still smaller time-intervals, and examined them with a stroboscopic disk.

A closer consideration of the figures shows that the direction of the force changes from instant to instant for such points as lie either in the axis of z or in the plane xy. If we represent the force at a point, therefore, in the customary way by a line, the end point of this line oscillates, not indeed in a straight line, but in an ellipse. In order to see whether there are points for which this ellipse approximates to a circle, in which, therefore, the forces go through all the directions of a windrose without important change of magnitude, let us superpose two of the representations expressing times which differ by $\frac{1}{2}$T ; for instance, Figs. 1 and 3, or 2 and 4.

For the points we seek, the lines of the one set must plainly cut those of the other system orthogonally, and the distances of the lines of the one figure must be equal to those of the other. The small quadrangles formed by the superposition of the two systems must therefore be squares for the sought points.

There may be now remarked, in actual fact, a region of the kind sought: it is represented in Figs. 1 and 2 by circular arrows, whose directions give at once the direction of the rotation of the force. The dotted lines are inserted for convenience; they belong to the line system of Figs. 3 and 4.

One finds, moreover, that the force exhibits the behaviour here described, not only at the specified points, but also in the whole strip-formed region which, spreading out from those points, forms the neighbourhood of the z axis. Nevertheless, the magnitude of the force decreases so quickly in these directions, that only in the points above-mentioned can its singular behaviour be important.

The system of forces now described and required by theory can be quite well recognized in an incomplete observation, not hitherto indicated by theory, which I formerly described (*Wied. Ann.* xxxiv. p. 155, 1888). One cannot, indeed, explain everything about those experiments, but one can get the main points correctly.

By both experiment and theory the distribution of force in the neighbourhood of the oscillator is chiefly an electrostatic distribution. By both experiment and theory the force spreads out chiefly in the equatorial plane and decreases in that plane at first quickly, afterwards slowly, without being zero at a mean distance. By both theory and experiment the force, in the equatorial plane, in the axis, and at great distances, is of constant direction and varying magnitude, while at intermediate points it changes its magnitude but little and its direction much. The correspondence between theory and those experiments only breaks down in this, that at great distances, according to theory, the force remains always normal to the straight line through the source, while by experiment it appears to be parallel to the oscillator. For the neighbourhood of the equatorial plane where the forces are strongest this follows from the equations too, but not for directions which lie between the equatorial plane and the axis. I believe that the error is on the side of experiment. In these experiments the direction of the oscillator was parallel to both the main walls of the laboratory, and the component of the force which was parallel to the oscillator might be thereby strengthened in proportion to the normal components.

I have therefore repeated the experiment with a different arrangement of the primary oscillator, and found that with certain arrangements the result corresponds with theory. I did not attain an exact result, but found that at great distances, and in regions of small intensity of force, disturbances due to the boundary of the space available were already too considerable to permit a safe verdict.

While the oscillator is at work, the energy vibrates in and out of the spherical surfaces surrounding the origin. More energy goes out, however, through any spherical surface during an oscillation than comes back; and indeed the same excess quantity goes through all spherical surfaces. This extra quantity represents the loss of energy during the period of swing due to radiation. We can easily calculate its value for a spherical surface whose radius, ρ, is so great that it is permissible to employ a simplified formula. Thus the energy going out of the spherical zone between θ and $\theta + d\theta$ in the time dt will be—

$$2\pi\rho \sin\theta\, \rho d\theta\, dt . \frac{P}{4\pi A} (Z \sin\theta - R\cos\theta).$$

Putting into this the values of Z, P, and R, which are proper for great distances, and integrating from $\theta = 0$ to π, and from $t = 0$ to T, we get, as the energy going out through the whole sphere during every half complete swing,—

$$\tfrac{1}{3}E^2l^2m^3nT = \frac{\pi^4E^2l^2}{3\lambda^3}.$$

Let us try to obtain an approximate estimate of the amount of this corresponding to our actual experiments. In those we charged two spheres of 15 centimetres radius in opposite senses up to a spark length of 1 centimetre about. We may estimate the difference of potential between these spheres as 120 C.G.S. electrostatic units, so each sphere was charged to half this potential, and its charge was therefore E = 900 C.G.S. units.

The total store of energy which the oscillator originally possessed amounted to 60 × 900 = 54,000 ergs, or 55 centimetre-grammes. The length of the oscillators, moreover, was 1 metre approximately, and the wave-length was about 480 centimetres.

So the loss of energy in half a swing comes out about 2400 ergs. It seems, therefore, that after eleven half-swings one-half of the energy must have gone in radiation. The quick damping which the experiments made manifest was therefore necessitated by radiation, and could not be prevented even if the resistance of conductor and spark were negligible.

A loss of energy of 2400 ergs in 1·5/100,000,000 of a second means a performance of work equal to 22 horse-power. The primary oscillator must be supplied with energy at at least this rate if the oscillation is to be permanently maintained at constant intensity in spite of the radiation. During the first few oscillations the intensity of the radiation at about 12 metres distant from the vibrator corresponds with the intensity of solar radiation at the surface of the earth.

(To be continued.)

GENERAL EQUATIONS OF FLUID MOTION.

THE general equations of the motion of a fluid can all be comprehended in a single form, which seems to be deserving of special notice.

Taking the ordinary notation, u, v, w, for the velocity-components at any point, P, of the fluid at any instant, and denoting the components of vortical spin at the point by ω_1, ω_2, ω_3, the usual Cartesian equations can be at once put into the form—

$$\frac{du}{dt} + \frac{d}{dx}\left(\tfrac{1}{2}q^2 + \int\frac{dp}{\rho}\right) + 2(w\omega_2 - v\omega_3) = X,$$

and two analogues, q being the resultant velocity. If through the point P we draw any curve whatever, the direction-cosines of whose tangent are l, m, n, and multiply the above and its two analogues, respectively, by l, m, n, we obtain by addition the equation—

$$\frac{d\dot{s}}{dt} + \frac{dU}{ds} + 12\Delta = S \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (a)$$

in which $\dot{s}$ stands for the component of velocity along the tangent to the curve, $U = \frac{1}{2}q^2 + \int\frac{dp}{\rho}$, S = component of external force-intensity along the tangent, and Δ is the volume of the tetrahedron formed by the vector drawn at P to represent q, the resultant velocity, the vector drawn to represent Ω, the resultant vortical spin, and the vector representing a unit length along the tangent to the curve at P. (Strictly speaking, the notation $\dot{s}$ is not a good one, but it is the best that presents itself.)

This equation (a) is that which I propose, as typical of all fluid motion, and as including all the special Cartesian equations in current use.

Some simple results follow at once for the case of steady motion. Thus, if we integrate (a) between any two points, A, B, of the curve,

$$U_B - U_A + 12\int\Delta ds = \int S ds \quad . \quad . \quad . \quad . \quad (1)$$

where U_B and U_A are the values of U at B and A.

Now, in particular, if the curve drawn at P is a stream-line, $\Delta = 0$ at every point of it; also, if the curve is a vortex-line, $\Delta = 0$ at every point, and we have the simple result,

$$U_B - U_A = \int S ds \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

a result which has long been known for a stream-line, but, apparently, not so long known for a vortex-line. It holds also for an infinite number of curves that can be drawn through P, all lying on a certain surface, as is pointed out by Lamb ("Motion of Fluids," p. 173), the surface in question being formed of a network of stream- and vortex-lines. That such surfaces exist in the fluid when the external forces have a potential, is proved most satisfactorily by taking the integral of (α) along a circuit through P, of which a part consists of stream-line and a part of vortex-line; but into the details of this we need not enter.

I observe, also, that this equation (2) holds for the portion of any curve whatever connecting any two points, A, B, on a network surface, although this curve does not lie on the surface.

Another point to which I would call attention is an analytical expression of the state of non-vortical motion. The physical expression has, of course, reference to the non-rotation of the three principal axes of the little ellipsoid into which, at each instant, a small sphere is deforming. The analytical expression of the fact takes usually the form that there is a velocity potential, *i.e.* $\frac{du}{dy} = \frac{dv}{dx}$, with two Cartesian analogues. Here, again, I would suggest a single equation, having no reference to special axes. This equation is simply

$$\frac{d\dot{s}}{d\sigma} = \frac{d\dot{\sigma}}{ds} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (\beta)$$

where s and σ denote arcs of *any two curves whatever* drawn at the point P, and $\dot{s}$ and $\dot{\sigma}$ the component velocities of the fluid along them.

It is obvious that these contain the whole three of the usual Cartesian expressions. The proof is very easy.

Cooper's Hill. GEORGE M. MINCHIN.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The following Examiners in Natural Science have been appointed for the Honour Examinations:—Mr. J. V. Jones and Mr. A. L. Selby (Physics); Prof. McLeod and Mr. V. H. Veley (Chemistry); Prof. Milnes Marshall and Mr. W. Hatchett Jackson (Morphology); Prof. Sanderson and Prof. Schäfer (Physiology); Prof. Boyd Dawkins and Prof. Green (Geology).

The conditions of tenure of the Burdett-Coutts Geological Scholarship are to be altered, so as to make it necessary for the holders to devote themselves to Geology, and to work with the Professor.

Scholarships in Natural Science are announced for competition at Merton and at New College. The examination begins on July 2.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 21.—"The Influence of Bile on the Digestion of Starch. (1) Its Influence on Pancreatic Digestion in the Pig." By Sidney Martin, M.D., B.Sc., British Medical Association Scholar, and Dawson Williams, M.D. (From the Physiological Laboratory, University College, London.)

The experiments of the authors have shown that if pig's bile be added to a solution of starch with pancreatic extract the digestion goes on with greater rapidity than without the bile. The rapidity of digestion is increased with the addition of quantities up to 4 per cent. of dried bile (equivalent to at least 30 per cent. of fresh bile). The rapidity was tested by noticing when the iodine reaction of starch had disappeared. On further research, it was found that this property of the bile depended on the bile salts (hyoglycocholate of sodium). The increased rapidity of digestion was well seen if 0·6 to 2 per cent. of bile salts were added to the digestive mixtures.

It was also found that not only was the change of starch into dextrine hastened, but also the change into sugar; and that the amount of dextrine and sugar formed when bile-salts wer present was one-fifth more than when they were absent. Fo the methods used in estimating the amount of dextrine and sugar, the original paper must be consulted.

"The Innervation of the Renal Blood-vessels." By J. Rose Bradford, M.B., D.Sc., George Henry Lewes Student. Communicated by E. A. Schäfer, F.R.S. (From the Physiological Laboratory of University College, London.)

The research was undertaken in order to map out the origin, cause, and nature of the renal nerves in the dog more accurately than had hitherto been attempted. The method employed consisted in exciting the roots of the spinal nerves, and observing simultaneously the effects produced on the general blood-pressure and on the volume of the kidney, the latter being investigated by means of Roy's oncometer. The anæsthetics used were chloroform and morphia. The general results were shortly as follows:—

No efferent vasomotor fibres were found in the posterior roots.

The efferent vasomotor fibres for the blood-vessels of the kidney leave the cord in the anterior roots of the nerves, extending from the second dorsal to the second lumbar. The renal nerves are, however, most abundant in the tenth, eleventh, twelfth, and thirteenth dorsal nerves.

In individual cases, however, there may be small variations in the number of fibres going on the one hand to the kidney, and on the other hand to the other abdominal viscera.

When quick rates of excitation are used, only contraction of the kidney and increase of general blood-pressure are observed, *i.e.* the vaso-constrictor fibres are excited.

With slow rates, however, expansion of the kidney with no increase of blood-pressure occurs, *i.e.* the vaso-dilator fibres are stimulated.

Hence the renal vessels not only receive constrictor fibres, but also dilator, and these are also most abundant in the eleventh, twelfth, and thirteen dorsal nerves.

Similarly when the peripheral end of the divided splanchnic nerve is excited with slow rates, a fall of blood-pressure is observed instead of the rise seen with quick rates.

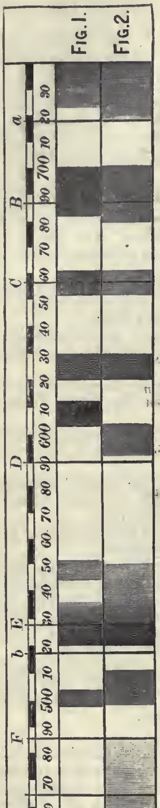
Hence the splanchnic contains not only vaso-constrictor fibres for the abdominal vessels, but also vaso-dilators.

The results of reflex excitation can be summed up shortly by saying that the excitation of an afferent nerve causing a rise of blood-pressure is accompanied by a renal contraction, unless the nerve is one of what may be called the renal area. In this case the rise of blood-pressure is accompanied, as a rule, by either a renal expansion or else by a mixed kidney effect.

The main conclusion of this communication is the demonstration of dilator fibres in the splanchnic and in the renal nerves, and also the fact that these vaso-dilator fibres reach the kidney by the same paths as the constrictor fibres.

Chemical Society, February 7.—Mr. W. Crookes, F.R.S., in the chair.—The following papers were read:—Researches on the constitution of azo- and diazo-derivatives; compounds of the naphthalene-β-series (continued), by Prof. R. Meldola, F.R.S., and Mr. G. T. Morgan.—The action of nitric acid on anthracene, by Mr. A. G. Perkin. Hitherto, only anthraquinone and nitro-anthraquinones have been obtained by treating anthracene with nitric acid; the author, however, finds that nitro- and dinitro-anthracene can readily be prepared by the action of nitric acid upon anthracene if care is taken at once to decompose any nitrous acid which may be formed.—The preparation of glyceric acid, by Dr. Lewkowitsch.—The relation of cobalt to iron as indicated by absorption-spectra, by Dr. W. J. Russell, F.R.S., and Mr. W. J. Orsman, Junr. It is well known that when examined spectroscopically, some coloured metallic compounds are found only to produce a general absorption, but from previous observations it seemed possible to the authors that in some cases at least this might be resolved into bands by employing more powerful chemical agents than are generally used in such cases; experience had indicated that the chloride is usually the most suitable salt, and that it should be dissolved in chlorhydric acid and the liquid saturated with hydrogen chloride, also that, if possible, ether should be taken as solvent. Applying these views to iron, it was found that ferric chloride gave a banded spectrum strikingly similar to that of cobalt chloride. Irons of all kinds were examined: pig-iron, commercial cast-iron, and various manufactured articles; steel in the form of

wire, needles, and knives; and a number of specimens of reputed pure iron, viz. Demidorff's sheet-iron, a sample of which was kindly given to the authors by Mr. Crookes, electro-deposited iron, and some ancient Indian iron from Prof. Roberts-Austen, and iron prepared by the late Dr. Matthiessen. Also a large number of iron ores—hæmatite Elba ore, Welsh bog ore, micaceous ore, ordinary spathic ore, a spathic ore found in cryolite, for which the authors have to thank Dr. Müller; Giderite, pyrites from the chalk, wolfram and rouge. Iron was also separated from the ignited residue of blood. All the specimens examined gave the same result. Fig. 1 represents the bands seen in a solution of cobalt chloride to a scale of wave-lengths; the three most refrangible bands are easily photographed, but are not visible to the eye under ordinary conditions. The iron spectrum (Fig. 2) in general appearance closely resembles the cobalt spectrum, but the band which in cobalt is at 605 is slightly shifted nearer the blue, as shown in the diagram; there appears also to be a shift in the 501 band, but in the opposite direction. It was found that ether always dissolves out of the ferric chloride a substance which gave a band of extraordinary intensity, exactly agreeing in position with the 530 band in the cobalt spectrum; further, that on increasing the strength of the ethereal solution, other bands became visible, agreeing with the bands observed in the strong chlorhydric solution of ferric chloride, and differing only in the case of the 690 and 655 bands, which in the ethereal solution were nearer the blue. Fig. 2 is the spectrum observed in a solution of iron in chlorhydric acid, peroxidized by any ordinary means. For a variety of reasons the authors believe that this spectrum (Fig. 2) does not arise from the presence of cobalt in the iron. In the first place, there is a constant difference between the two spectra, as shown in the position and appearance of the band at 597. A trace of cobalt dissolved along with the iron gives the same spectrum as pure cobalt dissolved in chlorhydric acid. Again, on gradually increasing the strength of a pure cobalt chloride solution, the bands in the red are the first to appear, and the band at 530 is not visible until the general absorption has crept up as far as 580, completely blocking up the red end of the spectrum; in an ethereal solution from iron, on the contrary, this 530 band is the first to appear, and the bands in the red only become visible in comparatively strong solutions. Ether extracts the band-giving substance from the ferric chloride with great ease; but it abstracts nothing from the cobalt chloride. Again, on dissolving iron in chlorhydric acid, no bands are visible, and so long as the iron is in the ferrous state even ether extracts no band-giving substance; but on converting the ferrous into ferric chloride by nitric acid, or potassium chlorate, &c., the band-yielding substance is at once apparent. A known weight of Mr. Crookes's Demidorff iron was converted into chloride and dissolved in a known volume of ether, and the intensity of the bands compared with those given by cobalt chloride dissolved in a similar bulk of chlorhydric acid; it was found that approximately it required a weight of cobalt equal to that of the iron to give bands of similar intensity. Prof. J. Norman Lockyer, F.R.S., said that some years since, in a paper communicated to the Royal Society, he had suggested that there were many different molecular groupings of the same element possible, and that spectrum analysis would disclose these: if the same molecular grouping were demonstrated in several substances, then undoubtedly there was a common constituent. If the bands described by the authors represent a substance common to iron and cobalt, it should be possible to obtain spectroscopic evidence of its presence at some temperature on volatilizing the metals; although he had not fully studied cobalt and nickel comparatively, he had, in fact, found that under certain special conditions some of the spectroscopic appearances were common to both, and in such a marked degree as to render it improbable that they were caused by impurities. Dr. Perkin referred to the non-appearance of bands in an alcoholic solution of purpurin and their appearance in an ethereal solution, as an illustration of the influence of the solvent. Prof. Armstrong remarked that the slight shift of the bands which had been referred to did not necessarily indicate that different substances were primarily the cause of the absorptions, as it is well known that such effects were observed on employing different solvents; the absorbing substance might in the one case be held in combination more firmly than in the other; this view was in harmony with the statement that ether did not extract the band-yielding subtance in all cases. Dr. Russell in reply said that not the spectrum as a whole, but only one of the bands was shifted. His view was that the solvents had broken up the substance into a finer state.—Note on methyl fluoride, by Dr. N. Collie. Methyl fluoride assumes the critical state at 44°·9 C. and at a pressure of 47,123 mm. This pressure is probably slightly too high, owing to a trace of air, and the temperature too low. The error in pressure probably does not exceed 1500 mm., and of temperature 0°·2 C.—The nitration of naphthalene-β-sulphonic acid, by Prof. H. E. Armstrong, F.R.S., and Mr. W. P. Wynne. According to Cleve three isomeric α-nitro-β-sulphonic acids are produced on nitrating naphthalene-β-sulphonic acid; the chlorides of which melt respectively at 169°, 140°, and 125°. The authors find, contrary to the view put forward provisionally by Cleve (*Ber. der Deut. Chem. Gesells.*, xxi. 3275), that the first compound is a heteronucleal derivative and corresponds in constitution with the dichloronaphthalene melting at 63°·5. All attempts to obtain the sulphochloride of intermediate melting-point have been unattended with success.—Action of bromine and chlorine on the salts of tetrethylphosphonium, by Prof. O. Masson and Mr. J. B. Kirkland.—Preparation of the salts of triethylsulphine, tetrethylphosphonium, and analogous bases, by the same.



Linnean Society, February 21.—Mr. Carruthers, F.R.S., President, in the chair.—Mr. George Murray exhibited a fossil Alga, *Nematophycus Logani*, Carr.—Mr. G. C. Druce exhibited some rare British plants from Scotland, amongst which were *Calamagrostis borealis*, *Ranunculus acris*, var. *pumilus*, and *Bromus mollis*, var. *decipiens*.—Prof. Marshall Ward exhibited a sclerotium of a Fungus produced from a Botrytis spore, and explained the method by which it had been obtained.—A paper was then read by Mr. F. Townsend, M.P., on *Euphrasia officinalis*, with a description of a new sub-species, and a discussion followed, in which the President, Mr. J. G. Baker, and others took part.—In the absence of the author, a paper by Mr. C. T. Druery, on sexual apospory in *Polystichum angulare*, was read by the Botanical Secretary, Mr. B. D. Jackson, upon which remarks were made by Mr. Murray and Dr. D. H. Scott.—Mr. Murray then gave the substance of a paper on a new genus of Green Algæ, proposed to be named *Boodlea*, and in so doing made some instructive observations on the affinities and distinguishing characters of allied genera. The paper was criticized by Messrs. A. W. Bennett, Reay Greene, and D. H. Scott.—In continuation of his researches upon the eyes of insects, Mr. B. T. Lowne gave an admirable exposition of the structure of the retina in the blow-fly, illustrated by preparations under the microscope, and some excellent photographs.

Geological Society, February 15.—Annual General Meeting.—Dr. W. T. Blanford, F.R.S., President, in the chair.—The Secretaries read the reports of the Council and of the Library and Museum Committee for the year 1888. The Council stated

that they had once more to congratulate the Fellows upon the prosperous state of the Society's affairs. The report of the Library and Museum Committee, after enumerating the additions made to the Society's Library and collections during 1888, referred briefly to the work done in the Museum, in the way of cleaning and putting it in order.—The President then presented the Wollaston Gold Medal to Prof. T. G. Bonney, F.R.S.; the Murchison Medal to Mr. William Topley, F.R.S., for transmission to Prof. James Geikie, F.R.S.; the Lyell Medal to Prof. W. Boyd Dawkins, F.R.S.; the Bigsby Medal to Mr. J. J. Harris Teall; the balance of the proceeds of the Wollaston Fund to Mr. A. Smith Woodward; the balance of the Murchison Geological Fund to Mr. Grenville A. J. Cole; and the balance of the proceeds of the Lyell Geological Fund to M. Louis Dollo.—The President read his Anniversary Address, in which, after giving obituary notices of Mr. W. Hellier Baily, Mr. H. Carvill Lewis, Vice-Admiral T. A. B. Spratt, Viscount Eversley, Mr. John Brown, Mr. W. Ogilby, and other deceased Fellows, together with notices of the Foreign Members and Correspondents of the Society who had died since the last anniversary meeting (Prof. Gerhard Vom Rath, Prof. T. Kjerulf, Prof. Giuseppe Meneghini, and Prof. Giuseppe Seguenza), he noticed the papers which had been published by the Society during the past year. The remainder of the address consisted chiefly of a discussion of the work of the International Congress from its commencement to the last meeting in London in 1888, and dwelt upon the influence which such meetings exercise upon the progress of geological science, quite apart from any formal resolutions which may be arrived at by the members.—The ballot for the Council and Officers was taken, and the following were duly elected for the ensuing year:—President: Dr. W. T. Blanford, F.R.S. Vice-Presidents: Dr. John Evans, F.R.S., Prof. T. McKenny Hughes, Prof. J. W. Judd, F.R.S., Prof. J. Prestwich, F.R.S. Secretaries: Mr. W. H. Hudleston, F.R.S., Mr. J. E. Marr. Foreign Secretary: Sir Warington W. Symth, F.R.S. Treasurer: Prof. T. Wiltshire. Council: Prof. J. F. Blake, Dr. W. T. Blanford, F.R.S., Prof. T. G. Bonney, F.R.S., Mr. James Carter, Dr. John Evans, F.R.S., Mr. L. Fletcher, Dr. A. Geikie, F.R.S., Prof. A. H. Green, F.R.S., Rev. Edwin Hill, Mr. W. H. Hudleston, F.R.S., Prof. T. McKenny Hughes, Prof. J. W. Judd, F.R.S., Major-General C. A. McMahon, Mr. J. E. Marr, Mr. E. T. Newton, Prof. J. Prestwich, F.R.S., Mr. F. W. Rudler, Prof. H. G. Seeley, F.R.S., Sir Warington W. Smyth, F.R.S., Mr. W. Topley, F.R.S., Rev. G. F. Whidborne, Prof. T. Wiltshire, Rev. H. H. Winwood.

Zoological Society, February 19.—Dr. St. George Mivart, Vice-President, in the chair.—Mr. Sclater exhibited specimens of the eggs and chicks of the Hoatzin (*Opisthocomus cristatus*) from a series collected by Mr. R. Quelch in British Guiana, and called attention to the extraordinary development of the wings in the chick, in reference to the statement that these organs are used like hands for climbing-purposes.—Mr. Sclater exhibited heads and skins of a new Antelope obtained by Mr. H. C. V. Hunter, in Eastern Africa, which he proposed to call *Damalis hunteri*, after its discoverer.—Sir E. G. Loder, Bart., exhibited and made some remarks on a skeleton of the Rocky Mountain Goat (*Haplocerus montanus*).—Dr. Günther exhibited a mounted specimen of Thomson's Gazelle (*Gazella thomsoni*), and pointed out its complete distinctness from Grant's Gazelle (*Gazella granti*). The specimen in question had been obtained in Masai-land by Mr. H. C. V. Hunter.—Mr. R. Lydekker read a paper on the skull of *Lytoloma*, an extinct genus of Chelonians allied to *Chelone*.—Mr. R. Lydekker pointed out the characters of an apparently new species of *Hyracodontotherium*, based on specimens from the phosphorites of Bach, near Lalbengue, in France.—Dr. A. Günther, F.R.S., described some new fishes from the Kilima-njaro district in Eastern Africa, based on specimens obtained by Mr. F. J. Jackson during his recent expedition into that country. He also exhibited a dried specimen of a fish obtained by Mr. H. C. V. Hunter from one of the crater-lakes in the same district, which he referred to a new genus and species of Chromidæ, proposed to be called *Oreochromis hunteri*.—Dr. Günther also exhibited a pair of horns of an Antelope obtained many years ago in the interior of Southern Central Africa, which were remarkable for their length and gentle backward curvature, with only a very slight twist near the tips. He referred these horns to a new species, proposed to be called *Antilope triangularis*.—Dr. Günther read some notes on a Bornean Porcupine, which he had formerly described as being without a tail, and named *Trichys lipura*. It now appeared that some specimens of this animal possessed a long and slender tail, but that other characters would necessitate the retention of the genus as distinct from *Atherura*.—Mr. F. E. Beddard read a paper directing attention to certain points in the anatomy of the Accipitres with reference to the affinities of *Polyboroides*. This form was shown to belong to the Falconidæ, and to have no real affinities with *Serpentarius*.—Sir Walter Buller read a paper on a species of Crested Penguin from the Auckland Islands, based on a specimen lately living in the Society's Gardens, which he proposed to call *Eudyptes sclateri*.

Anthropological Institute, February 26.—Dr. J. Beddoe, F.R.S., President, in the chair.—Mr. Francis Galton exhibited a new instrument for testing the delicacy of perception of differences of tint; also an instrument for telling reaction time. Both instruments will be exhibited in the Paris Exhibition.—Major C. R. Conder, R.E., read a paper on "The Early Races of Western Asia."

EDINBURGH.

Royal Society, February 4.—The Rev. Prof. Flint, Vice-President, in the chair.—Prof. T. R. Frazer read a paper on the natural history, chemistry, and pharmacology, of *Strophanthus hispidus*.—Mr. John Aitken exhibited and described his improved apparatus for counting the dust particles in the atmosphere.—Prof. Rutherford read a paper by Dr. G. N. Stewart, on the electrotonic variation in nerve with strong polarizing currents.

February 18.—Dr. Thomas Muir, Vice-President, in the chair.—Prof. Crum Brown communicated a paper by Mr. Alex. Johnstone, on the prolonged action of sea-water on pure natural magnesium silicates.—A paper by Dr. A. B. Griffiths on the so-called liver of *Carcinus mænas* was also read.—Dr. Muir communicated a paper by Mr. Alex. M'Aulay, Melbourne, on the differentiation of any scalar power of a quaternion, and a note by Prof. Tait on Mr. M'Aulay's paper.—Prof. Crum Brown read an account by Mr. Albert Campbell of the change in the thermo-electric properties of Wood's fusible metal at its melting-point.—Prof. Brown also read a paper by Mr. Frank Beddard on the anatomy and physiology of *Phreoryctes*.

PARIS.

Academy of Sciences, February 25.—M. Des Cloizeaux, President, in the chair.—Note on the question, whether their original infectious properties can be recovered by pathogenic microbes, which have apparently preserved nothing beyond the power of vegetating outside the living animal organism, by M. A. Chauveau. In continuation of his recent communication (*Comptes rendus*, cviii. p. 319), the author here describes some experiments which show that, in *Bacillus anthracis* apparently deprived of all infectious virulence, this virulence may be as easily restored as the simply diminished virulence is renovated in M. Pasteur's attenuated microbes. It results generally from these studies that in losing or recovering their virulence pathogenic microbes undergo no specific transformation. These physiological metamorphoses are merely an extension of the law well known to botanists that the conditions of culture may modify not only the form, but also and specially the functions of plants.—On some points in the theory of the sextant, by M. Gruey. The points here discussed are (1) the possibility of constructing the sextant with a single glass, which is decided in the affirmative, a means being indicated by which the practical inconvenience of such an instrument may be obviated; (2) the use of the transparent part of the small glass. This is suppressed by some, preserved by others, and M. Gruey considers that it is in fact useless.—On a question in the doctrine of probabilities, by M. E. Mayer. A solution is here proposed of M. Bertrand's 57th problem, dealing with the case of two players with equal chances and equal capital, and the probability of one ruining the other in a given number of throws.—Remarks on the conductivity and mode of electrolysis of concentrated sulphuric acid solutions, by M. E. Bouty. The main object of these experiments is to measure the molecular conductivity of sulphuric acid at or about the temperature of 0° C. An attempt is also made to determine the coefficients of temperature α and β in the formula—

$$C_t = C_0(1 + \alpha t + \beta t^2).$$

—On the electro-chemical measurement of the intensity of currents, by M. A. Potier. Arguments are advanced to show that the electrolytic measurement of intensity cannot be regarded

as rigorously accurate except on the condition of the electrodes presenting no trace of polarization. This condition is generally supposed to be strictly complied with when the electrodes are formed of molten metals; but the present researches prove that such is not always the case.—On the reciprocal influence of two rectangular magnetizings in iron, by M. Paul Janet. A piece of iron being magnetized in a given direction by a given magnetic force, the author inquires whether this magnetic state becomes modified by the establishing or interrupting a fresh magnetic current perpendicular to the first.—On drops of mercury as electrodes, by M. Ostwald.—A correction as regards the action of sulphurous acid on the alkaline thiosulphates, by M. A. Villiers. In a previous note (*Comptes rendus*, cvi. pp. 851 and 1354) the author described the sodium salt of a new oxy-acid of sulphur as obtained by the action of sulphurous acid on the sodium thiosulphate, and as having the formula $S_4O_8Na_2$. But he has since discovered that this salt contains two atoms of hydrogen, so that its formula is $S_4O_8Na_2H_4 = S_4O_6Na_2.2H_2O$; that is to say, it is hydrated tetrathionate of soda.—On the valency of aluminium, by M. Alphonse Combes. The vapour-density of $Al(C_5H_7O_2)_3$ at 360° in an atmosphere of nitrogen was found to be 11·25, agreeing with the above formula. Its valency at this comparatively low temperature therefore shows its analogy with indium and other triad elements.—Combination of mannite with the aldehydes of the fatty series: ethylic acetal, by M. J. Meunier. Two processes are described, by means of which the ethylic acetal of mannite may easily be prepared. The combination of mannite with an aldehyde of the aromatic series (benzoic aldehyde) has already been studied. It now appears that an acid solution of mannite, mixed with equal molecular weights of acetic and benzoic aldehydes, yields ethyl acetal, and not an acetal resulting from the simultaneous combination of the two aldehydes.—M. A. Haller describes the preparation of some new neutral and acid ethers of the camphols, and also gives an easy process for the separation of camphor and camphol.—M. Aimé Girard reports the results of some protracted experiments on the cultivation of the potato in France, with a view to the selection of the best tubers, and a more abundant yield of starch-producing roots.—M. G. Hayem studies the causes of the fatal effects resulting from the transfusion of blood between animals of different species, and more especially from the injection of dogs' blood in the rabbit.—The porphyritic rocks of Cavenac, near Saint-Pons, are described by MM. P. de Rouville and Auguste Delage; and those of the Forez district by M. U. Le Verrier.—M. Ed. Piette gives an account of some human and animal remains representing a transitional epoch between Quaternary and modern times, recently discovered by him in a cave on the left bank of the Arize.

Astronomical Society, February 6.—M. Flammarion in the chair.—M. Guiot, of Soissons, sent observations of Uranus made with the naked eye, and of Neptune with an opera-glass.—M. Schmoll showed diagrams of solar activity during 1888. He had noted 190 days without spots. M. Bruguière placed the minimum at 1888·8. MM. Lihou and Jacquot sent some remarks on the same subject.—M. Flammarion read a paper on γ Arietis, calling attention to the remarkable relative fixity of the two components. His measures at Juvisy gave 8″·51 and 359°·1.—M. Ch. Moussette made some remarks on the lunar eclipse of January 17.—General Parmentier read a note on the planetoids discovered in 1888, and showed that they confirmed the classification of those bodies which he published a few years ago.—M. Gunziger exhibited some Thompson's disks, and showed their utility for drawing and accurately placing sun-spots.

STOCKHOLM.

Royal Academy of Sciences, February 13.—Sir Joseph Lister was elected a Foreign Member of the Academy.—Prof. Wittrock gave an account of the present state of the Bergian Garden belonging to the Academy.—An examination of some Algæ referred to the genus Adenocystis, Hooker fil. et Harvey, by Prof. F. R. Kjellman.—Contributions to the flora of Medelpad, by Dr. L. M. Neuman.—Report on investigations relating to the flora and fauna of the peat-bogs of Scania, by Herr G. Andersson.—Report on investigations relating to the Ascomycetes, especially the coprophilous, of Öland, by Herr C. Starbäck.—A special case of the problem of three bodies, by Prof. Gyldén.—On Odonatæ collected during the Swedish Expedition to Yenisei in 1876, by Dr. F. Trybom.—*Ichneumones pneustici*, by the late Lector A. E. Holmgren.—An experiment with an electric spark and a small flame, by Dr. C. A. Mebius.—Prof. Nilsson gave an account of the researches of Dr. Krüss on cobalt and nickel.—On the singular points of the common algebraic differential equations, by Dr. J. Möller.—On maximi and minimi convergents of a certain class of distinct integrals, by Herr C. B. Cavallin.—On naphtoë acids, &c., by Dr. Ekstrand.—On the b^1-b^2-brom-naphthalin-sulphon acid, by Herr Forsling.—On the reaction of the fuming sulphuric acid on a^1-b^1-chlor-naphthylamin and on a^1-b^1-chloracetnaphthalid, both combined with hydrochloric acid, by Herr P. Hellström.

THURSDAY, MARCH 14, 1889.

THROUGH THE HEART OF ASIA.

Through the Heart of Asia: Over the Pamir to India. By Gabriel Bonvalot. Translated from the French by C. B. Pitman. (London: Chapman and Hall, 1889.)

THIS is a translation of the account of a very remarkable journey taken in the year 1886 by M. Bonvalot through Central Asia. It is not the first time that M. Bonvalot has traversed that region, for in the years 1880–82, accompanied by M. Capus, and starting from Moscow, he entered Turkestan from Siberia, explored part of Bokhara and the mountains of Kohistan and Chitral, and returning home by Samarcand and Bokhara, descended the Amu-daria to Khiva, and finally crossed the desert of Ust-Urt in the depth of winter. That journey, however, only embraced the country north of the Oxus, and the present one was undertaken to complete the exploration of Central Asia. Shortly speaking, the latter journey—that of which this work treats—began at Batum, whither MM. Bonvalot and Capus had gone by ship from Marseilles, and continued through the Caucasus along the south-west shore of the Caspian Sea into Persia, thence into Bokhara. At Chitral, on the borders of Afghanistan, they were detained as prisoners by Ishak Khan, of whom we have heard so much lately. He was then in revolt against Abdurrahman, and his captives were not released till the Indian Government interfered on their behalf.

There is very much to interest us in M. Bonvalot's account of the feelings of the native tribes in that vast region towards England and towards Russia, but that we shall pass over, merely pointing out what is most important from a geographical or ethnological point of view in the work. At Adshi-Cabul, which is on the south-west shore of the Caspian, he says that the population is Turkish, though the country is Tartar. The men are tall, with good features, and are plainly a mixture of Caucasian and Persian. Their dress differs from that of other Mahometans in that the tight-fitting upper garments with long skirts are not frequently seen; they seldom reach below the knee, and are often open at the breast. The head-dress is higher and broader at the top than the usual Mahometan head-dress, and in place of high boots they wear broad slippers or sandals, with very large wooden heels and curled-up toes. The feet are bare, and are covered with woollen socks, which have fantastic coloured figures worked on them. It was the festival of the New Year when the travellers arrived at Adshi-Cabul, and the whole place was *en fête*. The Mahometans of the region on such occasions dye their hands, beard, and hair a bright red, with henna. The Turkish language was the only one spoken there, but a few stages further on it seemed as if a new world was reached, where the Russian tongue, Russian fashions, Russian cattle and horses, were everywhere. This, it appears, was due to the descendants of a body of Russian settlers, called Malakanes, who had left their homes on account of their religion, but it is not quite clear in what respect they differed from the orthodox Russian Church. The country—that is, the region north-west of Resht—is wonderfully fertile, but the inhabitants suffer terribly from fevers. The waters swarm with duck, teal, herons, and cormorants; eagles and foxes abound there.

Further on, still on the shores of the Caspian, may be seen "all the birds of creation." Generally speaking, the ground held by the Tartars is badly cultivated: the men are incorrigible idlers, lying in the fields while the women sow the seed; and in harvest-time, instead of gathering in the crops themselves, they sell them as they stand in the fields to the mountaineers for about a third of their value. Though there is an abundance of good timber at hand, they live in wretched hovels with thatched roofs, or in huts made of reeds, with a thin facing of mud, and in the coldest weather prefer to lie shivering in their huts to gathering the firewood which lies almost at their hand. They are badly clad, and, as has been said, suffer terribly from the fevers that are so prevalent. A little further south, towards the confines of Persia, though the month was March, the foliage and the flowers were marvellous: wild pomegranate trees and wild briars growing under acacias and beeches were well covered with leaves; anemones, violets, and daisies bloomed everywhere. At Chifa Rud, near Resht, Talichi, a peculiar Turkish dialect is spoken, but some of the people also use Guilek. Rice and fish, of which there is abundance, are the food of the inhabitants, bread being unknown. From Teheran the travellers journeyed to Meshed, travelling almost due east, and skirting the Great Salt Desert, which presented the appearance of heaps of sand that had been lately washed by the waves of the sea. The journey through the mountains at this part was very trying. The sun was scorching, and there was not the slightest shelter to be had. The River Tchaï flows through the valley which they traversed, and was the only thing in motion in the whole region. The waters of the river are salt. Dehinemek (the "Salt Village") consists of only a few houses, and the inhabitants of it are as idle as those on the border of the Caspian, cultivating just enough to feed their families and to supply passing pilgrims. Here, as in the whole country, everything seems covered with salt. It is seen on the walls of the houses and on the banks of the rivers, and and the water one drinks is very salt. There are many travelling saltpetre-makers to be found in this region, who in summer go from place to place wherever they can find materials to work upon. Their mode of operation is a very rough and ready one. Holes in the earth serve as vats and boilers, and below these are placed ovens. Abundance of brushwood supplies them with material for their fires. They collect from the surface of the earth heaps of a compost of salt and animal manure. This is soaked for twenty-four hours in water, then filtered, and then boiled for twenty-four hours, cleansed, and placed in the sun, so that the water may evaporate. An ordinary workman can make about fifty pounds in a day, and this he sells at the rate of a penny a pound. The workers appear quite contented with their lot, and the industry is preserved in their families for generations.

Around Bostan and Shahrud, numbers of gypsy encampments were met. The inhabitants said they were natives of Seistan, and gained their living by making brass wire and working metal. Each family pays a small yearly contribution to the chief of the Shah's footmen.

They are constantly on the move, and make their tents or huts so lightly that they can dismantle them at a moment's notice. They resemble the natives very much in features, and have the same filthy habits, but they are more swarthy in complexion, and much thinner. With regard to the Turkomans, they are, or rather were—for they have ceased their depredations—the terror of the Persian pilgrims and traders. M. Bonvalot thinks that they have received a bad name which they do not deserve. They are frank, gentle, hospitable, affable, and truthful; while their victims, the Persians, are the incarnation of deceit and lying. The Turkomans, he says, have all the good qualities of the Turks, a race which has been more calumniated than any other, but from which some of the more highly esteemed European nations might with advantage learn many things. From Samarcand they journeyed to the Amu-daria, whence, completing an irregular curve, they returned to Samarcand. Upon leaving Sari-jui, they came up with a number of Uzbegs, who were coming down from the summer encampments in the mountains to their winter-quarters in the valleys. The men of the tribe ride in front, driving the cattle and horses before them, and the younger children look after lambs, goats, and calves. Some are bareheaded; others wear a dirty turban. Though they are filthy in their habits, they are wonderfully strong. Their dwellings are strong, but easily taken to pieces. As a rule, the Turkoman is not a nomad, like the Uzbeg; he has not very many cattle, so that it is not necessary for him to move to different pastures with the changes of the seasons. In the valley of the Surkhan they met many encampments of gypsies, who appear to lead the same sort of life all over Central Asia. Their tents are of the most primitive kind—two poles, with a piece of cloth spread over them. From this to Regar the country is very rich, well watered, abounding in rice-fields, but, like the other parts of Central Asia where there is a copious rainfall, fevers abound. At Kara-tagh, besides English, French, Russian, and Indian goods, various products of the district itself are sold in the market, as, for instance, rice, barley, wheat, grapes, and dried apricots. In the towns there are many blacksmiths and saddlers, and a few potters, who are very skilful in making and enamelling cups and dishes. Strange to say, the occupation which has the most numerous representatives is that of druggist. A funeral procession amongst the Uzbegs, who regard death as a blessing and not as an evil, is thus described:—

"A small stream which crosses the road is salt, and we notice a group of men ascending its course with very rapid steps. They are carrying something on a stretcher, but, instead of going as slowly as they can, like bearers of a dead body in the West, they march at full speed, as if they were conveying some one who was very ill, or had met with an accident, to the doctor's. They go across the fields, and stumble in their hurry. They talk loudly, as if they were quarrelling, and there is not the least trace of sadness upon their faces. There are about ten of them, and they are dressed as plainly as usual. . . . In advance are several men with poles, which will be used for forming a vault on the grave, and behind comes an aged mollah, leaning upon a stick."

The travellers reached Samarcand in December, and were about to abandon the idea of going further, when General Karalkoff suggested that they should try to enter India by Pamir. It was worth trying, for nobody had ever before thought of attempting such a thing in winter. The undertaking was a great one, and they took every care in their outfit before setting out. Boots made of double felt with leather soles, with strips of skin protecting the seams, were made for them. Long stockings, made of felt, reaching up to the thigh, lined trousers with leather trousers over them, were the protections for the legs. The body was covered with two garments, one of them made of Kasghar sheepskin with the wool left on. A sheep-skin cap covered the head and ears, and a huge hood of the same material enveloped the whole head and face, with the exception of the eyes. With regard to the food supply, the more remarkable portions were immense numbers of small slabs of bread soaked in fat and baked twice over; mutton boiled down, salted, and placed in bladders; roasted millet seed, and dried apricots. The journey really began at Osh on March 6, and for over a month the whole party underwent the severest privations; the goal, however, was reached at last. We have not space to say much about this journey over the Pamir, one of the most remarkable feats of travel ever accomplished, but a few extracts in M. Bonvalot's own words will show what the enterprising explorer and his companions went through:—

"March 13. . . . The variations of temperature are very great, for at 9 a.m. the thermometer marks 75° F. in the sun and 10° F. below freezing in the shade, while at 2 p.m. it is nearly 100° F. in the sun and 3° below freezing in the shade; at 6 p.m., there are 18° of frost, while at 9.20 p.m. the glass is several degrees below zero."

"March 17 (when crossing the Alai). We are all of us exhausted and out of breath, devoid of all strength, and nearly blind. We have splitting headaches and a feeling of suffocation. One man is stretched out on his back, close beside his horse, which is lying on its side; another man is asleep as he stands with his head resting against the saddle; a third is whipping his poor horse, to the tail of which he clings like a drowning man to a buoy. Some of the men were bleeding from the nose, and so were the horses, the blood freezing as it trickled down their muzzles, and looking like ruby stones. . . At 6 in the morning there were 75° of frost."

On March 22 they reached an altitude of 15,000 feet on Kizilart. On March 27, when at the height of 15,700 feet—that is, at the summit of the pass of Kizil-Djek—a terrific snow-storm burst on them.

"March 30. . . . At 2.20 a.m., with the moon still so luminous that I could distinguish objects inside the tent, I go out to look at the thermometer, and find that the mercury has vanished. It has evidently been frozen. Thinking that I may be mistaken, I show the instrument to Capus, and we light a candle, the result being that we find the mercury really has frozen up, and is no bigger than a leaden pellet."

About the beginning of April they approached human habitations, and here, near the source of the Oxus, they found numbers of monuments to the dead:—

"The tumuli are built south-west to north-east, so that the dead may have their faces turned towards the holy city. They extend around four mausoleums made of earth, almost double the height of an *oui* (felt tent), and with a frontage of about 30 feet. The cupolas are pointed, and the architecture very simple, as there are no materials handy to attempt anything ambitious. Moreover, if a higher building had been erected, the wind,

which is the terror of the Pamir, would soon have brought it to the ground. At the four corners of the largest of the mausoleums a rude attempt has been made to carve pigeons. At the end of the humbler tombs are some stones sunk in the earth. Some of them have a sort of railing round them, formed of stakes bound together by wooden cords."

The numerous illustrations are excellent, and the translation is well done, but it is a pity that Mr. Pitman has not given the English names of places. Many readers will not recognize in French forms names which in English forms are perfectly well-known.

THE TESTING OF MATERIALS OF CONSTRUCTION.

The Testing of Materials of Construction. By William Cawthorne Unwin, F.R.S., M. Inst.C.E. (London: Longmans, Green, and Co., 1888.)

IN a volume of about 480 pages, Prof. Unwin has condensed probably all our knowledge of the strength of materials used in construction. The work is unique in its way, there being no other equally trustworthy, as far as we are aware, in existence.

Engineering structures of to-day are designed with due regard to the strength of their individual parts, and each part is so proportioned that it will safely carry its load, yet not be of greater strength than is necessary for this special purpose. In the Forth Bridge, for example, the strains in each member are calculated to a nicety, and the section of metal is duly proportioned. This could not be done if we did not know exactly the actual strength of the various materials used, as well as their behaviour under varying conditions of load less than the breaking load of the material. It is therefore necessary that these data should be obtained by using the most perfect apparatus obtainable, and that the experiments should be made by persons who have given much time and thought to the subject. Bearing this in mind, we gladly welcome Prof. Unwin's work; his name is well known among engineers as one thoroughly able to write such a work successfully.

The volume consists of three parts. In the first, the mechanical properties of materials are explained—that is, the phenomena of elasticity and plasticity, and the relations between stress and deformation, so far as they have been scientifically ascertained. In the second, the apparatus used in the engineering laboratory is described. Lastly, the third part contains a collection of the most complete and trustworthy results of testing of all the ordinary materials in use. Chapters IV. to VII. contain admirable descriptions of various kinds of testing machines, measuring instruments, and other useful appliances used in an engineering laboratory. These chapters are freely illustrated with excellent woodcuts of the different instruments, the larger ones of the testing machines being remarkably good.

The chapters dealing with iron and steel show a large knowledge of their practical working and characteristics. We agree with the author that a standard form for tensile test pieces ought to be accepted by engineers in this country, so that results may be more easily compared.

In all the large steel-works in this country there is now to be found a testing machine with the necessary apparatus for testing the material. This is intended for the makers' own information, and it is also used by the engineers or their assistants under whose specification the steel is being made. Take, for instance, steel plates for the bridge work under the Indian Government specification. Every plate rolled is tested in the following manner in order to guard against the acceptance of brittle or dangerous steel. As each plate is delivered from the rolls, and before it is sheared to dimensions, four samples in duplicate are marked off in the spare material for testing purposes. Tensile test pieces are taken both lengthwise and across the plate, and similar ones for the quenched bend tests. These test pieces are all stamped with suitable numbers before they are sheared off the plate to be tested. The steel must be of such a strength and quality as to be equal to a tensile strength of between twenty-seven and thirty-one tons per square inch, and to indicate a contraction of the tested area at the point of fracture of not less than 35 per cent.; the percentage of elongation in a length of 10 inches must be not less than 20.

The bend test pieces, heated to a low cherry heat, and cooled in water at a temperature of 82° F., must stand bending double round a curve of which the diameter is not more than three times the thickness of the piece tested. If these requirements are not in every case satisfactory, the plate represented by a defective test is rejected; unless it can be shown that the tested specimen has surface or other defects, in which case the duplicate test-piece is duly tested to take its place.

It must be evident, therefore, that a tremendous amount of testing is now being carried out in this and other countries, and the value of the material, the acceptance or rejection of which depends on the results of the tests, will reach a large amount. On this account we are always glad to increase our knowledge of the behaviour of the material under test, and of the machinery used in the process.

Prof. Unwin is to be congratulated on having successfully fulfilled his task. The work is worthy of his reputation, and should find a place in every engineer's library.

OUR BOOK SHELF.

Entomology for Beginners. For the Use of Young Folks, Fruit-growers, Farmers, and Gardeners. By A. S. Packard, M.D., Ph.D. Small 8vo, pp. xvi. and 367. (New York: Henry Holt and Co., 1888.)

DR. PACKARD'S works on entomological subjects are so well and favourably known, that the book he has now written under the above modest title will certainly obtain a large circulation.

As its name implies, it is a work especially addressed to beginners in the study of entomology, and gives them a brief outline of the extent of the subject, and descriptions of the various methods pursued in its research.

In some respects this work is based upon the same author's "Guide to the Study of Insects," many of the paragraphs being the same in both books and also many of the woodcuts which illustrate them. But the portion relating to classification is much abridged in the smaller book, whilst that which treats of the mounting of microscopic preparations, &c., is given at much greater length. It is this latter part that will be found of more permanent value to the student, who will soon master the brief classification put before him.

The demand for works like the present, we are glad to think, is likely to increase. It is in the examination of the embryology and in the dissection of insects in their various stages of development that the labours of entomologists will be largely engaged when the discovery and description of new species of insects begin to grow slack.

It is when we consider the vastness of the subject of entomology, and the practically inexhaustible field of investigation lying before us, that we feel grateful for such works as Dr. Packard's, which bring before us in a concise form recent methods employed in the treatment of subjects always difficult to manipulate and to render fit for microscopic examination. O. S.

The First Ascent of the Kasai: being some Records of Service under the Lone Star. By C. S. L. Bateman. (London: George Philip and Son, 1889.)

WHEN Lieutenant Wissmann made his memorable descent of the River Kasai, he was accompanied by a number of natives whose good-will he had secured by wise and kindly treatment. At Léopoldville, whence Lieutenant Wissmann returned to Europe, it was decided that Dr. Wolf should take the various members of this escort back to their homes, and that the Expedition under his command should be sent on to establish a station at the confluence of the Lulua with the Luebo. This Expedition was joined by Mr. Bateman as second in command; and in the present volume he records his experiences in the ascent of the Kasai, and during the time when he was engaged in directing the making of the Luebo station. Mr. Bateman is sometimes tempted to indulge rather too much in fine writing, but, notwithstanding this drawback, his book is one of considerable interest. He gives a good general idea of the manner in which he was impressed by the scenery through which he passed or in the midst of which he lived; and he is at great pains to describe, as accurately as possible, the various native tribes with whom he came in contact. Above all, the book is valuable for the light it throws on the influence that is being exerted by the Congo State. Mr. Bateman worked as one of its officials at the Luebo station, and no one who reads the record of what he accomplished can doubt that acting through such agents the new State is preparing the way for the growth of legitimate commerce, and for the development of wholesome relations generally between Europeans and the natives. The volume contains many illustrations, produced from the author's original sketches in pencil, water-colour, pen and ink, or sepia.

Tabular List of all the Australian Birds. By E. P. Ramsay. Pp. 1–38, with Map. (Sydney: Published by the Author, 1888.)

THE present list by Dr. E. P. Ramsay shows that a considerable increase in our knowledge of Australian ornithology has taken place since the year 1878, when the author last issued a list of the birds of Australia. The method adopted in this most useful publication is of the simplest and most effective nature, fourteen natural districts being recognized by Dr. Ramsay, and the distribution of each species being shown by an indication of a number corresponding to the number of the district in the table, so that the known range of every Australian species is seen at a glance. References are given to all the newly-described species, and on the opposite page to each table Dr. Ramsay gives critical notes of great importance to the student. A map is also given which indicates the natural areas of the different provinces of Australia, and enumerates most of the places where well-known collections have been made. A list of the 39 species known from Lord Howe Island and Norfolk Island is also appended, and a new species of owl from the former is described as *Ninox albaria*.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Meteoric Theory of Nebulæ, &c.

IN his interesting letter (p. 436), Mr. Preston draws attention to a point which was not referred to in my paper.

It has generally been supposed that the incandescence of the trail of a falling star was an evidence of the volatilization of the solid materials of a meteorite, and in the lower regions of the atmosphere this must certainly be true to a greater or less degree. But, in a paper read before the French Academy on February 18 (see abstract in NATURE, February 28, p. 432), M. E. Minary argues that the incandescence of meteorites cannot be explained by the transformation of motion into heat; and, after the reading of the paper, M. Cornu remarked that the luminosity of the trail of a meteorite might be an electrical phenomenon, without any considerable rise of temperature. I quote this in order to show that we should be cautious in accepting Mr. Preston's conclusion as to the rapid retardation and volatilization of meteorites when moving through a highly rarefied gas.

It may be admitted that, when a swarm of meteorites is closely packed, it will soon assume the form of gas throughout, but I cannot believe that gaseous friction affords a valid objection to the meteoric theory, when the meteorites are in loose order. The solidification of volatilized metals would, I suppose, take place in a few minutes or seconds, and the mean interval between collisions was shown, in my paper, to be conveniently measured in hours or days. It would not be unreasonable to suppose that the so-called permanent gases also solidify, when cooled to the low temperature which must obtain. But, apart from this possible solidification, Mr. Lockyer suggests that the permanent gases would be quickly occluded in the solids volatilized at the same instant.

The fusion of meteorites, so as to compensate fractures, forms, as I have myself said, perhaps the most serious difficulty in the theory. It cannot be supposed that fusions take place except under favourable circumstances; but, if a swarm of meteorites does not degrade into dust, these favourable circumstances must occur often enough to counterbalance fractures.

Mr. Preston does not seem to be correct in respect to Clausius's theory of the constant ratio of internal to translatory energy in a gas. Clausius assumes, and does not prove that, in the average of a number of collisions, the molecule will absorb an amount of energy proportional to the mean violence of the blows with which it has been struck. Clausius's law must be at least approximately true within considerable variations of temperature, but it is certainly not a rigorous law of mechanical systems.

The case of meteorites in collision is totally different; they are incapable of taking up more than an infinitesimal amount of vibratory energy. The energy which, in the molecules of a gas, is absorbed, in the case of meteorites goes in volatilizing solids. There seems to be no reason why the particular ratio which Clausius determines from the numerical value of the ratio of the two specific heats (γ) in a gas, should hold good in a swarm of meteorites. We have no idea of the ratio of the two quasi-specific heats in a swarm of meteorites, and therefore we are not entitled to use the equation $\beta = \frac{2}{3}\frac{1}{\gamma - 1}$, and to put $\gamma = 1{\cdot}4$, deducing $\beta = \frac{5}{3}$.[1] In other words, I do not see room for making any deduction as to the ratio between the kinetic energy of a swarm of meteorites and the thermal energy existing in the volatilized gases.

I fail to see any parallelism between Clausius's law and the conclusion drawn as to the lost potential energy in the formation of a swarm of meteorites. The loss of energy is an outcome of the law of gravitation, as applicable to the formation of a gaseous star, and is deducible without any reference to the kinetic theory of gases, or to its analogue for meteorites.

G. H. DARWIN.

[1] Maxwell, "Theory of Heat" (1875), p. 317. Mr. Preston's statement of the law is inaccurate.

The Formation of Ledges on Hill-sides.

IN NATURE for February 28, Mr. Ernst draws attention to the formation of these ledges as observed by himself in Caracas. They are probably to be found in many places, if carefully looked for. The following diagram, taken from a photograph, illustrates one of the most striking instances I know, to be found near Ballantrae, on the Ballantrae–Girvan road, Ayrshire. The ledges, which are very numerous and fairly regular, occur on the western face of a series of low hills, very near to the sea-shore. The subsoil is thin and open. The angle of slope ranges from perhaps 30° to 60°, seldom higher. Where the angle is much higher, the soil slips away bodily, and the grass with it, leaving a bare space; indeed, at one point of the road the precipitated soil forms readily visible mounds at the base of the cliff.

The whole locality is very unfavourable to earthworms, and I agree with Mr. Ernst that the earthworm theory must, as far as any practical effect is concerned, be surrendered.

On the other hand, had the ridges been due to anything like glacier action, as Mr. Ernst suggests, I should have expected

detrital mounds below the ledges at the foot of each slope. These, however, do not occur, and the soil meets the narrow strip of plain with surprising angular sharpness.

It seems clear that the ledges owe their origin to the action of rain-water, which would naturally penetrate below the surface covering of grass, and dissolve with comparative rapidity portions of the porous soil below. The grass layer would eventually have nothing to support it in places, and would collapse to a lower level. The effect of collapse, supposing the layer to hold together, would necessarily be a wrinkle or ledge at right angles to the ground slope. EDMUND J. MILLS.

Glasgow, March 4.

Weight, Mass, and Force.

IF Mr. Gray, as in his teaching he no doubt unconsciously often does, will always say "force of a pound" instead of "weight of a pound" when he wishes to express the force of attraction of the Earth on a pound weight, there will be no divergence between his theoretical instruction and the language of practical men and of every-day life.

But to the majority the expression "weight of a pound" will always call up the mental picture of a "pound weight," so that the idea of the mass of a pound and of the force with which it is attracted by the earth cannot be dissociated in the use of the word "weight."

Supposing, however, we accept the definition of the "weight of a body" as never meaning anything else than the "force with which the earth attracts the body," how are we to interpret "the weight of the Sun, of the Moon, of Jupiter, &c.," and what is the "weight of the Earth?"

As Mr. Gray declines my previous challenge, will he condescend to point out the fallacy in the following argument? "The weight of the Moon being the force with which the Moon is attracted by the Earth, *ergo*, by the law that Action and Reaction are equal and opposite, the weight of the Earth is equal to the weight of the Moon."

With our present system of instruction in elementary theoretical dynamics we run the risk of wasting our time on a mechanics which is as unreal as is the mediæval Greek grammar taught in our schools, a grammar that was never vernacular even in the palmiest days of Attic literature.

The warning note in the introduction to "Numerical Examples in Practical Mechanics," by R. G. Blaine, is well timed and deserves careful attention. A. G. GREENHILL.

The Inheritance of Acquired Characters.

A VERY strong *a priori* objection to the line on which most experiments on the inheritance of acquired characters are carried on is the following. These experiments involve mutilation; and a tendency to transmit characters so produced would, considering that every accident or fight produces some slight mutilation, involve the animals in a process of degeneration. Hence the tendency to transmit the characters acquired *by mutilation* would be constantly bred out by natural selection. But a tendency to transmit characters acquired *by habit* in youth rests on quite another basis, and would tend to the conservation of the race.

I do not know if observations have been made on the physique of the offspring of persons engaged in trades where apprenticeship begins before puberty: they would be most valuable.

But the following case seems to me to be thoroughly to the point. A. B. is moderately myopic and very astigmatic in the left eye; extremely myopic in the right. As the left eye gave such bad images for near objects, he was compelled in childhood to mask it, and acquired the habit of leaning his head on his left arm for writing, so as to blind that eye; or of resting the left temple and eye on the hand, with the elbow on the table. At the age of fifteen the eyes were equalized by the use of suitable spectacles, and he soon lost the habit completely and permanently. He is now the father of two children—a boy and a girl—whose vision (tested repeatedly and fully) is emmetropic in both eyes, so that they have not inherited the *congenital* optical defect of their father. All the same, they both have inherited his early acquired habit, and need constant watchfulness to prevent their hiding the left eye, when writing, by resting the head on the left fore-arm or hand. Imitation is here quite out of the question.

Considering that every habit involves changes in the proportional development of the muscular and osseous systems, and hence, probably, of the nervous system also, the importance of inherited habits, natural or acquired, cannot be

overlooked in the general theory of inheritance. I am fully aware that I shall be accused of flat Lamarckism; but a nickname is not an argument. MARCUS M. HARTOG.

Cork, March 6.

A Fine Meteor.

A FINE meteor was visible here to-night at 6.36 p.m. It fell perpendicularly almost due north-north-east, disappearing about 20° above the horizon, and was then as nearly as possible of the brilliancy and colour of Venus, which was shining in the south-west at the time. Length of path, I think, about 20°, but I am not positive that I saw the beginning of it.

B. WOODD SMITH.

Hampstead Heath, N.W., March 11.

Bishop's Ring.

I AM informed by Miss E. Brown, of Cirencester, that she saw Bishop's ring in full day-time as recently as last month, not far from 12 o'clock one day, the sun being hidden behind a cloud at the time. It appeared very similar in extent, as well as colour, though not intensity, to what it did after the Krakatão eruption. Also another day she noticed something like it when looking at the sun simply through a dark glass.

I have very occasionally myself in the last few years seen a somewhat similar phenomenon, but duller and dirtier in colour than Bishop's ring usually was, and which gave me the impression of being lower down in the atmosphere than that. I attributed this to smoke or some other local impurity. It would appear that the phenomenon seen by Miss Brown, out in the country, cannot have been thus caused; but I suppose that she must really have seen the corona produced by volcanic dust, through an exceptionally pure lower atmosphere.

Sunderland, March. T. W. BACKHOUSE.

The Philosophical Transactions.

MOST people who interest themselves in science would be glad to possess a complete set of the Philosophical Transactions. But in the first place complete sets are scarce, and in the second it would be much too expensive for ordinary people; furthermore, it is not in everyone's library that room could be found for its reception. Now, Drs. Hutton, Shaw, and Pearson brought out a first-rate abridgment of this valuable publication from its commencement to the end of the year 1800. May I venture to suggest that the Royal Society would be doing a good work by publishing on the same lines a continuation up to the year 1900? If they commenced now, and brought out a volume at intervals, the whole thing might be completed in the early years of the twentieth century. The cost ought not to be very great, and probably nearly every free library would subscribe. S.

ON THE COMPOSITION OF WATER.[1]

DURING the past year I have continued the work described in a former communication on the relative densities of hydrogen and oxygen (Roy. Soc. Proc., February 1888, vol. xliii. p. 356; see also NATURE, vol. xxxvii. p. 418), in the hope of being able to prepare lighter hydrogen than was then found possible. To this end, various modifications have been made in the generating apparatus. Hydrogen has been prepared from potash, in place of acid. In one set of experiments the gas was liberated by aluminium. In this case the generator consisted of a large closed tube sealed to the remainder of the apparatus; and the aluminium was attached to an iron armature so arranged that, by means of an external electro-magnet, it was possible to lower it into the potash, or to remove it therefrom. The liberated gas passed through tubes containing liquid potash,[2] corrosive sublimate, finely powdered solid potash, and, lastly, a long length of phosphoric anhydride. But the result was disappointing, for the hydrogen proved to be no lighter than that formerly obtained from sulphuric acid.

I have also tried to purify hydrogen yet further by absorption in palladium. In his recent important memoir (*Amer. Chem. Journ.*, vol. x. No. 4), "On the Combustion of Weighed Quantities of Hydrogen and the Atomic Weight of Oxygen," Mr. Keiser describes experiments from which it appears that palladium will not occlude nitrogen—a very probable impurity in even the most carefully prepared gas. My palladium was placed in a tube sealed, as a lateral attachment, to the middle of that containing the phosphoric anhydride; so that the hydrogen was submitted in a thorough manner to this reagent, both before and after absorption by the palladium. Any impurity that might be rejected by the palladium was washed out of the tube by a current of hydrogen before the gas was collected for weighing. But as the result of even this treatment I have no improvement to report, the density of the gas being almost exactly as before.

Hitherto the observations have related merely to the densities of hydrogen and oxygen, giving the ratio 15·884, as formerly explained. To infer the composition of water by weight, this number had to be combined with that found by Mr. Scott as representing the ratio of volumes. The result was—

$$\frac{2 \times 15\cdot884}{1\cdot9965} = 15\cdot914.$$

The experiments now to be described are an attempt at an entirely independent determination of the relative weights by actual combustion of weighed quantities of the two gases. It will be remembered that in Dumas's investigation the composition of water is inferred from the weights of the oxygen and of the water, the hydrogen being unweighed. In order to avoid the very unfavourable conditions of this method, recent workers have made it a point to weigh the hydrogen, whether in the gaseous state, as in the experiments of Prof. Cooke and my own, or occluded in palladium, as in Mr. Keiser's practice. So long as the hydrogen is weighed, it is not very material whether the second weighing relate to the water or to the oxygen. The former is the case in the work of Cooke and Keiser, the latter in the preliminary experiments now to be reported.

Nothing could be simpler in principle than the method adopted. Globes of the same size as those employed for the density determinations are filled to atmospheric pressure with the two gases, and are then carefully weighed. By means of Sprengel pumps the gases are exhausted into a mixing chamber, sealed below with mercury, and thence by means of a third Sprengel are conducted into a eudiometer, also sealed below with mercury, where they are fired by electric sparks in the usual way. After sufficient quantities of the gases have been withdrawn, the taps of the globes are turned, the leading tubes and mixing chamber are cleared of all remaining gas, and, after a final explosion in the eudiometer, the nature and amount of the residual gas are determined. The quantities taken from the globes can be found from the weights before and after operations. From the quantity of that gas which proved to be in excess, the calculated weight of the residue is subtracted. This gives the weight of the two gases which actually took part in the combustion.

In practice, the operation is more difficult than might be supposed from the above description. The efficient capacity of the eudiometer being necessarily somewhat limited, the gases must be fed in throughout in very nearly the equivalent proportions; otherwise there would soon be such an accumulation of residue that no further progress could be made. For this reason nothing could be done until the intermediate mixing chamber was provided. In starting a combustion, this vessel, originally full of mercury, was charged with

[1] A Paper read at the Royal Society, by Lord Rayleigh, Sec. R.S., on March 7.

[2] Of course, this tube was superfluous in the present case, but it was more convenient to retain it.

equivalent quantities of the two gases. The oxygen was first admitted until the level of the mercury had dropped to a certain mark, and subsequently the hydrogen down to a second mark, whose position relatively to the first was determined by preliminary measurements of volume. The mixed gases might then be drawn off into the eudiometer until exhausted, after which the chamber might be re-charged as before. But a good deal of time may be saved by replenishing the chamber from the globes simultaneously with the exhaustion into the eudiometer. In order to do this without losing the proper proportion, simple mercury manometers were provided for indicating the pressures of the gases at any time remaining in the globes. But even with this assistance close attention was necessary to obviate an accumulation of residual gas in the eudiometer, such as would endanger the success of the experiment, or, at least, entail tedious delay. To obtain a reasonable control, two sparking places were provided, of which the upper was situate nearly at the top of the eudiometer. This was employed at the close, and whenever in the course of the combustion the residual gas chanced to be much reduced in quantity; but, as a rule, the explosions were made from the lower sparking point. The most convenient state of things was attained when the tube contained excess of oxygen down to a point somewhat below the lower sparking wires. Under these circumstances, each bubble of explosive gas readily found its way to the sparks, and there was no tendency to a dangerous accumulation of mixed gas before an explosion took place. When the gas in excess was hydrogen, the manipulation was more difficult, on account of the greater density of the explosive gas retarding its travel to the necessary height.

In spite of all precautions several attempted determinations have failed from various causes, such as fracture of the eudiometer and others which it is not necessary here to particularize, leading to the loss of much labour. Five results only can at present be reported, and are as follows:—

December 24, 1888	... ...	15·93
January 3, 1889	... ...	15·98
,, 21, ,,	... ...	15·98
February 2, ,,	... ...	15·93
,, 13, ,,	... ...	15·92
Mean	... ...	15·95

This number represents the atomic ratio of oxygen and hydrogen as deduced immediately from the weighings with allowance for the unburnt residue. It is subject to the correction for buoyancy rendered necessary by the shrinkage of the external volume of the globes when internally exhausted, as explained in my former communication.[1] In these experiments, the globe which contained the hydrogen was the same (14) as that employed for the density determinations. The necessary correction is thus four parts in a thousand, reducing the final number for the atomic weight of oxygen to—

15·89,

somewhat lower than that which I formerly obtained (15·91) by the use of Mr. Scott's value of the volume ratio. It may be convenient to recall that the corresponding number obtained by Cooke and Richards (corrected for shrinkage) is 15·87, while that of Keiser is 15·95.

In the present incomplete state of the investigation, I do not wish to lay much stress upon the above number, more especially as the agreement of the several results is not so good as it should be. The principal source of error, of a non-chemical character, is in the estimation of the weight of the hydrogen. Although this part of the work cannot be conducted under quite such favourable conditions as in the case of a density determination, the error in the difference of the two weighings should not exceed 0·0002 gramme. The whole weight of the hydrogen used is about 0·1 gramme;[1] so that the error should not exceed 3 in the last figure of the final number. It is thus scarcely possible to explain the variations among the five numbers as due merely to errors of the weighings.

The following are the details of the determination of February 2, chosen at random:—

Before combustion ... $G_{14} + H + 0·2906 = G_{11}$ ... pointer 20·05
After ,, ... $G_{14} + H + 0·4006 = G_{11}$ ... pointer 20·31

Hydrogen taken = 0·1100 − 0·0000$_5$ = 0·10995 gramme.

Before combustion ... $G_{13} + O = G_{11} + 2·237$ ... pointer 20·00
After ,, ... $G_{13} + O = G_{11} + 1·357$ ... pointer 19·3

Oxygen taken = 0·8800 + 0·0001 = 0·8801 gramme.

At the close of operations the residue in the eudiometer was oxygen, occupying 7·8 cubic centimetres. This was at a total pressure of 29·6 − 16·2 = 13·4 inches of mercury. Subtracting 0·4 inch for the pressure of the water vapour, we get 13·0 as representing the oxygen pressure. The temperature was about 12° C. Thus, taking the weight of a cubic centimetre of oxygen at 0° C., and under a pressure of 76·0 centimetres of mercury to be 0·00143 gramme, we get as the weight of the residual oxygen—

$$0·00143 \frac{7·8}{1 + 12 \times 0·00367} \frac{13·0 \times 2·54}{76·0} = 0·0046 \text{ gramme.}$$

The weight of oxygen burnt was, therefore, 0·8801 − 0·0046 = 0·8755 gramme.

Finally, for the rate of atomic weight—

$$\frac{\text{Oxygen}}{\frac{1}{2}\text{ Hydrogen}} = 15·926.$$

In several cases the residual gas was subjected to analysis. Thus, after the determination of February 2, the volume was reduced by additions of hydrogen to 1·2 cubic centimetre. On introduction of potash there was shrinkage to about 0·9, and, on addition of pyrogallic acid, to 0·1 or 0·2. These volumes of gas are here measured at a pressure of $\frac{1}{3}$ atmosphere, and are, therefore, to be divided by 3 if we wish to estimate the quantities of gas under standard conditions. The final residue of (say) 0·05 cubic centimetre should be nitrogen, and, even if originally mixed with the hydrogen—the most unfavourable case—would involve an error of only $\frac{1}{2000}$ in the final result. The 0·1 cubic centimetre of carbonic anhydride, if originally contained in the hydrogen, would be more important, but this is very improbable. If originally mixed with the oxygen, or due to leakage through india-rubber into the combustion apparatus, it would lead to no appreciable error.

The aggregate impurity of 0·15, here indicated, is tolerably satisfactory in comparison with the total quantity of gas dealt with—2000 cubic centimetres. It is possible, however, that nitrogen might be oxidized, and thus not manifest itself under the above tests. In another experiment the water of combustion was examined for acidity, but without definite indications of nitric acid. The slight reddening observed appeared to be rather that due to carbonic acid, some of which, it must be remembered, would be dissolved in the water. These and other matters demand further attention.

The somewhat complicated glass-blowing required for the combustion apparatus has all been done at home by my assistant, Mr. Gordon, on whom has also fallen most of the rather tedious work connected with the evacuation of globes and other apparatus, and with the preparation of the gases.

[1] The necessity of this correction was recognized at an early stage, and, if I remember rightly, was one of the reasons which led me to think that a re-determination of the density of hydrogen was desirable. In the meantime, however, the question was discussed by Agamennone (*Atti* (*Rendiconti*) *d. R. Accad. dei Lincei*, 1885), and some notice of his work reached me. When writing my paper last year I could not recall the circumstances; but since the matter has attracted attention I have made inquiry, and take this opportunity of pointing out that the credit of first publication is due to Agamennone.

[1] It was usual to take for combustion from two-thirds to three-fourths of the contents of the globe.

EXAMINATIONS IN ELEMENTARY GEOMETRY.

IN the spring of 1870 a letter appeared in the columns of NATURE suggesting the formation of an Association which should have for its object the improvement of geometrical teaching. As to the great desirability of such improvement there could be no doubt. It was felt that one of the greatest obstacles in the way of effecting it was the nature of the examinations, and that no change in that nature was likely to be brought about except by the combined action of those who desired it. The idea took root, and a circular was drawn up in which the objects of the proposed Association were stated to be—

(1) To collect and distribute information as to the prevailing methods of instruction in geometry practised in this and other countries, and to ascertain whether the desire for change was general.

(2) To use its influence to induce examining bodies to frame their questions in geometry without reference to any particular text-book.

(3) To stamp with its approval some text-book already published, or to bring out a new one under its own auspices.

The movement led to a conference at University College in 1871, which resulted in the formation of the Association for the Improvement of Geometrical Teaching. Many difficulties beset the way of the desired improvement. In addition to all the arguments which may be used against radical change in any department of affairs, the uncomprising supporters of Euclid (or rather of Simson's edition of his works) had the very cogent one that a Commission appointed by the Italian Government to inquire into the state of geometrical teaching in Italy found it "so unsatisfactory, and the number of bad text-books so great and so much on the increase, as to compel them to recommend the adoption of Euclid pure and simple,"[1] and were able to quote the authority of distinguished French mathematicians as to the great merits of Euclid as compared with modern French writers. We need not wonder, then, and need perhaps scarcely regret, that the outward and direct progress of the Association towards the realization of the aims set forth in its programme was slow.

One of its first steps was to attempt to draw up a Syllabus of Geometry in place of Euclid's scheme of propositions, which might form the basis of future text-books. Members were requested to send in, and the Committee of Management to report upon, programmes of the subjects which a text-book ought to include. Eleven programmes were sent in, which agreed upon many fundamental points; and after much work by a sub-committee, and much discussion from time to time at the general meetings of the Association, a Syllabus of Geometry was at last published as the work of the Association. It is worthy of remark that a Committee of the British Association, containing such eminent mathematicians as Profs. Cayley, Clifford, H. J. S. Smith, and Sylvester, appointed for the purpose of considering the possibility of improving the methods of instruction in elementary geometry, and reappointed to consider this Syllabus, reported that "it appears to have been drawn up with such care and with such regard to the essential conditions of the problem as to render it highly desirable that it should be considered in detail by authorized representatives of the Universities and other great examining bodies of the United Kingdom, with a view to its adoption, subject to any modification which such detailed consideration may show to be necessary, as the standard for examinations."

The secretaries then applied to many of the principal examining bodies, submitting the Syllabus for their consideration, with a view to its adoption as the basis of examination.

[1] See First Annual Report of the A.I.G.T.

The direct result of this application was small. It was felt that the non-existence of a text-book based on the Syllabus was a bar to its adoption, and a sub-committee was appointed to prepare proofs of the propositions. A text-book embodying these, and entitled "The Elements of Plane Geometry," was published by Messrs. Sonnenschein and Co. The appearance of Part II. of this work in 1886 seemed to afford a fitting opportunity for memorializing the Universities as to the advisability of relaxing their regulations. The following petition was drawn up, and received about 180 signatures, among which may be noticed those of Sir R. S. Ball, Prof. Chrystal, Prof. Henrici, Dr. Hirst, and Prof. Tait :—

"We, the undersigned members of the Association for the Improvement of Geometrical Teaching, and others interested in the teaching of elementary geometry, believing that greater freedom in the teaching of that subject than is consistent with a rigid adherence to the letter of Euclid's 'Elements' is highly desirable, would welcome such a change in the examinations in elementary geometry conducted by the Universities and other examining bodies as would admit of the subject being studied from text-books other than editions of Euclid, without the student being thereby placed at a disadvantage in those examinations."

The Council forwarded the petition to the Universities, praying them to take the subject of the petition into their favourable consideration, with a view to adapting the regulations for the examinations in elementary geometry conducted by the Universities so as to meet the desire for greater freedom felt by a large number of teachers, and supported by the judgment of many eminent mathematicians.

The Hebdomadal Council of the University of Oxford having referred the application of the Association to the Board of the Faculty of Natural Science, the Board reported as follows :—

(1) "That a rigid adherence to the ordinary text-books of Euclid should no longer be insisted on, but that a greater freedom of demonstration should be allowed, both in geometrical teaching and in examination.

(2) "That, nevertheless, Euclid's *method* should be required in all pass examinations in geometry in so far as that no axioms other than those of Euclid shall be admitted, and that no proof of a proposition be allowed which assumes the truth of any proposition which does not precede it according to Euclid's order.

(3) "That the University should not prescribe the use of any particular text-book or text-books."

This Report was adopted by the Hebdomadal Council on June 20, 1887.

The Senate of the University of Cambridge having referred to the Special Board for Mathematics, the Board reported as follows :—

"The majority of the Board are of opinion that the rigid adherence to Euclid's text is prejudicial to the interests of education, and that greater freedom in the method of teaching geometry is desirable. As it appears that this greater freedom cannot be attained while a knowledge of Euclid's text is insisted upon in the examinations of the University, they consider that such alterations should be made in the regulations of the examinations as to admit other proofs besides those of Euclid, while following, however, his general sequence of propositions, so that no proof of any proposition occurring in Euclid should be accepted in which a subsequent proposition in Euclid's order is assumed.

"To give effect to this view, the Board recommend that for Regulation 10 (2) of the previous examination (*Ordinationes*, p. 8) the following be substituted :—

"Elementary geometry, viz. the substance of the first three books, the definitions 1–10 of Book V., and the substance of the first nineteen propositions of the Sixth Book of Euclid's 'Elements.' Euclid's definitions will be

required, and no axioms or postulates except Euclid's may be assumed. The actual proofs of propositions as given in Euclid will not be required, but no proof of any proposition occurring in Euclid will be admitted in which use is made of any proposition which in Euclid's order occurs subsequently."

The subject came on for discussion in the School on January 26, 1888, and a grace finally passed the Senate (March 8, 1888), making the alteration in the regulations for the previous examination recommended in the Report.

The Council of the Association then forwarded an Address to Her Majesty's Civil Service Commissioners, drawing their attention to the recent Reports of the University Boards, and asking for corresponding alterations in the regulations for the Woolwich and Sandhurst examinations, as follows:

"In view of the above facts, the Council feel themselves justified in inviting the attention of Her Majesty's Civil Service Commissioners to the desirability of a change in one of the existing regulations for the examinations conducted under their authority, especially those for admission to Sandhurst and Woolwich. By this a candidate is required to 'satisfy the Commissioners in Euclid, Books I.-IV. and VI.' The Council, having reason to believe that this regulation is very generally understood to imply that Euclid's text is required without any but mere verbal variations, beg to suggest that the subject should be defined as 'Elementary Geometry to the extent of Books I.-IV. and VI. of Euclid's "Elements,"' with a note to the effect that 'any proofs will be admitted which are themselves sound, do not assume other axioms than those of Euclid, and are not inconsistent with the logical sequence of Euclid's theorems.'

"The Council would prefer to have no particular text-book prescribed, and to have the candidate's general knowledge of geometry tested, rather than his power of reproducing Euclid's text.

"While making this request, however, the Council wishes to express its acknowledgment of the high character of the papers in Euclid set by the Civil Service Examiners, and particularly of the frequent introduction of stimulative exercises on the book work set.

"The Council would esteem it a favour if they were allowed to express their views on this important question more at large by a deputation from their body at an interview with the Commissioners."

The following reply was received from the Commissioners:—

"*Civil Service Commission, June* 30, 1888.

"Sir,—I am directed by the Civil Service Commissioners to acknowledge the receipt of a circular signed by you in behalf of the Council of the Association for the Improvement of Geometrical Teaching, requesting that certain changes may be introduced into the regulations for the examinations held under their authority, and in particular those for admission to Sandhurst and Woolwich;

"And, in reply, I am to acquaint you, for the information of the Council, that the regulations for the military examinations are framed and issued by the military authorities, and that the Commissioners have no power to alter them, but that the interpretation which the Commissioners have given them has been substantially in accordance with the views expressed by the Cambridge Special Board for Mathematics and the Oxford Board of the Faculty of Natural Science. They have, that is to say, instructed their occasional examiners to make no deduction from the marks allotted to a question because a candidate substitutes another proof for Euclid's, if this proof is a sound one and keeps to Euclid's sequence of propositions. To remove any misconception which may exist, the Commissioners propose to introduce a note to this effect in the examination papers. It will be understood, however, that they do not intend thereby to fetter their discretion of changing their practice whenever they may consider it expedient.

"In conclusion, while thanking the Council for their offer to express their views on this question more at large by the medium of a deputation from their body, the Commissioners think that the agreement of their opinion on this matter renders it unnecessary that the members of the Council should give themselves the trouble of an interview.

"I have the honour to be, Sir,
"Your obedient servant,
"E. POSTE."

Doubtless these concessions are in form the sorriest minimum of change that could well be granted; but the spirit of the Reports is excellent, particularly if examiners allow themselves, as it is quite open for them to do, to interpret "Euclid's order" as his *logical* and not merely his *numerical* order. Probably, if there is a strong desire for further relaxation generally felt and expressed by teachers, there will be no great difficulty in getting it granted; but it is by no means clear that such a desire exists at present to a sufficient degree to bring pressure to bear on the authorities. One does not easily see why the sequence of the Syllabus and the "Elements" should not have been granted as an alternative to that of Euclid, as is done by the University of Edinburgh. These works are the outcome of considerable discussion and deliberation by practised teachers, and it seems scarcely right to ignore them so entirely. As far as Cambridge is concerned, there is one detail of reform which might be effected without going beyond the terms of the grace of the Senate; *i.e.* the authorization of a list of additional propositions not contained in Euclid's text, to be freely used in the demonstration of all propositions subsequent to the position they may be regarded as occupying in Euclid's sequence. Such a list need not be long, and its adoption would be a boon to those teachers who wish to use the Syllabus.

ELECTROSTATIC MEASUREMENT.[1]

THE number of electrostatic units of potential or electromotive force in the electro-magnetic unit of potential is essentially a velocity, and experiments have proved it to be so nearly equal to the velocity of light that from all the direct observations hitherto made we cannot tell whether it is a little greater than, or a little less than, or absolutely equal to, the velocity of light.

Sir W. Thomson is engaged now in making a set of electrometers which will measure by electrostatic force potentials of from 40 volts to 50,000 volts. The standardization of these instruments up to 200 or 300 volts is made exceedingly easy, by aid of his centiampere balance and continuous rheostat, with a voltaic battery of any kind, primary or secondary, capable of giving a fairly steady current of $\frac{1}{10}$ of an ampere through it and the platinoid resistance in series with it. The accuracy of the electro-magnetic standardization, within the range of the direct application of this method, is quite within $\frac{1}{20}$ per cent. A method of multiplication by aid of condensers, which was explained, gives an accuracy quite within $^1/_5$ per cent. for the measurement in volts up to 2000 or 3000 volts; and with not much less accuracy, by aid of an intermediate electrometer, up to 10,000 volts. Such a potential as 10,000 volts is convenient for measurement by an absolute electrostatic balance, which was fully explained in the lecture, and illustrated by a drawing. But hitherto he has not been able to make sure of the absolute accuracy of the electrostatic balance to closer than $^1/_2$ per cent. The results of a great number of measurements made in the Physical Laboratory of the University of Glasgow during the last

[1] Abstract of part of Sir William Thomson's Royal Institution Lecture of Friday evening, February 8, relating to the velocity of light.

two months, give the required number, commonly called "v," within $1/2$ per cent. of 300,000 kilometres per second; the velocity of light is known to be within $1/4$ per cent. of 300,000 kilometres per second. Results of previous observers for determining "v" had almost absolutely proved at least as close an agreement with the 300,000,000 metres as this. He expressed his obligations to his assistants and students in the Physical Laboratory of Glasgow University, Messrs. Meikle, Shields, Sutherland, and Carver, who worked with the greatest perseverance and accuracy, in the laborious and often irksome observations by which he had attempted to determine "v" by the direct electrometer method, as exactly as, or more exactly than, it has been determined by other observers and other methods.

The measurement of "v" by Sir William Thomson and Profs. Ayrton and Perry, communicated to the British Association at Bath, was too small (292) on account of the accidental omission of a correction regarding the effective area of the attracted disk in the absolute electrometer. When this correction is applied their result is brought up to 298, which exactly agrees with Profs. Ayrton and Perry's previous determination by another method, in Japan. Prof. J. J. Thomson's result is 296·3. It is understood that Rowland has found 299. The result of Sir William Thomson's latest observations, founded wholly on the comparison of electrometric and electro-magnetic determinations of potential in absolute measure, is 30·1 legal ohms, or 30·04 Rayleigh ohms. Assuming, as is now highly probable, that the Rayleigh ohm is considerably nearer than the legal ohm to the true ohm, the result for "v" is 300,400,000 metres per second. Sir William does not consider that this result can be trusted as demonstrating the truth within $1/3$ per cent.

NOTES.

THE Royal Society's Bakerian Lecture for the present year is to be "On a Magnetic Survey of the British Isles for the epoch January 1, 1886," by Prof. A. W. Rücker, F.R.S., and Prof. T. E. Thorpe, F.R.S.

CAPTAIN W. J. L. WHARTON, R.N., F.R.S., Hydrographer to the Admiralty, has been elected a member of the Athenæum Club, in accordance with the rule which empowers the Committee to elect annually a certain number of persons of distinguished eminence in literature, science, or art, or for public services.

THE American Association for the Advancement of Science will meet this year at Toronto from August 27 to September 3. It is expected that the attendance will rival that at the Boston meeting of 1880. The President of the Association is Prof. Mendenhall. Major Powell, as retiring President, gives the address.

THE French Association for the Advancement of Science will meet at Paris from August 8 to 15.

THE French Ministry of Public Instruction has decided to create a laboratory of pathological physiology at the École des Hautes Études, Paris. The Director will be M. François-Franck, assistant of M. Marey at the Collège de France.

DR. SELMAR SCHÖNLAND, of the Botanic Garden, Oxford, has been appointed to the Curatorship of the Albany Museum, Grahamstown, Cape Colony.

IN the spring, M. Hasselberg will go from Pulkowa to Stockholm, having been elected Fellow of the Royal Academy of Sciences, and Director of the Physical Institution of the Academy, in succession to Prof. Edlund.

THE Bombay Anthropological Society has resolved to communicate with the executors of Mr. E. T. Leith, the founder o the Society, with a view to secure the publication of his literary remains under the supervision and at the expense of the Society.

FURTHER experiments are to be carried out shortly at Chatham by the Balloon Department with the Bruce system of electric balloon signalling. The apparatus used will be that which the Government purchased of the inventor, Mr. Eric Stuart Bruce.

WE regret to hear of the death of Captain John Ericsson, the famous Swedish engineer. He died the other day at New York, at the age of eighty-six. Captain Ericsson was a man of extraordinary intellectual resource, and his name stands high among the great inventors of the present century. An effective screw-propeller was invented independently both by him and by Francis Pettit Smith. Smith's patent was taken out in May 1836, a little before Ericsson's; but the date of Ericsson's invention was considerably earlier than that of his English rival. The screw-propeller of Ericsson was at once adopted by the United States Navy, but in England he had the mortification of being officially informed that it was useless, because, "the power being applied at the stern, it would be absolutely impossible to make the vessel steer." Afterwards he had occasion to learn that an inventor's difficulties may be not less formidable in the New World than in the Old, for he was badly treated in connection with the *Princeton* screw steamer, designed by him for the United States Government in 1844, and in connection with the *Monitor*, which he built during the Civil War. During his last years he was much occupied with what he called "the sun motor," an article on which, by himself, recently appeared in NATURE (vol. xxxviii. p. 319).

DR. JOHN CALL DALTON, the physiologist, died at New York on February 12, at the age of sixty-four.

AFTER the ordinary meeting of the Royal Meteorological Society, at 25 Great George Street, Westminster, on Wednesday, the 20th inst., the Fellows and their friends will inspect the Society's tenth annual Exhibition of Instruments. The Exhibition will remain open until Friday, the 22nd inst. It promises to be very interesting and instructive. It will be specially devoted to actinometers and solar radiation apparatus, but will also include several new instruments, and a number of photographs of flashes of lightning, clouds, &c. Persons, not Fellows, wishing to visit the Exhibition, can obtain tickets on application to Mr. W. Marriott, Royal Meteorological Society, 30 Great George Street, S.W.

WE have received, from the Meteorological Reporter to the Government of India, the "Registers of Original Observations" made at seven selected observatories during the months of January to July 1888. These observations, although not exactly in the form prescribed, are published in pursuance of a decision of the Meteorological Congress held at Vienna in 1873, that each country should publish daily observations for a certain number of stations. The Indian observations have been published in this monthly form since January 1879, while for the years 1875-78 they formed an appendix to the Annual Reports. They contain complete information of all the principal elements for four hours daily, together with daily means, and monthly means for each of the four hours. The registers also contain means of the chief elements for each hour of the day at Alipore (Calcutta), and the hourly movement of the wind at Lucknow and Nagpur. The more rapid dissemination of the information by the publication of monthly parts, instead of annual volumes, renders it more valuable to persons interested in meteorological investigations.

M. KLOSSOVSKI, who published some time ago an important work on the thunderstorms of Russia, has now made another valuable contribution to the meteorology of South

Russia, dealing with the amounts of rain and snow in the Governments of Kherson and Bessarabia (Memoirs of the Odessa Society of Naturalists, vol. xiii. Part 1). Pluviometric observations were made in 1887 at 158 stations, and 1160 descriptions of thunderstorms have been sent in. It appears that the average yearly amount of rain and snow in the Government of Kherson is about 411 millimetres (434 millimetres at Odessa), a line drawn from the mouth of the Dniester to Orenburg separating the regions which receive more than 400 millimetres of rain every year from those in the south which have less than that. The Caucasus shore of the Black Sea, with its heavy rains (1500 to 2000 millimetres every year), makes, of course, an exception to the rule. The rains and the snow are usually brought to Bessarabia by cyclones, those which come from the south bringing with them the heaviest rains. No fewer than 96 per cent. of the cyclones which come from Hungary and the Balkan Peninsula are sure to bring with them more or less heavy rains to Kherson, and the like is true of 51 per cent. of those which follow a course to the south of Odessa altogether. The approach of cyclones can be easily foreseen, but the changes of weather are so sudden in South Russia that storm-warnings ought to be given from Odessa instead of St. Petersburg.

AN earthquake was noticed at Kasina, in Croatia, on February 23. At Aquila, in the Abruzzi, on February 28, five shocks occurred between 4 and 5 a.m. No damage was done.

A SLIGHT shock of earthquake occurred in Eastern Pennsylvania on March 8. It was felt at Lancaster, Harrisburg, Gettysburg, and their environs, and also at Wilmington (Delaware), and several places in Maryland and New Jersey.

ANOTHER beautiful instance of the formation of geometrical isomers, compounds precisely similar in constitution, and differing only in the relative position of their atoms in space, has been discovered by Prof. Wislicenus and Herr Hölz. The compound in question is dibromide of crotonylene, $CH_3—CBr=CBr—CH_3$. Crotonylene itself, $CH_3—C\equiv C—CH_3$, is the third member of the acetylene series of hydrocarbons, and combines directly with bromine to form a dibromide of the above constitution, which is now shown to have its atoms arranged in space in the manner

$$\begin{array}{l} CH_3—C—Br \\ \quad\;\; \| \\ CH_3—C—Br \end{array}$$

, the two similar groups being symmetrical to an imaginary plane lying between them. On attempting, however, to prepare crotonylene dibromide from the tetrabromide by abstraction of two atoms of bromine, or from one of the tribrombutanes, $CH_3—CHBr—CBr_2—CH_3$, by splitting off a molecule of hydrobromic acid, quite a different substance was obtained. Analyses indicated exactly the same empirical formula as before, but the boiling-point was found to be about 3° higher than that of the first isomer, and its behaviour with zinc dust was markedly different. These facts can only be explained on the supposition that its arrangement in space differs in being centro-symmetrical,

$$\begin{array}{l} CH_3—C—Br \\ \quad\;\; \| \\ \;\;Br—C—CH_3 \end{array}$$

, and this second isomer is therefore termed iso-crotonylene dibromide. Both compounds combine directly with a further quantity of bromine to form the same crystalline tetrabromide, $CH_3—CBr_2—CBr_2—CH_3$. In order to prepare the ordinary compound, the equivalent of a molecule of liquid bromine is allowed to drop from the fine jet of a dropping-funnel into a quantity of crotonylene contained in a flask surrounded by a freezing mixture, as crotonylene boils at 18° C. The reaction is very violent, each drop producing loud hissing; the product is washed with soda, dried over calcium chloride, and distilled. After two fractionations, the dibromide is obtained boiling constantly between 146° and 147°. On the addition of another molecule of bromine, the whole solidifies in large octahedral crystals of the tetrabromide. The iso-compound is best obtained by dropping in a similar manner one molecular equivalent of bromine into cooled monobrom-butylene; distillation of the resulting product yields tribrom-butane. This is diluted with alcohol, and a molecular equivalent of sodium ethylate added: a most violent reaction again occurs with elimination of a molecule of hydrobromic acid. On addition of water, the iso-compound is precipitated as an oil, which, on drying and subsequent distillation, is found to boil constantly between 149° and 150°. Addition of another molecule of bromine resulted in the production of octahedral crystals of the tetrabromide identical with those given by the ordinary compound. On reduction of each of the compounds in alcoholic solution with zinc dust, the plane-symmetrical ordinary compound is much more rapidly attacked than the centro-symmetrical iso-dibromide; when the reaction in each case was allowed to proceed under the same conditions for one hour, 99·6 per cent. of the ordinary compound was converted back to crotonylene, while only 60·6 per cent. of the iso- had been attacked.

THE Bureau des Longitudes has just issued an extract from the *Connaissance des Temps* (1890), for the use of schools of hydrography and aspirants to the grade of captain, either for coasting or ocean service, a recent resolution of the Minister of Marine having rendered such an extract very desirable. It contains the tables of the rising and setting of the sun and moon, and the place of the sun and sidereal time at mean noon for each day of the year. The moon's position is given only for every twelve hours throughout the year, instead of for every hour as in the complete edition, and the tables of lunar distances have been reduced to one star for each day. The positions of only thirty of the principal stars are given, as against 300 in the complete edition. The tables of refraction, and corrections for parallax, are reproduced in full, as are also the tables for conversion of mean time to sidereal time. The positions of the planets, Jupiter's satellites, &c., have been entirely omitted. Useful extracts from the data relating to tides already published in the *Annuaire des Marées* are given, with instructions for their use. The "establishment of the port" for every important port in the world is given, as well as the unit from which the height of the tide can be calculated. Our own authorities would do well to follow the example of the Bureau des Longitudes, and publish a similar extract from the *Nautical Almanac*.

THE Director of the Marine Biological Association reports that the breeding season of a large number of marine animals has begun, and that embryologists may find ample opportunities for study at the sea-side. Of Teleostean fishes, the spawning season of the herring has passed some time since, that of the plaice and flounder is just over, whilst the whiting, whiting pout, and merry sole (*Arnoglossus megastoma*) are now ripe. Nudibranch Mollusks are now visiting the shores to deposit their eggs, and large specimens of *Doris tuberculata* and *Eolis papillosa* may commonly be taken on the rocks at Plymouth. The uncommon *Capulus hungaricus* has been found with ova attached. Among the Crustacea the common shrimp, the prawn, and *Pandalus annulicornis* are hatching out, and the surface net begins to show numerous zoeæ of *Porcellana longicornis*. The Nauplii of Balanus and of Copepods are also abundant at this season of the year. The trochosphere larvæ of Chætopods (*Terebella* and *Phyllodoce*) are beginning to make their appearance, and ova and larvæ of Echinoderms are very abundant, particularly the ova of Ophiura, and Bipinnaria and Plutcus larvæ of Asterids and Echinids. The gonophores of the Hydrozoa are for the most part well developed, and filled with ripe ova during the coming month.

AT a meeting of the Royal Botanic Society on Saturday, a branch of coffee thickly set with ripe fruit from a plant growing in the Society's conservatory was shown. Dr. Prior mentioned

as a curious fact that in parts of Abyssinia the fleshy outside husk only was eaten, the part we use being thrown away as worthless.

In the February number of *Himmel und Erde*, Herr O. Jesse, of the Berlin Astronomical Observatory, calls attention to the importance of an accurate study of the luminous night-clouds which, since 1885, have been visible in Europe in the months of June and July. Herr Jesse is of opinion that these phenomena are interesting from an astronomical as well as from a meteorological point of view, because their periodic movement, taken in conjunction with their extraordinary height, suggests that they manifest the activity of cosmical forces. He holds, therefore, that they may throw some light upon the question whether cosmical space is filled with a resisting medium, and that their action may be a repetition of occurrences which played a great part in the earlier period of the development of the earth and of the planets generally. He urges that the phenomena should be carefully observed, and appeals to all who may take this task in hand to send him the results of their observations.

Mr. A. T. Drummond, in recent Canadian publications, takes the view that Lake Superior is the most ancient of the St. Lawrence Great Lakes, dating back to Cambrian and, it may be, earlier times, and that whilst its waters at perhaps more than one period found an outlet to the ocean through the Mississippi valley, the lake formed in other ages one of the sources of a great river system which terminated on the Atlantic seaboard. He traces the course of this river from the Michigan basin, and from Lake Superior across Lake Huron to the headlands at the entrance to the Georgian Bay. Here its waters were hurled over the cliffs in a great fall more than rivalling Niagara. At the lower level another considerable stream joined it from the north, and the united rivers then skirted the face of the continuous, shaly, precipitous cliffs which cross Ontario to the Lake Ontario valley. Following the course of the escarpments which they created in this valley, the waters eventually reached the sea through the Mohawk and Hudson Rivers. At a recent period, the elevation of the land between the Georgian Bay and Lake Ontario blocked the course of the river, and, filling the Georgian Bay with water, created a new outlet, not by the present St. Clair River, which was of later birth, but to the south-eastward of Lake Huron, where, through a channel now buried by clays, the Erie basin was reached. The course from this basin to the Ontario valley was through the great fracture in the limestones at Hamilton, and not over the Niagara Falls. The change in the flow of these waters to the Niagara River was one of the opening episodes in the later history of Lake Erie. The Ottawa River was at this time a large stream flowing much in the same course as now, whilst the St. Lawrence was a less important river, taking its rise in the Adirondack Mountains, which, at their then greater elevation, blocked the present outlet of Lake Ontario.

Mr. Thomas Wilson, of the Smithsonian Institution, Washington, writing in the current number of the *American Naturalist*, gives a rather gloomy account of the treatment accorded by public authorities in the United States to science in general, and to archæology in particular. "The States of Ohio," he says, "or Wisconsin, or West Virginia, or Mississippi, not to mention New York or New England, have either of them within their borders as much unstudied, unsearched, and unclassified archæologic riches as has any one of the great countries of Europe: England, France, Germany, Spain, or Italy. Yet these countries, each of them, do more for archæology than equals the combined efforts of the United States and all the State Governments. I confess to a feeling of depression when, on visiting the Prehistoric Museum at Salisbury, England, I found there stored and displayed, in a beautiful building, erected in the midst of a lovely park, for its sole occupancy, the prehistoric collection of Squier and Davis, gathered by them from the mounds of the United States in the Ohio and Mississippi valleys. It went begging through the United States, knocked at the door of Congress, and besought a purchaser at the ludicrous price of $1000, but without finding a response. And in disgust with their countrymen, and in despair of ever being able to interest their Government or fellow-citizens, they sold their collection to England and retired from the field of archæologic investigation."

We learn from an article in *Science* that the pottery industry in the United States gives employment directly to about ten thousand people, to whom wages amounting annually to four million dollars are paid, this amount being nearly 50 per cent. of the total value of the output of the potteries. In addition to these, there are many thousand more employed in the preparation of the materials for the potters' use, such as mining the clays, quartz, and felspar, and grinding and washing the materials. To these people nearly as much more in wages is paid. According to *Science*, the American potter does not claim to be the peer of his foreign competitor in art productions, but he does claim to equal any foreign manufacturer in the class of china which he produces for the American people—both fine and common "crockery" for domestic uses. "To-day," says *Science*, "the English potter is copying American shapes, designs, and styles of decorations. How different is this state of affairs from that which existed a few years ago, when the American potter depended upon foreign ideas for his shapes and designs! With the development of the manufacturing process, talent for designing shapes and patterns or styles of decoration has likewise progressed, until we have made our own American shapes and designs, which foreigners have been compelled to copy and adopt in order to find a market for their wares in the United States."

In his "Butterflies of the Eastern United States," a part of which we lately reviewed, Mr. Scudder has an interesting paper —Excursus xxiii.—on mimicry and protective resemblance among butterflies. He points out that cases of mimicry are far more common in the tropics than in temperate regions, even relatively. The accounts of travellers in the tropics constantly mention the attacks of birds upon butterflies, while instances of butterflies being seen pursued by birds are vastly more rare in the temperate regions. Mr. Scudder himself has never seen one. In the tropics, moreover, there are many other insectivorous animals, such as lizards. "In our own country, therefore," says Mr. Scudder, "we should not look for many instances of mimicry of any decided type. The most striking is unquestionably that of *Basilarchia archippus*, which mimics *Anosia plexippus*, and the closely related case of *Basilarchia eros* and *Tasitia berenice*, the last two butterflies largely supplanting the first two on the peninsula of Florida. In both these instances the mimicry is enjoyed by both sexes. A third case is found in the less close but still striking mimicry of *Basilarchia astyanax* by the female of *Semnopsyche diana*, an instance the more remarkable as the mimicked species belongs to the same genus as our two other mimicking forms."

At a recent meeting of the Ceylon Branch of the Royal Asiatic Society, two papers were read by Dr. Trimen and Mr. A. P. Green, describing a visit paid by them to Ritigala. Dr. Trimen's paper was devoted to an account of the flora to be found on the mountain, and the difference between it and that of the surrounding country. Ritigala is the highest ground between the central mountains of Ceylon and the mountains of Southern India. It is only 2506 feet high; next to it in height in the central plain of Ceylon being Friar's Hood (2147 feet), Westminster Abbey (1829 feet), and Gunner's Quoin

(1736 feet). Ritigala is completely isolated, and its summit is frequently surrounded by mist, especially during the south-west monsoon—that is, when the plains are suffering severely from drought. The branches of the stunted trees on the mountain are covered with masses of *Meteorium* moss and lichens, like those on the high mountains. Unfortunately the long-continued drought had withered up much of the vegetation, and therefore the expedition was not as productive as it otherwise would have been.

CAPTAIN MOORE, of H.M.S. *Rambler*, has lately described—in a paper read before the China Branch of the Royal Asiatic Society—the appearance and effects of the remarkable "bore" which often occurs in Hangchow Bay. This dangerous visitor is the result of the struggle between the advancing tide in the great estuary and the current of the river. Captain Moore and his officers on several occasions observed the progress of the wave, and their investigations may be summarized as follows:—The rate at which the bore travels varies from ten to about thirteen miles per hour. The height of the bore rarely exceeds 12 or 14 feet, and broken water, in which no small boat could live, follows it for some distance. With the passing of the wave the tide rises many feet in a few seconds; in one instance, observed by Captain Moore, it rose from 9 feet 4 inches below to 4 feet 7 inches above mean level. The rush of the bore was so strong that the force of the waves breaking against the broadside of the *Rambler* sent the water into the mizzen chains and the spray on to the poop. The junks in that region are protected by platforms, with narrow steps cut in the sides. To the north of the estuary is a great sea-wall, built to protect the surrounding country from being flooded by these great tidal-waves. It is thirty-five miles long, and it is strengthened, where the bore strikes most strongly, by an elliptical stone buttress, 253 feet long by 63 feet wide. Behind this the junks are drawn up for shelter.

IN one of the recent American Consular Reports the preparation of Japanese *koji* (yeast) is described by Prof. Georgeson, of the Imperial Agricultural College at Tokio. *Koji* is made not only in special factories, but also in *saké* (rice-beer) breweries. The materials used are water, rice of the common starchy kind only, and *tane* (seed or leaven), the spores of a fungus (*Eurotium oryzeæ*, Ahlb.). It is this latter substance which, when germinating on the rice, changes a portion of the starch into dextrose and dextrin, and produces the fermentation. The rice is carefully washed, and the thin covering of the seed is always removed. It is then allowed to remain for some hours in water, and having been steamed, it is spread on mats to cool, and when the temperature has fallen to about 100° F., the *tane* is scattered uniformly on the mass and then thoroughly mixed with it. The whole is then allowed to remain for eighteen or twenty hours covered with mats, after which the rice is spread in a thin layer in a number of shallow, wooden trays, which are taken to the warmest room in the factory, and there left standing for four or five hours, when the contents are stirred by the hand, and again after an interval of four hours the operation is repeated. On the third day the fungus grows very rapidly, and great heat is generated. Care, however, is taken that the heat does not become too great. This is the usual mode, but there are many other methods.

THE additions to the Zoological Society's Gardens during the past week include a Guinea Baboon (*Cynocephalus sphinx*) from West Africa, presented by Mr. W. J. Vinton; a Valentyn's Phalanger (*Cuscus orientalis* ♂) from the Solomon Islands, presented by Mr. Chas. M. Woodford, C.M.Z.S; an Owen's Apteryx (*Apteryx oweni*), two Tuatera Lizards (*Sphenodon punctatus*) from New Zealand, presented by Capt. C. A. Findlay, R.M.S. *Ruapehu*; two Nuthatches (*Sitta cæsia*), British, presented by Mr. J. Young, F.Z.S.; a Chimpanzee (*Anthropopithecus troglodytes* ♂) from West Africa, two Brown Cranes (*Grus canadensis*) from North America, three Black Swans (*Cygnus nigricollis*) from Australia, a Larger Hill-Mynah (*Gracula intermedia*) from India, deposited; a Hoffmann's Sloth (*Cholopus hoffmanni* ♀) from Panama, six Brent Geese (*Bernicla brenta*), European, purchased.

OUR ASTRONOMICAL COLUMN.

DISTRIBUTION OF SUN-SPOTS IN LATITUDE.—As remarked in the last issue of NATURE (p. 449), spots have been decidedly more numerous in the southern hemisphere of the sun during the last six years than in the northern. Since, however, the two hemispheres were about equally occupied in 1882, and the northern had the decided advantage in 1881 and 1880—whilst for nearly a quarter of a century previous there had been no long-continued difference between the two—it might be supposed that their present predominance in the southern hemisphere was one which would disappear in a series of observations spread over any great number of years. Prof. Spoerer, in a couple of valuable papers which he has just published—"Ueber die Periodicität der Sonnenflecken seit dem Jahre 1618," and "Sur les différences que présentent l'hémisphère nord et l'hémisphère sud du Soleil," the latter appearing in the *Bulletin Astronomique* for February—has given reason for believing that this is not the case, and that there have been at least two considerable periods, previous to the present one, in which the southern hemisphere was by far the more prolific in spots. The first of these was from 1621 to 1625, during which Scheiner's observations give us no spots in the northern hemisphere for 1621 and 1622, very few up to February 1625, and decidedly fewer than in the southern hemisphere until 1626, when a practical equality was established. The second period was in every way a more remarkable one, lasting for more than forty years. We have no record of any northern spots from 1672 to 1704; a few were seen in 1705, but their appearance there was looked upon as a most remarkable circumstance: Cassini and Maraldi recorded that they had never seen spots in the northern hemisphere before; and later, in 1714, on the occasion of the appearance of three northern spots, it was stated in a paper in the *Mémoires* of the Paris Academy that that hemisphere had been free from spots for forty years. This period, 1672–1713, seems to have been an exceptional one from several points of view. For much of the time there seem to have been scarcely any spots visible at all. Cassini, noting the third spot seen in 1676, remarks that in that year they had been more frequent than in the twenty preceding years. Flamsteed, in 1684, says that a spot he saw then was the first he had seen since 1676. Cassini, later on, states that the only spot seen since 1686 was that of May 1688, whilst in 1705 it is recorded ("Histoire de l'Académie," 1795, p. 128) that since Scheiner's observations, made sixty years before, two groups of spots had hardly ever been seen at the same time. Ten years later a similar remark is made; but, in 1716, spots became much more numerous, and as many as eight groups were seen at one time, from August 30 to September 3. The "law of zones," which Prof. Spoerer demonstrated for recent periods, the law that, from minimum to minimum, the spots show a tendency to seek lower and lower latitudes, breaking out afresh in high latitudes directly the next minimum is passed, seems to have been in abeyance during this remarkable period. The mean latitude seems to have been about 8° or 9°, but there was no regular drift downward made evident. The law, as Prof. Spoerer shows in the first of the above-named papers, appears to be unmistakably illustrated by Scheiner's observations at the time of the minimum of 1619, whilst the observations of 1643 and 1644 gave also a low mean latitude previous to the minimum of 1645. Observations at minima since the exceptional period of 1672–1713 supply many illustrations of the law of zones, as Prof. Spoerer takes occasion to demonstrate for the minima of 1755, 1775, 1784, 1833, and 1844.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 *MARCH* 17–23.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on March 17

Sun rises, 6h. 11m.; souths, 12h. 8m. 23·5s.; sets, 18h. 7m.: right asc. on meridian, 23h. 49·4m.; decl. 1° 9′ S. Sidereal Time at Sunset, 5h. 48m.

Moon (Full on March 17, 12h.) rises, 18h. 10m.; souths, 0h. 42m.*; sets, 6h. 58m.*: right asc. on meridian, 12h. 24·6m.; decl. 2° 39′ N.

GEOGRAPHICAL NOTES.

THE paper on Monday night at the Royal Geographical Society was by the Hon. G. Curzon, M.P., and dealt with the Trans-Caspian Railway, over which Mr. Curzon recently travelled from the Caspian to Samarcand, a distance of 900 miles. Mr. Curzon described the structure of the railway, the engineering and other difficulties met with, the geographical features of the country traversed, and referred in some detail to the political, civilizing, and commercial results of the undertaking. The line is on a 5-foot gauge, which is uniform with the railway system of European Russia, but not with that of British India. The rails are of steel, from 19 to 22 feet long, and are laid upon wooden sleepers at the rate of 2000 sleepers to every mile, being simply spiked down without chairs or bolts. Every piece of timber, iron, and steel employed was brought from the forests or workshops of Russia, for the most part down the Volga and across the Caspian. The line is a single one from start to finish, except at the stations, where there are invariably sidings, and sometimes triangles, for an engine to reverse; it is laid upon a low earthwork or embankment thrown up with the soil scooped out of a shallow trench on either side. The permanent way is not metalled. It has been claimed that this railway is an astonishing engineering phenomenon, inasmuch as it traverses a country previously believed to be inaccessible to such a method of locomotion. But Mr. Curzon maintains, apart from the local lack of material due to the appalling dearth of the country, it is probably the easiest and simplest railway ever built. The region which it traverses is as flat as a billiard-table for almost the entire distance, the steepest gradient being 1 in 150. There are no tunnels, only a few insignificant cuttings, and but three bridges—across the Tejend, across the Murghab at Merv, and across the Amu-daria. The two main difficulties arose from scarcity of water and superabundance of sand. The former was not difficult to overcome, and the various means employed to check the destructive effects of sand will no doubt prove efficacious, though constant watchfulness along the whole line will be required. The really formidable sands are limited to three districts: (1) the first thirty miles from the Caspian; (2) the stretch between the Merv Oasis and the Oxus; and (3) the stretch between the Oxus and Bokhara. Here no vegetation is either visible or, with rare exceptions, possible; the sand, of the most brillant yellow hue, is piled in loose hillocks and mobile dunes, and is swept hither and thither by powerful winds. It has all the appearance of a sea of troubled waves, billow succeeding billow in melancholy succession, with the sand driving like spray from their summits, and great smooth-swept troughs lying between, on which the winds leave the imprint of their fingers in wavy indentations, just like an ebb tide on the sea-shore. Near the Caspian the permanent way was soaked with sea-water so as to give it consistency; in other parts it was covered with a sort of armour-plating of clay. Elsewhere, and in the more desolate regions, other plans were adopted. Light wooden palisades, 3 or 4 feet high, made of pine laths, were driven into the tops of the dunes and formed a barrier against which the winds might pile the sands with impunity. Nurseries for suitable desert plants were started in the Persian Mountains, and the product of these, tamarisk, wild oats, &c., were planted on the sand-hillocks contiguous to the line. Here, too, was planted that strange and interesting denizen of the wilderness the *Saxaoul* (*Haloxylon ammodendron*), which with a scanty and often ragged upper-growth, strikes its sturdy roots deep down into the sand, and somehow or other derives sustenance from that to which it gives stability and permanence. Fascines of the branches of this plant were also cut, laid at right angles to the rails along the edge of the earthwork or embankment, and covered over with a layer of sand. In spite of all these precautions, the sand must always constitute a serious danger to the line. In referring to Merv, and the miles and miles of ruins of the various old Mervs, Mr. Curzon gives the area of the oasis as 1600 square miles, with a population of not more than 100,000. The desert by which the oasis is surrounded is appalling. East and west, and north and south, stretches a troubled ocean of sand, each wave arrested, as it were, in mid career, when just curving to fall. Mr. Curzon never saw anything more melancholy than this wilderness with its sickle-shaped dome-like ridges of sand, succeeding each other with the regularity of infantry files. Each has the appearance of being cloven through the crown, the side facing towards the north-east, whence the prevailing winds blow, being uniform, convex, and smooth, while the southern face is vertical and abrupt. With regard to the famous bridge over the Oxus, Mr. Curzon states that its total length is 2000 yards, and that it rests on more than 3000 piles. The level of the rails is about 30 feet above low, but only 5 feet above high, water.

TO the March number of the *Scottish Geographical Magazine*, an instructive paper on the Islands of Melanesia is contributed by Dr. R. H. Codrington. Mr. Ravenstein, in a paper accompanied by a map, on Lake Bangweolo, corrects the configuration of the lake based on a wrong interpretation of Livingstone's observations. Comparing them with subsequent results, Mr. Ravenstein shows that the length of the lake is north and south, and that the Luapula issues from its south-west corner. Mr. Ralph Richardson brings together a useful collection of data on the Edinburgh earthquake of January last.

THE Foreign Office has just published some extracts from a journal kept by Mr. W. J. Archer, British Vice-Consul at Chiengmai, or Zimmé, of a visit to Chiengtung, in May and June 1888. Mr. Archer traversed the little-known and mountainous region lying between the Rivers Salween and Cambodia, taking altogether thirty-six days for his journey both ways. From Chiengmai to Chienghai there are only a few towns, some of them inhabited by Luwas, the aborigines of the country. The hills, which abound in tigers, are uncultivated, but the valleys and low-lying grounds appeared well tilled, and bearing good crops of rice and paddy. North of Chienghai he saw the effects of attacks by the dacoits on the villagers. The former were Ngios from the Chiengtung territory, led by a Lao. Mr. Archer says that he was surprised to see what little traffic there was on the road, but this, perhaps, was due to some extent to

the very heavy rains. The highest mountain-range of the whole region is a little south of Chiengtung, and is about 4400 feet high. After leaving Müang Hai, no signs of habitation were seen until Chiengtung was reached. As an instance of the insecurity of the country, he mentions that with one party he saw a young woman armed like the men. The plateau of Chiengtung is about 2700 feet above the sea-level, and is very bare and badly cultivated. The town itself is walled, and is situated in the southern corner of the plateau, which is inclosed by high mountains on the west, south, and east. The chief products are rice, cotton, and opium; tea is also cultivated on the hills. Cotton goods are imported from Moulmein; salt, silk, and other articles from Yünnan; cocoa-nuts and betel-nuts from Chienghai. The inhabitants of the district belong to several races; the majority are of the same people as the ruling family, but there are also numbers of Western Shans, of the hill tribes (the Kins, Kans, and Musös), and Lëms and Lüs. The houses of the people are as miserable as could be, and their great poverty is shown by the fact that, instead of their temples being made of brick, as is the case in Siam, they are wretched sheds, almost as miserable as the houses. Mr. Archer returned by a different road, and found whole districts uninhabited between Chiengtung and Muang Lën, which is close to the Cambodia River.

THE *Manchester Guardian* publishes some interesting information as to the movements of Dr. Lansdell. In October last he arrived at Khoten, whence he set out for Yarkand. He left Yarkand for Western Tibet and crossed the Kilian Pass at a height of 17,000 feet on December 2. On the 10th the Karakoram was passed without very much difficulty; but a few days later, when crossing the Saser, the party suffered very much from the intense cold. On November 14, Dr. Lansdell sighted at Changlung the first inhabited huts of the Tibetans. Crossing over Khardung Pass with great difficulty, he finally arrived at Leh, where he remained for a few days, setting out on December 5 to descend to Kashmir. To aid in this attempt, forty men were sent by the local authorities, and Zogiha Pass was crossed in safety, and Kashmir reached. In a few days Srinagur was reached, but Soultem Passes were blocked, and an attempt to penetrate them was abandoned. At Rawul Pindee, Dr. Lansdell's journey finished, he having travelled from Kuldja 2000 miles, crossing seven of the highest passes in the world.

THE Government Geologist who set out from Adelaide some months ago to explore Central Australia has just returned. He travelled as far north as Alice Springs—that is, to the Tropic of Capricorn—and spent nearly a fortnight there examining the ruby and gold fields. Between Anna Creek and Alice Springs the country is well watered, but at the diggings water is very scarce. In all, some 2400 miles were travelled, and, around the ruby fields, camels were employed. The heat was very great, on one occasion reaching as much as 124° F. in the shade.

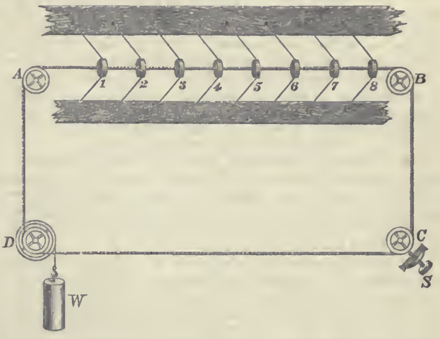
THE DISCHARGE OF A LEYDEN JAR.[1]

IT is one of the great generalizations established by Faraday, that all electrical charge and discharge is essentially the charge and discharge of a Leyden jar. It is impossible to charge one body alone. Whenever a body is charged positively, some other body is *ipso facto* charged negatively, and the two equal opposite charges are connected by lines of induction. The charges are, in fact, simply the ends of these lines, and it is as impossible to have one charge without its correlative as it is to have one end of a piece of string without there being somewhere, hidden it may be, split up into strands it may be, but somewhere existent, the other end of that string.

This I suppose familiar fact that all charge is virtually that of a Leyden jar being premised, our subject for this evening is at once seen to be a very wide one, ranging in fact over the whole domain of electricity. For the charge of a Leyden jar includes virtually the domain of electrostatics; while the discharge of a jar, since it constitutes a current, covers the ground of current electricity all except that portion which deals with phenomena peculiar to steady currents. And since a current of electricity necessarily magnetizes the space around it, whether it flow in a straight or in a curved path, whether it flow through wire or burst through air, the territory of magnetism is likewise invaded; and inasmuch as a Leyden jar discharge is oscillatory, and we now know the vibratory motion called light to be really an oscillating electric current, the domain of optics is seriously encroached upon.

But though the subject I have chosen would permit this wide range, and though it is highly desirable to keep before our minds the wide-reaching import of the most simple-seeming fact in connection with such a subject, yet to-night I do not intend to avail myself of any such latitude, but to keep as closely and distinctly as possible to the Leyden jar in its homely and well-known form, as constructed out of a glass bottle, two sheets of tinfoil, and some stickphast.

The act of charging such a jar I have permitted myself now for some time to illustrate by the mechanical analogy of an inextensible endless cord able to circulate over pulleys, and threading in some portion of its length a row of tightly-gripping beads which are connected to fixed beams by elastic threads.



Mechanical analogy of a circuit partly *dielectric*; for instance, of a charged condenser. A is its positive coat, B its negative.

The cord is to represent electricity; the beads represent successive strata in the thickness of the glass of the jar, or, if you like, atoms of dielectric or insulating matter. Extra tension in the cord represents negative potential, while a less tension (the nearest analogue to pressure adapted to the circumstances) represents positive potential. Forces applied to move the cord, such as winches or weights, are electromotive forces; a clamp or fixed obstruction represents a rheostat or contact-breaker; and an excess or defect of cord between two strata of matter represents a positive or a negative charge.

The act of charging a jar is now quite easily depicted as shown in the diagram.

To discharge the jar one must remove the charging E.M.F. and unclamp the screw, *i.e.* close the circuit. The stress in the elastic threads will then rapidly drive the cord back, the inertia of the beads will cause it to overshoot the mark, and for an instant the jar will possess an inverse charge. Back again the cord swings, however, and a charge of same sign as at first, but of rather less magnitude, would be found in the jar if the operation were now suspended. If it be allowed to go on, the oscillations gradually subside, and in a short time everything is quiescent, and the jar is completely discharged.

All this occurs in the Leyden jar, and the whole series of oscillations, accompanied by periodic reversal and re-reversal of the charges of the jar, is all accomplished in the incredibly short space of time occupied by a spark.

Consider now what the rate of oscillation depends on. Manifestly on the elasticity of the threads and on the inertia of the matter which is moved. Take the simplest mechanical analogy, that of the vibration of a loaded spring, like the reeds in a musical box. The stiffer the spring, and the less the load, the faster it vibrates. Give a mathematician these data, and he will calculate for you the time the spring takes to execute one complete vibration, the "period" of its swing. [Loaded lath in vice.]

The electrical problem and the electrical solution are precisely the same. That which corresponds to the flexibility of the spring is in electrical language called static capacity, or, by Mr. Heaviside, permittance. That which corresponds to the inertia of ordinary matter is called electro-magnetic inertia, or self-induction, or, by Mr. Heaviside, inductance.

[1] Friday evening discourse at the Royal Institution of Great Britain, on March 8, by Prof. Oliver J. Lodge, F.R.S.

Increase either of these, and the rate of oscillation is diminished. Increasing the static capacity corresponds to lengthening the spring; increasing the self-induction corresponds to loading it.

Now the static capacity is increased simply by using a larger jar, or by combining a number of jars into a battery in the very old-established way. Increase in the self-induction is attained by giving the discharge more space to magnetize, or by making it magnetize a given space more strongly. For electro-magnetic inertia is wholly due to the magnetization of the space surrounding a current, and this space may be increased or its magnetization intensified as much as we please.

To increase the space we have only to make the discharge take a long circuit instead of a short one. Thus we may send it by a wire all round the room, or by a telegraph wire all round a town, and all the space inside it and some of that outside will be more or less magnetized. More or less, I say, and it is a case of less rather than more. Practically very little effect is felt except close to the conductor, and accordingly the self-induction increases very nearly proportionally to the length of the wire, and not in proportion to the area inclosed: provided also the going and return wires are kept a reasonable distance apart, so as not to encroach upon each other's appreciably magnetized regions.

But it is just as effective, and more compact, to intensify the magnetization of a given space by sending the current hundreds of times round it instead of only once; and this is done by inserting a coil of wire into the discharge circuit.

Yet a third way there is of increasing the magnetization of a given space, and that is to fill it with some very magnetizable substance such as iron. This, indeed, is a most powerful method under many circumstances, it being possible to increase the magnetization and therefore the self-induction or inertia of the current some 5000 times by the use of iron.

But in the case of the discharge of a Leyden jar iron is of no advantage. The current oscillates so quickly that any iron introduced into its circuit, however subdivided into thin wires it may be, is protected from magnetism by inverse currents induced in its outer skin, as your Professor of Natural Philosophy[1] has shown, and accordingly it does not get magnetized; and so far from increasing the inductance of the discharge circuit it positively diminishes it by the reaction effect of these induced currents: it acts, in fact, much as a mass of copper might be expected to do.

The conditions determining rate of oscillation being understood, we have next to consider what regulates the damping out of the vibrations, *i.e.* the total duration of the discharge.

Resistance is one thing. To check the oscillations of a vibrating spring you apply to it friction, or make it move in a viscous medium, and its vibrations are speedily damped out. The friction may be made so great that oscillations are entirely prevented, the motion being a mere dead-beat return to the position of equilibrium; or, again, it may be greater still, and the motion may correspond to a mere leak or slow sliding back, taking hours or days for its accomplishment. With very large condensers, such as are used in telegraphy, this kind of discharge is frequent, but in the case of a Leyden jar discharge it is entirely exceptional. It can be caused by including in the circuit a wet string, or a capillary tube full of distilled water, or a slab of wood, or other atrociously bad conductor of that sort; but the conditions ordinarily associated with the discharge of a Leyden jar, whether it discharge through a long or a short wire, or simply through its tongs, or whether it overflow its edge or puncture its glass, are such as correspond to oscillations, and not to leak. [Discharge jar first through wire and next through wood.]

When the jar is made to leak through wood or water the discharge is found to be still not steady: it is not oscillatory indeed, but it is intermittent. It occurs in a series of little jerks, as when a thing is made to slide over a resined surface. The reason of this is that the terminals discharge faster than the circuit can supply the electricity, and so the flow is continually stopped and begun again.

Such a discharge as this, consisting really of a succession of small sparks, may readily appeal to the eye as a single flash, but it lacks the noise and violence of the ordinary discharge; and any kind of moving mirror will easily analyze it into its constituents and show it to be intermittent. [Shake a mirror, or waggle head or opera-glass.]

It is pretty safe to say, then, that whenever a jar discharge is not oscillatory it is intermittent, and when not intermittent is oscillatory. There is an intermediate case when it is really dead-beat, but it could only be hit upon with special care, while its occurrence by accident must be rare.

[1] Lord Rayleigh.

So far I have only mentioned resistance or friction as the cause of the dying out of the vibrations; but there is another cause, and that a most exciting one.

The vibrations of a reed are damped partly indeed by friction and imperfect elasticity, but partly also by the energy transferred to the surrounding medium and consumed in the production of sound. It is the formation and propagation of sound-waves which largely damp out the vibrations of any musical instrument. So it is also in electricity. The oscillatory discharge of a Leyden jar disturbs the medium surrounding it, carves it into waves which travel away from it into space: travel with a velocity of 185,000 miles a second: travel precisely with the velocity of light. [Tuning-fork.]

The second cause, then, which damps out the oscillations in a discharge circuit is *radiation: electrical* radiation if you like so to distinguish it, but it differs in no respect from ordinary radiation (or "radiant heat" as it has so often been called in this place); it differs in no respect from Light except in the physiological fact that the retinal mechanism, whatever it may be, responds only to waves of a particular, and that a very small, size, while radiation in general may have waves which range from 10,000 miles to a millionth of an inch in length.

The seeds of this great discovery of the nature of light were sown in this place: it is all the outcome of Faraday's magneto-electric and electrostatic induction: the development of them into a rich and full-blown theory was the greatest part of the life-work of Clerk-Maxwell: the harvest of experimental verification is now being reaped by a German. But by no ordinary German. Dr. Hertz, now Professor in the Polytechnicum of Karlsruhe, is a young investigator of the highest type. Trained in the school of Helmholtz, and endowed with both mathematical knowledge and great experimental skill, he has immortalized himself by a brilliant series of investigations which have cut right into the ripe corn of scientific opinion in these islands, and by the same strokes as have harvested the grain have opened up wide and many branching avenues to other investigators.

At one time I had thought of addressing you this evening on the subject of these researches of Hertz, but the experiments are not yet reproducible on a scale suited to a large audience, and I have been so closely occupied with some not wholly dissimilar, but independently conducted, researches of my own—researches led up to through the unlikely avenue of lightning-conductors—that I have had as yet no time to do more than verify some of them for my own edification.

In this work of repetition and verification Prof. Fitzgerald has, as related in a recent number of NATURE (February 21, p. 391), probably gone further; and if I may venture a suggestion to your Honorary Secretary, I feel sure that a discourse on Hertz's researches from Prof. Fitzgerald next year would be not only acceptable to you, but would be highly conducive to the progress of science.

I have wandered a little from my Leyden jar, and I must return to it and its oscillations. Let me very briefly run over the history of our knowledge of the oscillatory character of a Leyden jar discharge. It was first clearly realized and distinctly stated by that excellent experimentalist, Joseph Henry, of Washington, a man not wholly unlike Faraday in his mode of work, though doubtless possessing to a less degress that astonishing insight into intricate and obscure phenomena; wanting also in Faraday's circumstantial advantages.

This great man arrived at a conviction that the Leyden jar discharge was oscillatory by studying the singular phenomena attending the magnetization of steel needles by a Leyden jar discharge, first observed in 1824 by Savary. Fine needles, when taken out of the magnetizing helices, were found to be not always magnetized in the right direction, and the subject is referred to in German books as anomalous magnetization. It is not the magnetization which is anomalous, but the currents which have no simple direction; and we find in a memoir published by Henry in 1842, the following words:—

"This anomaly, which has remained so long unexplained, and which, at first sight, appears at variance with all our theoretical ideas of the connection of electricity and magnetism, was, after considerable study, satisfactorily referred by the author to an action of the discharge of the Leyden jar which had never before been recognized. The discharge, whatever may be its nature, is not correctly represented (employing for simplicity the theory of Franklin) by the single transfer of an imponderable fluid

from one side of the jar to the other; the phenomenon requires us to admit *the existence of a principal discharge in one direction and then several reflex actions backward and forward, each more feeble than the preceding, until the equilibrium is obtained.* All the facts are shown to be in accordance with this hypothesis, and a ready explanation is afforded by it of a number of phenomena, which are to be found in the older works on electricity, but which have until this time remained unexplained."[1]

The italics are Henry's. Now if this were an isolated passage it might be nothing more than a lucky guess. But it is not. The conclusion is one at which he arrives after a laborious repetition and serious study of the facts, and he keeps the idea constantly before him when once grasped, and uses it in all the rest of his researches on the subject. The facts studied by Henry do in my opinion support his conclusion, and if I am right in this it follows that he is the original discoverer of the oscillatory character of a spark, although he does not attempt to state its theory. That was first done, and completely done, in 1853, by Sir William Thomson; and the progress of experiment by Feddersen, Helmholtz, Schiller, and others has done nothing but substantiate it.

The writings of Henry have been only quite recently collected and published by the Smithsonian Institution of Washington in accessible form, and accordingly they have been far too much ignored. The two volumes contain a wealth of beautiful experiments clearly recorded, and well repay perusal.

The discovery of the oscillatory character of a Leyden jar discharge may seem a small matter, but it is not. One has only to recall the fact that the oscillators of Hertz are essentially Leyden jars—one has only to use the phrase "electro-magnetic theory of light"—to have some of the momentous issues of this discovery flash before one.

One more extract I must make from that same memoir by Henry,[2] and it is a most interesting one; it shows how near he was, or might have been, to obtaining some of the results of Hertz; though, if he had obtained them, neither he nor any other experimentalist could possibly have divined their real significance.

It is, after all, the genius of Maxwell and of a few other great theoretical physicists whose names are on everyone's lips[3] which endows the simple induction experiments of Hertz and others with such stupendous importance.

Here is the quotation:—

"In extending the researches relative to this part of the investigations, a remarkable result was obtained in regard to the distance at which induction effects are produced by a very small quantity of electricity; a single spark from the prime conductor of a machine, of about an inch long, thrown on to the end of a circuit of wire in an upper room, produced an induction sufficiently powerful to magnetize needles in a parallel circuit of iron placed in the cellar beneath, at a perpendicular distance of 30 feet, with two floors and ceilings, each 14 inches thick, intervening. The author is disposed to adopt the hypothesis of an electrical *plenum* [in other words, of an ether], and from the foregoing experiment it would appear that a single spark is sufficient to disturb perceptibly the electricity of space throughout at least a cube of 400,000 feet of capacity; and when it is considered that the magnetism of the needle is the result of the difference of two actions, it may be further inferred that the diffusion of motion in this case is almost comparable with that of a spark from a flint and steel in the case of light."

Comparable it is, indeed, for we now know it to be the self-same process.

One immediate consequence and easy proof of the oscillatory character of a Leyden jar discharge is the occurrence of phenomena of sympathetic resonance.

Everyone knows that one tuning-fork can excite another at a reasonable distance if both are tuned to the same note. Everyone knows, also, that a fork can throw a stretched string attached to it into sympathetic vibration if the two are tuned to unison or to some simple harmonic. Both these facts have their electrical analogue. I have not time to go fully into the matter to-night, but I may just mention the two cases which I have myself specially noticed.

A Leyden jar discharge can so excite a similarly-timed neighbouring Leyden jar circuit as to cause the latter to burst its dielectric if thin and weak enough. The well-timed impulses accumulate in the neighbouring circuit till they break through a quite perceptible thickness of air.

Put the circuits out of unison by varying the capacity or by including a longer wire in one of them; then, although the added wire be a coil of several turns, well adapted to assist mutual induction as ordinarily understood, the effect will no longer occur.

That is one case, and it is the electrical analogue of one tuning-fork exciting another. It is too small at present to show here satisfactorily, for I only recently observed it, but it is exhibited in the library at the back.

The other case, analogous to the excitation of a stretched string of proper length by a tuning-fork, I published last year under the name of the experiment of the recoil kick, where a Leyden jar circuit sends waves along a wire connected by one end with it, which waves splash off at the far end with an electric brush or long spark.

I will show merely one phase of it to-night, and that is the reaction of the impulse accumulated in the wire upon the jar itself, causing it to either overflow or burst. [Sparks of gallon or pint jar made to overflow by wire round room.[1]]

The early observations by Franklin on the bursting of Leyden jars, and the extraordinary complexity or multiplicity of the fracture that often results, are most interesting.

His electric experiments as well as Henry's well repay perusal, though of course they belong to the infancy of the subject.

He notes the striking fact that the bursting of a jar is an extra occurrence, it does not replace the ordinary discharge in the proper place, it accompanies it; and we now know that it is precipitated by it, that the spark occurring properly between the knobs sets up such violent surgings that the jar is far more violently strained than by the static charge or mere difference of potentials between its coatings; and if the surgings are at all even roughly properly timed, the jar is bound to either overflow or burst.

Hence a jar should always be made without a lid, and with a lip protruding a carefully considered distance above its coatings: not so far as to fail to act as a safety valve, but far enough to prevent overflow under ordinary and easy circumstances.

And now we come to what is after all the main subject of my discourse this evening, viz. the optical and audible demonstration of the oscillations occurring in the Leyden jar spark. Such a demonstration has, so far as I know, never before been attempted, but if nothing goes wrong we shall easily accomplish it.

And first I will do it audibly. To this end the oscillations must be brought down from their extraordinary frequency of a million or hundred thousand a second to a rate within the limits of human audition. One does it exactly as in the case of the spring—one first increases the flexibility and then one loads it. [Spark from battery of jars and varying sound of same.]

Using the largest battery of jars at our disposal, I take the spark between these two knobs—not a long spark, ¼ inch will be quite sufficient. Notwithstanding the great capacity, the rate of vibration is still far above the limit of audibility, and nothing but the customary crack is heard. I next add inertia to the circuit by including a great coil of wire, and at once the spark changes character, becoming a very shrill but an unmistakable whistle, of a quality approximating to the cry of a bat. Add another coil, and down comes the pace once more, to something like 5000 per second, or about the highest note of a piano. Again and again I load the circuit with magnetizability, and at last the spark has only 500 vibrations a second, giving the octave, or perhaps the double octave, above the middle C.

[1] "Scientific Writings of Joseph Henry," vol. i. p. 201. Published by the Smithsonian Institution, Washington, 1886.

[2] *Loc. cit.*, p. 204.

[3] And of one whose name is not yet on everybody's lips, but whose profound researches into electro-magnetic waves have penetrated further than anybody yet understands into the depths of the subject, and whose papers have very likely contributed largely to the theoretical inspiration of Hertz—I mean that powerful mathematical physicist, Mr. Oliver Heaviside.

[1] During the course of this experiment, the gilt paper on the wall was observed by the audience to be sparkling, every gilt patch over a certain area discharging into the next, after the manner of a spangled jar. It was probably due to some kind of sympathetic resonance. Electricity splashes about in conductors in a surprising way everywhere in the neighbourhood of a discharge. For instance, a telescope in the hand of one of the audience was reported afterwards to be giving off little sparks at every discharge of the jar. Everything which happens to have a period of electric oscillation corresponding to some harmonic of the main oscillation of a discharge is liable to behave in this way. When light falls on an opaque surface it is quenched. What the audience saw was probably the result of waves of electrical radiation being quenched by the walls of the room, and generating electrical currents in the act. It is these electric surgings which render such severe caution necessary in the erection of lightning-conductors. This explanation is merely tentative. I have had no time to investigate the matter locally.

One sees clearly why one gets a musical note: the noise of the spark is due to a sudden heating of the air; now if the heat is oscillatory, the sound will be oscillatory too, but both will be an octave above the electric oscillation, if I may so express it, because two heat-pulses will accompany every complete electric vibration, the heat production being independent of direction of current.

Having thus got the frequency of oscillation down to so manageable a value, the optical analysis of it presents no difficulty: a simple looking-glass waggled in the hand will suffice to spread out the spark into a serrated band, just as can be done with a singing or a sensitive flame, a band too of very much the same appearance.

Using an ordinary four-square rotating mirror driven electromagnetically at the rate of some two or three revolutions per second, the band is at the lowest pitch seen to be quite coarsely serrated; and fine serrations can be seen with four revolutions per second in even the shrill whistling sparks.

The only difficulty in seeing these effects is to catch them at the right moment. They are only visible for a minute fraction of a revolution, though the band may appear drawn out to some length. The further away a spark is from the mirror, the more drawn out it is, but also the less chance there is of catching it.

With a single observer it is easy to arrange a contact maker on the axle of the mirror which shall bring on the discharge at the right place in the revolution, and the observer may then conveniently watch for the image in a telescope or opera-glass, though at the lower pitches nothing of the kind is necessary.

But to show it to a large audience various plans can be adopted. One is to arrange for several sparks instead of one; another is to multiply images of a single spark by suitably adjusted reflectors, which if they are concave will give magnified images; another is to use several rotating mirrors; and indeed I do use two, one adjusted so as to suit the spectators in the gallery.

But the best plan that has struck me is to combine an intermittent and an oscillatory discharge. Have the circuit in two branches, one of high resistance so as to give intermittences, the other of ordinary resistance so as to be oscillatory, and let the mirror analyze every constituent of the intermittent discharge into a serrated band. There will thus be not one spark, but a multitude of successive sparks, close enough together to sound almost like one, separate enough in the rotating mirror to be visible on all sides at once.

But to achieve it one must have great exciting power. In spite of the power of this magnificent Wimshurst machine, it takes some time to charge up our great Leyden battery, and it is tedious waiting for each spark. A Wimshurst does admirably for a single observer, but for a multitude one wants an instrument which shall charge the battery not once only but many times over, with overflows between, and all in the twinkling of an eye.

To get this I must abandon my friend Mr. Wimshurst, and return to Michael Faraday. In front of the table is a great induction coil; its secondary has the resistance needed to give an intermittent discharge. The quantity it supplies at a single spark will fill our jars to overflowing several times over. The discharge circuit and all its circumstances shall remain unchanged. [Excite jars by coil.]

Running over the gamut with this coil now used as our exciter instead of the Wimshurst machine—everything else remaining exactly as it was—you hear the sparks give the same notes as before, but with a slight rattle in addition, indicating intermittence as well as alternation. Rotate the mirror, and everyone should see one or other of the serrated bands of light at nearly every break of the primary current of the coil. [Rotating mirror to analyze sparks.]

The musical sparks which I have now shown you were obtained by me during a special digression[1] which I made while examining the effect of discharging a Leyden jar round heavy glass or bisulphide of carbon. The rotation of the plane of polarization of light by a steady current, or by a magnetic field of any kind properly disposed with respect to the rays of light, is a very familiar one in this place. Perhaps it is known also that it can be done by a Leyden jar current. But I do not think it is; and the fact seems to me very interesting. It is not exactly new—in fact, as things go now it may be almost called old, for it was investigated six or seven years ago by two most highly skilled French experimenters, Messrs. Bichat and Blondlot.

[1] Most likely it was a conversation which I had with Sir Wm. Thomson, at Christmas, which caused me to see the interest of getting slow oscillations. My attention has mainly been directed to getting them quick.

But it is exceedingly interesting as showing how short a time, how absolutely no time, is needed by heavy glass to throw itself into the suitable rotatory condition. Some observers have thought they had proved that heavy glass requires time to develop the effect, by spinning it between the poles of a magnet and seeing the effect decrease; but their conclusions cannot be right, for the polarized light follows every oscillation in a discharge, the plane of polarization being waved to and fro as often as 70,000 times a second in my own observation.

Very few persons in the world have seen the effect. In fact, I doubt if anyone had seen it a month ago except Messrs. Bichat and Blondlot. But I hope to make it visible to most persons here, though I hardly hope to make it visible to all.

Returning to the Wimshurst machine as exciter, I pass a discharge round the spiral of wire inclosing this long tube of CS_2, and the analyzing Nicol being turned to darkness, there may be seen a faint—by those close to not so faint, but a very momentary—restoration of light on the screen at every spark. [CS_2 tube experiment on screen.]

Now I say that this light restoration is also oscillatory. One way of proving this fact is to insert a biquartz betweeen the Nicols. With a steady current it constitutes a sensitive detector of rotation, its sensitive tint turning green on one side and red on the other. But with this oscillatory current a biquartz does absolutely nothing. [Biquartz.]

That is one proof. Another is that rotating the analyzer either way weakens the extra brightening of the field, and weakens it equally either way.

But the most convincing proof is to reflect the light coming through the tube upon our rotating mirror, and to look now not at the spark, or not only at the spark, but at the faint band into which the last residue of light coming through polarizer and tube and analyzer is drawn out. [Analyze the light in rotating mirror.]

At every discharge this faint streak brightens in places into a beaded band: these are the oscillations of the polarized light: and when examined side by side they are as absolutely synchronous with the oscillations of the spark itself as can be perceived.

Out of a multitude of phenomena connected with the Leyden jar discharge I have selected a few only to present to you here this evening. Many more might have been shown, and great numbers more are not at present adapted for presentation to an audience, being only visible with difficulty and close to.

An old and trite subject is seen to have in the light of theory an unexpected charm and brilliancy. So it is with a great number of other old familiar facts at the present time.

The present is an epoch of astounding activity in physical science. Progress is a thing of months and weeks, almost of days. The long line of isolated ripples of past discovery seem blending into a mighty wave, on the crest of which one begins to discern some oncoming magnificent generalization. The suspense is becoming feverish, at times almost painful. One feels like a boy who has been long strumming on the silent keyboard of a deserted organ, into the chest of which an unseen power begins to blow a vivifying breath. Astonished, he now finds that the touch of a finger elicits a responsive note, and he hesitates, half delighted, half affrighted, lest he be deafened by the chords which it would seem he can now summon forth almost at will.

ON THE LIMIT OF THE SOLAR SPECTRUM, THE BLUE OF THE SKY, AND THE FLUORESCENCE OF OZONE.

THERE are two facts of particular interest which have been observed in connection with the light which we receive from the sun and the sky. First, though the ultra-violet spectrum of the sun is very well represented by the iron spectrum taken from the electric arc, yet its length is nothing like so great, and there is no fading away of feeble lines and a weakening of strong ones, which would be the case if the rays were affected by a turbid medium through which they were transmitted, but there is a sudden and sharp extinction which points to a very definite absorption. Secondly, light from the clearest sky, unaffected by aqueous vapour, is of a deep and beautiful blue colour, more of

an indigo-violet tint than ordinary so-called sky-blue. There is nothing more beautiful in Nature than the blueness of the heavens.

The limitation of the solar spectrum has been the subject of elaborate investigation by M. Cornu.[1] He proved by direct experiment that the ultra violet rays are absorbed with energy by the atmosphere, and showed that there is a variation in the amount of absorption corresponding with different altitudes, so that the absorbent matter is at each elevation proportional to the barometric pressure, and consequently in constant relation to the mass of the atmosphere. This fact alone is sufficient to exclude water-vapour from consideration as being the medium of absorption. Moreover, water-vapour, while it absorbs the red and infra-red rays, transmits the ultra-violet very completely.

Photographs taken in 1879 on the Riffelberg, at an altitude therefore of 8414 feet, reached to wave-length 2932; but at Viège, an altitude of 2165 feet, to only 2954.

In short, it was shown that within the limits of altitude at which Cornu's observations were made there was a difference of 10 tenth-metrets of wave-length for every 984 feet of dry atmosphere, the shortening of the spectrum being due to the gaseous constituents. Notwithstanding this, it was stated by Prof. Liveing, in a lecture delivered at the Royal Institution on March 9, 1883, that we must suppose the absorbent substance, whatever it may be, is not in our atmosphere, because, when observations are made upon the summit of an elevation like the Riffelberg, the lengthening of the spectrum reaches only a very trifle beyond U. "The same reason will lead us to reject the notion that the absorption can be due to matter in interplanetary space, for it is not easy to suppose that the gases which pervade that space in extreme tenuity can differ much from those in our atmosphere, because the earth in its annual course must pick up whatever they are, and they must then diffuse into our atmosphere. The absorption is, therefore, probably neither in our atmosphere nor in interplanetary space, and we must look for it in the solar atmosphere."

It is then suggested that the blotting out of the sun's light beyond U is caused by something in the solar atmosphere higher up than the metallic vapours which give rise to Fraunhofer's lines, but at a lower temperature. It has been shown by Young that the Fraunhofer lines are bright lines, but appear black against the brilliant light of the photosphere. It never appeared to me that Prof. Liveing's objection to Cornu's explanation of the limitation of the solar spectrum by our atmosphere was valid, because it was proved beyond question that the atmosphere absorbs the ultra-violet rays, and also that on the same day and hour, at different elevations, the extent of rays absorbed was proportional to the barometric pressure—that is, to the quantity of air through which the rays passed. A considerable acquaintance with absorption-spectra in the ultra-violet region has proved to me that when an absorption-band has been blotted out by increasing the proportion of substance, or by increase of the thickness of the absorbent layer, a stage is soon reached at which any further increase only causes a trifling difference in absorbent action, and in fact that many substances attain a maximum of absorption beyond which there is no change unless we increase the density of the substance, and so probably alter its molecular structure. Under the same conditions of pressure, increased thickness of the absorbent layer only very slightly increases the absorbent action, and that in a degree which is by no means proportional to the layer of material.

There is a difficulty in accepting Prof. Liveing's views, because we know nothing, as he remarks, in the solar atmosphere capable of causing such absorption, and at the same time of transmitting the Fraunhofer lines of the less refrangible portions of the spectrum in the condition in which we observe them.

The matter was very fully considered by me two years previously—that is to say, in the year 1881. The absorption spectra of various gases were examined by photographing the ultra-violet rays which were transmitted by carefully measured quantities of gas at the atmospheric pressure, and one of these gases was ozone. It proved to be a substance with most extraordinary absorptive powers, so that even when very much diluted it exhibited an absorption-band of great intensity which was carefully investigated. By examining the spectrum transmitted by increasing quantities of ozone the band disappeared, and there was a complete and total absorption of rays extending to about wave-length 3160. Any further increase did not cause a

[1] "Sur l'Absorption Atmosphérique des Radiations ultra-violettes," *Journ. de Physique*, t. x. 1881.

corresponding shortening of the spectrum. The band was observed between wave-lengths about 2850 and 2320; but with increased proportions of ozone the rays transmitted were restricted to about 2920, and became more restricted in presence of greater quantities of gas.[1] Thus:—

Extreme ray transmitted by ozonized oxygen.		Length of column of gas traversed by the rays.		Actual volume of ozone per square centimetre of sectional area of column.
λ.		Centimetres.		Cubic cent.metres.
3035	...	92	...	1·012
3150	...	196·5	...	2·162
3160	...	288·5	...	3·175

It was found that a quantity of ozone proportional to the average quantity present in a vertical column of the atmosphere caused an absorption similar to that observed in the solar spectrum—that is to say, terminating about 2950. Largely increased quantities did not largely, but only in a trifling degree, increase the absorption. Furthermore, it was shown that the atmosphere contained ozone as a normal constituent, and that it was present in greater proportion in the upper regions than near the earth's surface. It was proved that all the other minute constituents of the atmosphere were either non absorbent or exerted absorption in a manner different from that of ozone, and that the quantity of ozone commonly present in the atmosphere is quite sufficient to account for the limitation of the solar spectrum, without taking into account the possible absorption caused by the great thickness of oxygen and of nitrogen. The possibility of oxygen being the absorptive substance seemed very great, considering the small difference in constitution between the molecules of ozone and oxygen. It must be understood that the conclusions were arrived at by reasoning from strictly quantitative experiments, and seemed almost incontrovertible, and it may be stated that none of the facts alleged have ever been questioned. It was impossible to deal with the matter further without costly appliances for the compression of oxygen and nitrogen into tubes capable of holding a quantity comparable with the amount of oxygen and of nitrogen in a vertical column of the atmosphere, and for this reason the investigation fell into abeyance.

It was also considered that the problem might be attacked in another manner.

Messrs. Liveing and Dewar have recently made a very interesting and important communication to the *Chemical News* (vol. lviii. p. 163), on the absorption-spectrum of oxygen. In a tube 1·6 metre in length, filled with the gas at a pressure of 160 atmospheres, all rays were absorbed beyond wave-length 2665, but they began to diminish at 2705. With a tube 6 metres or 20 feet long, and with a pressure of 90 atmospheres, it seems that an absorption-band is to be traced at wave-length 3640 to 3600, and there is a complete absorption beyond 3360.

The gas seen in quantity corresponding to that in a vertical column of the atmosphere appears to have a faint blue tint. There can be no doubt whatever that the oxygen of the air exerts a powerful absorption on the rays of the sun, but it does not appear from these experiments that this absorption is exactly the cause of the limitation of the spectrum, as described by Cornu, since when observed in tubes it is carried into a region of longer wave-length than is observed at the level of the sea; thus at Dublin the limit in summer is usually about 3130.[2] It is no doubt the high density of the gas which causes the absorption to be stronger than that of the atmosphere. It should be noted that the oxygen in the 20-foot tube was the quantity in a vertical column of the atmosphere. It is probable that there are several substances in interplanetary space, or in the solar atmosphere, which, besides oxygen and ozone in the air, cause an absorption of the sun's rays and a limitation of the length of the spectrum, but as Messrs. Liveing and Dewar point out, our atmosphere places a limit to the observations we can make on the rays of other heavenly bodies.

Touching the colour of the sky, Prof. Tyndall has told us that four centuries ago it was believed that the floating particles in the atmosphere render it a turbid medium through which we

[1] "On the Absorption-Spectrum of Ozone, and on the Absorption of Solar Rays by Atmospheric Ozone," Journ. Chem. Soc. 1881, xxxix., pp. 57, 111, 119.

[2] In the *Phil. Mag.*, September 1888, p. 288, Messrs. Liveing and Dewar refer only to my first paper on the absorption-spectrum of ozone, Journ. Chem Soc., xxxix, p. 57, but not to the more complete paper on this spectrum at pp. 111–119, *loc. cit.*, which indicates the possible limits of the ozone in the atmosphere.

look at the darkness of space. The blue colour, according to his view, is supposed to be caused by reflection from minute particles, which can reflect chiefly the blue rays by reason of their small size. Experiments on highly attenuated vapours during condensation to cloudy matter were the basis of this reasoning. It always seemed to me that if a view be seen through a turbid medium which reflects chiefly the blue rays, it would not appear blue, but the complementary colour, yellow; and therefore this theory could not account for the blue of distance. In fact, when a light mist hangs over the surface of the earth, and the rays of the sun are transmitted in a direction approaching the horizontal, the result is that the sun and all objects lying in the direction looking towards it appear yellow, while the mist in the opposite direction appears blue, and only translucent, not transparent. The blue of the sky, if caused by such a similar action of floating particles, would not be seen when the sun was overhead, nor could it be seen by looking in the direction of the sun.

The blue would not be transparent and in character similar to the blue of a clear distance, in which the outlines of mountains and rocks are perfectly distinct and sharp, the shadows being of an intensely deep blue, and the most distant objects the deepest in colour. In 1880, Messrs. Hautefeuille and Chappuis liquefied ozone, and found that its colour was indigo blue (*Comptes rendus*, xcv. p. 522). On December 12, 1880, M. Chappuis presented the Academy of Sciences of Paris with a paper on the visible spectrum of ozone. He recognized the most easily visible of the absorption-bands of ozone in the solar spectrum, and in consequence he stated that a theory of the blue colour of the sky could not be established without taking into account the presence of ozone in the atmosphere, for the luminous rays which reach us will of necessity be coloured blue by their transmission through the ozone contained in the atmosphere. And since ozone is an important constituent of the upper atmosphere, its blue colour certainly plays an important part in the colour of the sky. In March 1881, quantitative experiments made by me were published to show how much of blueness could be communicated to layers of gas of different thicknesses when given volumes of ozone are present. I showed that ozone is a normal constituent in the upper atmosphere, that it is commonly present in fresh air, and I accounted for its abundance during the prevalence of westerly and south-westerly winds. It was likewise shown that it was impossible to pass rays of light through as much as 5 miles of air without the rays being coloured sky-blue by the ozone commonly present, and that the blue of objects viewed on a clear day at greater distances up to 35 or 50 miles must be almost entirely the blueness of ozone in the air. The quantity of ozone giving a full sky-blue tint in a tube only 2 feet in length is 2½ milligrammes in each square centimetre of sectional area of the tube. It is necessary to mention that a theory of the blue of the sky was propounded by M. Lallemand ("Sur la Polarisation et la Fluorescence de l'Atmosphère," *Comptes rendus*, lxxv. p. 707, 1872) after his observations had been found inconsistent with all previous explanations. If the coloration be due to reflection from minute particles of floating matter, or if it be due to white light being transmitted through a blue gas, the blue portion of the sky should be polarized quite as much as white light coming from the same direction in the heavens. But the experiments of M. Lallemand prove that this is not so. Upon these experiments he bases his theory that the blue colour of the atmosphere is due to a blue fluorescence like that seen in acid solutions of sulphate of quinine—that is to say, caused by a change of refrangibility in the ultra-violet rays.

Ångström first threw out the idea of fluorescence being a property of certain gases in the atmosphere. To possess this property the gas must be capable of absorbing either in part or entirely the ultra-violet and violet rays, and of emitting them with a lowered refrangibility and without being polarized. Ozone possesses the property of absorption in the highest degree in the ultra-violet region, and I have now to announce that strongly ozonized oxygen is highly fluorescent when seen in a glass bottle two inches in diameter illuminated by an electric spark passing between cadmium electrodes. The colour of the fluorescence is a beautiful steel blue. This fluorescence has not been observed in other gases, but it is in the highest degree probable that oxygen is fluorescent, though this has yet to be proved. There can be, however, little doubt that the colour of the sky is caused in part by the fluorescence of ozone, and also to some extent by the transmission of rays through the blue gas. The blue of distance is doubtless to be attributed more to transmission than the blue of the sky, though it is quite conceivable that fluorescence also here comes into play. Whatever other cause concurs in the production of the blue of the heavens, it has certainly been established by M. Chappuis that the properties of ozone participate in its production.

In August 1884, a very short note was sent by me to NATURE concerning the red solar halo seen at Zermatt and on the Riffelberg with great distinctness. I recorded the occurrence of a dark band in the spectrum, slightly more refrangible than D, which was seen to vary in intensity; a second band a little less refrangible than D was also observed. On account of the altitude at which the observations were made, viz. 9000 feet, and the state of the weather at the time, these bands were considered to be due to some constituent of dry air.

The subject of the telluric rays has become of increased interest since M. Cornu has studied the dark lines in the neighbourhood of D, but unfortunately the rays absorbed to which I refer are both a little more and a little less refrangible than those figured on his map of this region. If we accept the number 5890 tenth-metres as approximately representing the mean value of the lines D^1 D^2, the narrow bands observed by me have wave-lengths about (1) 5950 and (2) 5770 at their darkest parts, as far as one can ascertain with a hand spectroscope giving excellent definition but small dispersion. They are very variable, being dependent on the state of the weather, and are more distinct and broader when viewed with the sun on the horizon. In London during the dry calm weather of June and July 1884, they were very strong, but variable in different parts of the sky.

The less refrangible band, or broad line as it usually appears, below D, is generally over-lapped by a band belonging to water vapour, the chief "rain-band." On this account observations at an elevation of 10,000 feet or so during perfectly dry weather were considered of interest. The bands were observed against the blue sky on several occasions, but they were also at other times entirely absent or barely visible. There is some liability to a group of iron, barium, and other solar lines being mistaken for the more refrangible band when it is not decidedly strong. Chappuis observed bands in the blue sky coincident with ozone bands, and I have on that account always expected to find some indication of the spectrum of ozone in the upper atmosphere, but the reason why there must always be a difficulty in obtaining evidence of any absorption due to this substance arises from the strongest visible band of ozone, with wave-length 6095 to 5935, being masked by the band of water vapour; and secondly, because the total amount of white light so preponderates as to overpower the effect of absorption—that is to say, the rays absorbed are only a small fraction of those transmitted, so that the bands are faint and the colour due to absorption is either not seen or seen only with difficulty. Owing to this fact we cannot distinguish the blue colour of the clouds when the sunlight is bright; but when the sky is completely over-clouded with cumuli a faintly bluish tint is given to the cloud-shadows, even at the zenith. Near the horizon not only are the bright parts of the clouds blue, but their shadows have a rich blue tint.[1] The blueness varies somewhat: at times it may be seen to shift about in the sky; it has been observed, for instance, to pass over from south-west to north-east. The second but less conspicuous band of ozone absorbs rays with wave-length 5770 to 5600. Both bands have been observed in a dry atmosphere at elevations varying from 6000 to 10,000 feet, both in the blue of the sky and against white clouds. The measurements, very imperfectly made under difficulties, showed them to have wave-lengths about (1) 5950, (2) 5770, in the centre of the dark portion, while, according to Chappuis, the bands of ozone are—

(1) 6095 to 5935	...	mean, 6010
(2) 5770 to 5600	...	mean, 5680.

On Ångström's chart, a dark band, diminishing in depth towards the east, extends from 5785 to 5680, which is classed among the *raies atmosphériques*; this is similar to the band observed by me when viewing the sun or bright clouds near the horizon, and is similar to the second ozone band.

The work of Prof. Piazzi-Smyth, "Madeira Spectroscopic," does not give that portion of the spectrum which would serve for comparison. The "low-sun band," δ, comes very near to band (2), wave-length 5770, while the "rain-band" comes very near (1), 6095. On several subsequent occasions the two bands were

[1] Prof. Pickering has proved that sunlight as it reaches us is blue, which must be the case if it has passed through a blue medium (Proc. American Academy of Sciences, 1880, p. 236).

observed at lower levels than Zermatt and the Riffel, but with even less intensity. On the last occasion (November 10, 1884) that such an observation was recorded, there was only a trace of these faintly seen. No doubt a clear atmosphere, free from the turbidity so easily created by condensing moisture, is essential to their visibility. Schœne has observed bands in a bright sky before sunrise and after sunset, during an intense frost in Central Russia. The measurements taken identified them with ozone bands, and leave scarcely any doubt whatever of the presence of ozone in the atmosphere, and if it can be so recognized, it must communicate its characteristic blue colour to the air (Journ. Chem. Soc. Abstracts, vol. xlviii. part 2, p. 713). The remarkable crepuscular phenomena seen at the close of 1883 proved highly favourable to such investigations.

In order to continue a series of observations on the solar spectrum near D it would be best to employ a fairly good dispersion and large lenses with long focus admitting a large amount of light to the eye, or, better still, to specially prepared photographic plates highly sensitive to the yellow rays.

The very extensive absorption of the ultra-violet rays by oxygen leads us to expect it to be fluorescent. All such absorbents are fluorescent more or less, and generally strongly, but when the absorbed rays are of very short wave-length the fluorescence is not always visible. Thus there are many substances which do not appear fluorescent by lime-light nor by dull daylight, but are strongly so when seen by electric light, especially if it has passed through no glass or other medium than a quartz lens and a short column of air. Some substances are not fluorescent when seen in glass vessels, because the glass has absorbed those rays of which the refrangibility would have been lowered by the fluorescent substance. In air, and by the light of an electric spark rich in ultra-violet rays, such as that from cadmium electrodes, almost everything is fluorescent. The whole range of the cadmium spectrum has been viewed by me, owing to the fluorescence of the purest white blotting-paper. The light, of course, is feeble, and the eye has to be trained to make observations in total darkness.

Pure water, however, never appears fluorescent. Some solutions in water, which transmit all the ultra-violet rays as far as 2304, are fluorescent, though whether this is caused by impurities or not has not been decided.

It cannot any longer be doubted (1) that the extreme limit of the solar spectrum observed by Cornu is caused by the gases in the atmosphere, probably both by oxygen and ozone; (2) that the blue of the sky is a phenomenon caused by the fluorescence of the gaseous constituents of the atmosphere, and probably ozone and oxygen are the chief fluorescent substances; (3) that ozone is generally present in the air in sufficient quantity to render its characteristic absorption-spectrum visible, and that therefore it gives a blue colour to the atmosphere by absorption, through which blue medium we observe distant views; (4) that water vapour does not participate in the coloration of the atmosphere under like conditions and in the same manner as ozone.

W. N. HARTLEY.

Royal College of Science, Dublin.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Vice-Chancellor of Cambridge University publishes the following:—

"*Ferndene, Gateshead, March* 4, 1889.

"SIR,—You may be aware that some years ago I erected here a refracting telescope, 25-inch aperture and 30 feet focal length.

"Owing to unfavourable atmospheric conditions and other reasons, the instrument has done no systematic work in its present position. I should much like to place it where it would work under capable direction.

"I contemplate offering my telescope and the dome and instruments connected with it to the University of Cambridge. The part that the University has taken of late years in the advancement of science induces me to hope that the possession of an instrument especially adapted to the study of stellar physics may give impetus to the development of the subject.

"I beg you therefore to give the matter consideration, and let me know what proposals can be made to insure proper use and maintenance of the instruments, and publication of yearly reports, in case my offer is acceptable to the University.

"I have the honour to be, Sir,

"Your obedient Servant,

"R. S. NEWALL.

"The Vice-Chancellor of the University of Cambridge."

At the Congregation to-day, at 2 p.m., the following Grace, having received the sanction of the Council, is to be offered to the Senate:—

"That the Vice-Chancellor, Dr. Routh, Dr. Glaisher, Prof. Adams, Prof. Liveing, Prof. Darwin, and Prof. Thomson, be appointed a Syndicate to consider Mr. R. S. Newall's munificent proposal to present his telescope to the University, and the arrangements and expenditure which would be necessary to maintain and utilize it for astronomical and physical research, and to report to the Senate."

SCIENTIFIC SERIALS.

IN the *Journal of Botany* for February and March, Mr. A. Fryer continues his notes on pond-weeds, the present instalment being characterized by two plates and the description of a new species, *Potamogeton falcatus*, from Huntingdonshire. Another addition to the British flora is recorded by the Rev. E. S. Marshall, in *Festuca heterophylla*, from Witley, in Surrey; and Mr. F. J. Hanbury describes no less than four species or sub-species of the difficult genus, *Hieracium*, new to science—all from the extreme north of Scotland. Messrs. G. Murray and L. A. Boodle commence a monograph of *Avrainvillea*, a genus of siphonocladaceous Algæ, which they consider most nearly allied to *Penicillus* and *Udotea*.

THE *Botanical Gazette* for January contains a short description and history, illustrated by five plates, of the new Botanical Laboratory at the University of Philadelphia. The occurrence of a new phosphorescent Fungus is noted, *Agaricus* (*Clitocybe*) *illudens*, in which the phosphorescence appears to reside in the hymenium. In the number for February, Dr. Henrietta E. Hooker gives a highly interesting description of the structure and mode of life of the common dodder of Massachusetts, *Cuscuta Gronovii*. It is stated to have a habit of entirely withdrawing its roots from the soil by the contraction of the coils of its twining stem as soon as it commences to lead a parasitic life on its host. Miss Emily L. Gregory continues her paper on the "Development of cork-wings on certain trees."

Rivista Scientifico-Industriale, January 31.—On the oxalate of lime in plants, by Prof. Aser Poli. In these remarks, which are made in connection with C. Acqua's recent contribution to the study of the crystals of the oxalate of lime in plants, it is argued that even on Acqua's own showing, the presence of these crystals cannot be regarded as necessary to the life of the plant. In some they are not found at all, and where they do exist they seem to be rather an inevitable consequence of the production of oxalic acid in the presence of the salts of lime.—Prof. Ercole Fossati continues, without concluding, his elaborate monograph on the thermic and electric properties of iron subjected to magnetic influences.

Bulletin de la Société des Naturalistes de Moscou, 1888, No. 3. —On the peculiarities of the skulls of the horned cattle of the Kalmucks, by P. Kuleschoff (in German), with photographs of skulls. The great likeness between the skulls of the Kalmuck race of horned cattle and those of *Bos sondaicus* and the zebra brings the author to the conclusion that the ancestors of the European cattle must be searched for in India.—On the Orthopteres of Crimea, by O. Retowski (with three plates).—On the structure of the pseudo-scorpions, or *Chernetidæ*, by A. Croneberg (both in German). The differences in the structure of this group and that of the scorpions proper are pointed out, and Thorell's views on the affinities of the *Chernetidæ* are confirmed.—Review of the generative organs of the *Pompilidæ*, by General Radoszkowski (in French, with four plates).—Supplementary note on the great comet 1887 I., by Th. Bredichin (in French). It belongs to the author's third class of comets—that is, it consists of heavy elements; and more accurate calculations convince the author that it could consist only of elements having a great molecular weight, such as gold, mercury, and lead.—Some additions to the flora of Moscow, by S. Milutin.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 21.—"The Innervation of the Pulmonary Vessels." By J. Rose Bradford, M.B., D.Sc., George Henry Lewes Student, and H. Percy Dean, M.B., B.S., B.Sc. Communicated by E. A. Schäfer, F.R.S. (From the Physiological Laboratory of University College, London.)

Hitherto no direct experimental proof of the existence of vasomotor fibres for the vessels of the mammalian lung has been obtained. The method used by us consisted in exciting the roots of the upper dorsal nerves, and recording simultaneously the effects produced on the aortic and pulmonary blood-pressure. The aortic pressure was measured in the usual way, *i.e.* a mercurial manometer was connected with the carotid artery. A second manometer was then connected with the branch of the pulmonary artery distributed to the lower lobe of the left lung. All the observations were made on dogs.

Before considering the results obtained by excitation of the upper dorsal nerves, it is necessary to know what effect a given rise of aortic pressure will have on the pulmonary pressure. This was determined by the three following methods:—

I. Excitation of the peripheral end of a divided splanchnic.

II. Excitation of the lower end of the spinal cord divided in the middle of the dorsal region.

III. Compression of the thoracic aorta.

By all these methods an enormous rise in the systemic blood-pressure is obtained, but the simultaneous pulmonary rise is very small. Thus the aortic pressure may be doubled or even quadrupled. The rise of the pulmonary pressure is always small and sometimes absent. The rise, as a rule, is about one-fifth of the total pulmonary pressure, *i.e.* the rise is then very small compared with the doubling or quadrupling of the systemic pressure. The relative ratio of the pulmonary rise to the carotid rise is that the former is about one-twentieth of the latter. Hence an enormous increase of systemic pressure is required in order to cause even a small rise of pressure in the pulmonary vessels.

The same occurs when the aorta is compressed, no rise of pulmonary pressure occurs unless the aortic rise is not only very marked but also of some duration, *e.g.* 30 seconds.

Excitation of the central end of the sciatic causes but a very slight pulmonary rise. The central end of the vagus gives larger effects, due to reflex contraction of the pulmonary arterioles, and the central end of a posterior root of one of the upper dorsal nerves gives still greater effects.

If the vasomotor centre in the medulla be excited, a great rise of both pulmonary and systemic pressure is produced. The same excitation of the medulla after division of the cord in the mid-dorsal region produces as great a pulmonary rise, but the systemic effect is now quite small.

Excitation of the upper dorsal roots, *i.e.* from the second to the seventh, produces rises of pulmonary pressure as marked as any of the preceding, but accompanied either by a small aortic rise or by no aortic effect. With the third nerve a marked rise of pulmonary pressure accompanied by a fall of aortic pressure is seen. Hence these nerves contain the vaso-constrictor fibres for the pulmonary vessels, since the effects produced on the pulmonary pressure must be due to constriction of the pulmonary arterioles, inasmuch as the simultaneous carotid effects are quite incompetent to cause them.

Finally, although it is undoubted from the results of the research that the mammalian pulmonary vessels receive vasomotor fibres, yet it is probable that this vasomotor mechanism is but poorly developed when compared to that regulating the systemic vessels.

Geological Society, February 20.—Dr. W. T. Blanford, F.R.S., President, in the chair.—The President announced that a special general meeting, for the consideration of the by-laws, would be called for Friday, March 15, at 4.30 p.m.—The following communications were read:—On the Cotteswold, Midford, and Yeovil Sands, and the division between Lias and Oolite, by S. S. Buckman. After giving a short sketch of the work and opinions of other writers, the author proceeded with the evidence on which his own views are based. He described a series of sections of the typical exposures of "sands" and contiguous strata, commencing near Stroud and terminating on the Dorset coast. Dividing the series into *seven* horizons, characterized by their distinctive Ammonites, viz. *Amm. communis*, *variabilis*, *striatulus*, *dispansus*, the genus *Dumortieria*, *Amm. Moorei*, and *opalinus*, and taking the *striatulus* beds as a fixed starting-point, the author demonstrated how the strata varied in regard to that horizon. The Cotteswold Sands, containing the *variabilis* and part of the *communis* horizons, were below the *striatulus* beds; the Midford Sands, containing the *dispansus* horizon, were above, *Gramm. striatulum* occupying a thin bed at the base; the Yeovil Sands, containing the *Moorei* and *Dumortieria* horizons, overlay a bed containing Ammonites of the *dispansus* horizon, and were consequently still later deposits. Since the different sands were deposited not on a horizontal plane, in point of time, but, as it were, obliquely, the deposit of Cotteswold Sands having ceased before that of Yeovil Sands commenced, it was incorrect to lump all the "sands" from the Cotteswolds to the Dorset coast under the single local name "Midford Sands," thereby implying a contemporaneity which did not exist, while the use of the present restricted local names was defended. The Ammonites were apparently uninfluenced by changes in the character of the deposit, since the same species are found in Limestone in the Cotteswolds, in Sands at Midford, and in argillaceous Marl at Ilminster. The change from argillaceous to arenaceous or calcareous deposits has been looked upon as so distinct a feature, that it has been utilized as a great argument in favour of drawing the line between Lias and Oolite at that point; but if this be done, the line is always drawn at different horizons in different districts. If lithology furnishes no reason for a dividing-line at this point, it was shown that neither did palæontology. It was also shown that the Ammonite family Hildoceratidæ dominated the period from the *falcifer* to the *concavus* zones, and that with the close of the latter zone they died out with singular abruptness, and that, furthermore, there exists, both in England and upon the Continent, a marked hiatus at the same point due to the absence of a zone or a number of zones. On account of these facts the proposal was put forward that d'Orbigny's term "Toarcien" should be employed to designate the strata fron the *falcifer* zone to the *concavus* zone inclusive, that this term should not be used in the sense of merely an extended "Upper Lias," but to mark an entirely distinct transition-formation—a definite part of the Jurassic period—separating the typical Lias from the mass of thoroughly Oolitic strata. The reading of the paper was followed by a discussion, in which the President, Mr. H. B. Woodward, Prof. Blake, Rev. H. H. Winwood, and Mr. Hudleston, took part.—On some nodular felstones of the Lleyn Peninsula, by Miss Catherine A. Raisin. Communicated by Prof. T. G. Bonney. Some remarks on the paper were made by Mr. Cole, Dr. Hicks, and Prof. Bonney.—On the action of pure water, and of water saturated with carbonic acid gas, on the minerals of the mica family, by Alexander Johnstone.

PARIS.

Academy of Sciences, March 4.—M. Des Cloizeaux, President, in the chair.—Remarks accompanying the presentation of a work entitled "Introduction à l'étude de la Chimie des anciens et du moyen age," by M. Berthelot. This work forms a sequel to the author's "Origines de l'Alchimie" and "Collection des anciens Alchimistes grecs," thus completing a series of historical researches which fully establish the true character of the old philosophic doctrines, methods, and practices, which were hitherto supposed to be mainly absurd and fanciful, but which must henceforth enter into the scheme of historical evolution of the positive sciences. Here M. Berthelot gives a full description and translation of the Leyden papyrus of Egyptian origin, the oldest extant treatise on chemistry. The signs, notations, and appliances of the ancient alchemists are also described and reproduced by the photogravure process.—On the artificial reproduction of halos and parhelic circles, by M. A. Cornu. The author obtains the halos more effectively than by Brewster's method, by depositing on a sheet of glass a crystalline powder of potash alum, which is obtained from a heated saturated solution shaken while cooling. The phenomenon is sufficiently bright to be projected and rendered visible to an audience. This remark applies also to the parhelic circles, which are obtained by an extremely simple process.—On the chondroid plaques in the tendons of birds, by M. L. Ranvier. By employing a solution of osmic acid, the author shows that the chondroid plaques in the tendons of the feet of finches and other small birds contain cellules filled with a fatty substance. By means of other reagents the presence is also revealed of glycogen and cartilage.—On the great storm of March 11, 12, and 13, 1888, in the United States, by M. H. Faye. Lieut. George Dyer's monograph on this terrific hurricane with its accompanying blizzard describes it as of an exceptional character,

to which is inapplicable the law based on the circular theory—that is, the eight-point rule. Instead of the usual barometric pressure in form of a basin, it is stated to have presented the aspect of an immense linear depression, a trough of low barometer moving eastwards. This view is incompatible with the well known hypothesis advocated by M. Faye, who accordingly endeavours here to account for the recorded phenomena without having recourse to the "highly improbable theory of a vast trough of low temperature."—On the complete rectification of the sextant, by M. Gruey. Two methods are proposed, dealing with the rectification of the axis of rotation, R, of the large mirror M, with the rectification of the large and small mirrors M and M', and with that of the axes U and S.—On the separation of zinc and cobalt, by M. H. Baubigny. In a previous paper (*Comptes rendus*, cviii. p. 236) the author described the process by which he has succeeded in completely separating zinc and nickel. The further experiments here carried out tend to show that, even in the state of sulphates, zinc and cobalt cannot be totally separated by sulphuretted hydrogen in presence of a small excess of free sulphuric acid unless the quantity of cobalt be relatively slight. The separation may also be effected with sufficient completeness if the quantity of zinc be slight.—Observations on saccharification by diastase, by M. L. Lindet. During saccharification the decomposition of the starch into maltose and dextrines is always accompanied by a secondary reaction in which the diastase attacks the dextrines and transforms them to maltose. This reaction is arrested by the presence of a certain quantity of maltose, which, however, may be removed by alcoholic fermentation, as maintained by Payen, although denied by O'Sullivan and others. Here M. Lindet confirms Payen's theory by another process, employing phenylhydrazine as a reagent for precipitating the maltose in the state of insoluble phenylmaltosazone.—On some new neutral and acid ethers of the camphols, by M. A. Haller. These ethers are formed under the same conditions as the succinates already described in the *Comptes rendus* of February 25.—Influence of mineral substances on the structure of plants, by M. Henri Jumelle. The experiments here carried out with lupins cultivated under like conditions, but some with distilled water, some with Knop's mineral solution, show that the presence of mineral substances is followed by a greater development of sap, and diminished formation of supporting elements; further, that the absence of salts considerably modifies the structure of plants, the modifications, however, being largely due less to the absence of the salts themselves than to the consequent diminution of water attracted and retained by the salts.—Papers were contributed by M. E. Goursat, on isogonal transformations in mechanics; by M. S. Arloing, on the general effects of the substances produced by *Bacillus heminecrobiophilus* under natural and artificial culture; by M. Stanislas Meunier, on the Carboniferous rocks containing *Bacillarites*, Stur; and by M. de Rouville, on the genus *Amphion* (*Pander*) in the Cabrières district, Hérault.

Berlin.

Physiological Society, February 1.—Prof. du Bois Reymond, President, in the chair.—Prof. Moebius spoke on the movements of the flying-fish through the air. He first described, from personal observation, the way in which the fish shoot out of the water from both bows of the ship, and then propel themselves horizontally for a distance of several ship's-lengths with their pectoral and abdominal fins stretched out flat, skimming along without moving their fins, always in the direction of the wind, but either with or against the same. When they meet the crest of a wave they raise themselves slightly in the air, falling again to the same extent in the succeeding trough of the sea. Occasionally a slight buzzing of the fins may be observed, similar to that of the movements of the wings in many insects. At night they frequently fall on the deck of the ship. As the result of a detailed investigation, the speaker had proved that these fish do not fly, since the anatomical arrangements of their fins and muscles are not adapted to this purpose. What really occurs is that when frightened by the approach of a ship or any enemy they shoot up out of the water, as do so many other fish, and are then carried along by the wind, which strikes on the under surface of their outstretched and evenly-balanced fins. Notwithstanding the general acceptance which was accorded to the above investigation, it was urged by many that the buzzing of the fins, the rising over the crest of a wave, and the falling overboard after having landed on the deck of a ship, were evidences that this fish really executes movements which result in flight. In reply to this, the speaker pointed out that the buzzing of the fins takes place when a strong current of air is directed against the outspread fins of a dead flying-fish by means of a bellows, and further, that the rising over the crest of a wave or the bulwarks of a ship may be explained by the ascending currents of air which are always produced whenever a strong horizontal wind strikes against any elevated object such as a wave or part of a ship. Thus, finally, with the exception of the movements involved in its oblique sudden exit from the sea, all the motions of a flying-fish when in the air are really passive.—Dr. Posner spoke on the conversion of mucous membrane into cuticular tissue. It has long been known that ectodermal tissue can become converted into that which is characteristic of the alimentary tract; thus, for instance, when pieces of skin are transplanted into the cavity of the mouth, they become completely converted into mucous membrane, and the epidermis becomes an epithelium. On the other hand, no observations existed as to whether the reverse conversion of mucous into epidermal tissue is possible. No conclusive evidence could be drawn from the cuticular conversions which occur in mucous membranes which are derived from ingrowths of the ectoderm, and equally inconclusive were the cases of cuticular conversion which are observed in strictures of the urethra, and in the bladder, and in cases of papilloma and pachydermia of the mucous membrane of the mouth, larynx, and œsophagus. The speaker had found in Leidig a hint that in those animals which do not chew their food a conversion of the gastric mucous membrane occurs, which often amounts to a real cuticular formation. It is true that in birds the gizzard is possessed of tubular glands which pour out a secretion which at once sets into a mass as hard as bone, and provides a means of comminuting the food. But, on the other hand, cuticular growths are observed in the stomachs of Edentata, which consist of a true conversion of epithelium into epidermis. The speaker had been able to study this conversion in the stomach of Manis, and found by chemical and microscopical investigation that the whole stomach, even down to the region of the pylorus, is lined with a true epidermis, and that typical papillæ are developed underneath the same. The conversion of endodermal into ectodermal structures is hereby clearly proved, a fact which is not devoid of significance in pathology.

February 15.—Prof. du Bois Reymond, President, in the chair.—Prof. F. E. Schulze spoke on the organization and mode of living of Sponges. The simplest form of Sponge consists of a sac, which, being composed of three layers, is equivalent to the embryonic form of the more complicated types. This sac is attached by its base, and has at its apex an opening—the osculum; its wall is composed of an outer layer of epithelial cells (ectoderm), a middle layer of connective-tissue with migratory cells (mesoderm), and an inner layer of collared flagellated cells (endoderm), and is perforated with round and regularly distributed apertures. The more complex forms arise by a thickening and folding of the wall, the thickening being still more marked in the most complicated forms. In these, a system of branched canals takes the place of the simple apertures in the wall, communicating with the exterior by round openings, and leading internally into cavities lined with collared flagellated cells (choanocytes); from these cavities a further system of branched canals leads into the now limited internal cavity with its osculum. The skeleton of the Sponge is composed of chalk, siliceous earth, spongin, or foreign substances. In the simplest Sponges, consisting of a simple sac, the skeleton is made up of the simplest star-shaped spicules, with three rays, so as to give support to a membrane which is perforated with regularly alternating apertures; in the more complicated forms, these spicules possess four or six rays, as supplying the most convenient supporting structure, while a collar of simple rays is developed round the osculum. According to the material of which the skeleton is chiefly composed, Sponges may be classified as chalky, siliceous, horny, or sandy. The Hexactinellidæ, with six-rayed spicules, inhabit deep seas. In all Sponges, a continuous stream of water is observed entering the openings on the surface of the body, and emerging at the osculum, so that the Sponges filter the water in which they live. The movement of the water is brought about by the flagella; the contraction and retraction of the osculum is produced by elongated protoplasmic cells, but these cannot be regarded as muscle-cells until it has been proved to a certainty that they are connected with nerves, and receive their impulse from these nerves. Only one observer has as yet described a nervous system

in Sponges, the majority not yet having seen it. Nothing has as yet been definitely ascertained as to the mode of nutrition of Sponges: from among the several hypotheses, some suppose that the solid organic particles which are suspended in the water are taken up by the ectoderm-cells and digested in the body; or else that these particles are taken up by the flagellated cells—that is to say, are passed from within outwards; or that the digestion is cellular, inasmuch as the amœboid migratory cells take up the food-particles, digest them, and pass on the digestive products to the rest of the body; or, finally, that Sponges, like plants, only absorb food-stuffs in solution. The reproduction of Sponges is both asexual and sexual, the first resulting from natural or artificial fission: natural fission, consisting of a simple separation, by constriction, of a portion of the body-substance, occurs in fresh-water Sponges. A further asexual mode of reproduction is by means of buds and gemmules. In the sexual mode of reproduction, the females develop eggs all over their surface, and the males spermatozoa, the latter consisting of a head and tail. The egg, after impregnation, goes through the various stages of segmentation met with in the higher animals, and then develops into a sac-like embryo.—Dr. Uhthoff gave an account of his researches on the dependence of visual acuteness in spectral colours upon the intensity and wave-length of the light; these have been recently reported to the Physical Society by Dr. Kœnig (NATURE, February 21, p. 408).

Physical Society, February 8.—Prof. Kundt, President, in the chair.—Dr. Michelson spoke on the normal rate of combustion of explosive mixtures of gases. When such a mixture is ignited at one point, and the temperature of combustion is propagated only by conduction from this point, then the surface at which combustion is taking place separates the burnt from the still unburnt portion of the mixture; the temperature of this unburnt portion is then raised by conduction to that at which it ignites, and it burns. Mallard and Le Chatelier have determined the rate at which this ignition is propagated, by observing the onward movement of the flame in a cylindrical vessel filled with the mixture of gases; Bunsen, on the other hand, allowed the explosive mixture to stream out of a burner with a known velocity, and took this as being equal to the rate of propagation of the combustion in the case where the flame was just on the point of striking back into the tube to which the burner was attached. An objection which may be urged against the first method is that the velocity with which the flame is propagated increases very rapidly the further it travels, so that it is uniform only at the beginning of the explosion. The objection to the second method is, that the flame is continually wavering in and out of the edge of the burner. Dr. Michelson made use, in his experiments, of the dark cone in the centre of the flame, in which the gases are still unburnt, and whose luminous envelope forms the limit of the commencing combustion. When the rate of supply of the combustible gases is uniform, this cone is very steady, and the rate at which the gases stream out from its surface is exactly equal to the rate of combustion of these gases. The volumes of the gases consumed were measured in accurate meters, and the size of the luminous envelope to the centre cone of the flame was determined from photographs of the flame. The mixtures examined were those of coal-gas and air, hydrogen and air, carbonic oxide and oxygen, hydrogen and oxygen, carbonic oxide and air, and of methane and air. With coal-gas and air the rate of combustion increased as the mixture contained more of the coal-gas, reaching a maximum with 18 per cent. of this gas, and then gradually became less; the maximum rate of propagation of the combustion was 70 centimetres per second. With hydrogen and air, the maximum rate was observed with 40 per cent. of hydrogen in the mixture, being then 270 centimetres per second, and then becoming less. The curve representing the rate of combustion of carbonic oxide and oxygen presented a very different appearance. The maximum rate was only obtained with 75 per cent. of the carbonic oxide, and was about equal to the maximum for coal-gas. For the other three mixtures, no curves could be drawn. With a mixture of hydrogen and oxygen, the speaker estimated the maximum rate of combustion as being about 10 metres per second, but no actual measurement was possible, since the mixture could not be expelled at this rate from the burner, which consisted of a glass tube 1 metre long.—Prof. Preyer spoke on combination-tones. He endeavoured to prove that difference- and summation-tones have no objective existence. The first of these are the outcome of a co-vibration in the inner ear. When two different tuning-forks are made to vibrate for a long time, and are then damped, and a third tuning-fork, whose vibration-frequency is only slightly greater than that of the difference in frequency of the other two, is applied to the head, the experimenter hears the corresponding beats. Persons with a defective tympanic membrane in one ear, and a normal membrane in the other, were unable to appreciate difference-tones with the former which they could perfectly well do with the latter. According to the speaker, the summation-tones are really difference-tones, due to the fundamental tone and over-tones of the vibrating forks.—Prof. H. W. Vogel exhibited a complete spectrum of cyanogen, which he had obtained by photographing the spectrum of an arc-light produced by a concave grating; the spectrum extended in the red beyond the line A. Most remarkable was the abundance of lines which were fixed on the photograph, and made visible. The speaker discussed briefly the respective advantages of a concave grating for laboratory experiments on spectra, and of the ordinary prism for practical purposes, especially for observations during solar eclipses.

BAKU PETROLEUM.

The Region of the Eternal Fire. By Charles Marvin. (London: Allen and Co., 1888.)

THIS book is not, as its title might imply, an eschatological treatise, nor is it a work of fiction after the manner of Mr. Rider Haggard. It is simply a plain, straightforward narrative of a journey to the petroleum region of the Caspian, undertaken with a view of investigating what Mr. Marvin terms "the kerosene factor of the Central Asian problem." It has, however, this connection with eschatology, that the region of which it treats is, or was, holy ground. The peninsula of Apsheron, on which Baku stands, has been famous from time immemorial, and even before the time of Cyrus thousands of the followers of Zoroaster had worshipped on its sacred soil. With the conquest of Persia, first by Heraclius, and twelve years later by the Arabs, the power of the Magi of the Zoroastrian sect was shattered; and the worship of the Eternal Fire in the Surakhani temple for ever passed away, and in its place are now the symbols of a new cult in the shape of greasy derricks and dingy kerosene distilleries.

The story of Baku and its Oil King, Ludwig Nobel, reads like a tale of the "Arabian Nights." Ten years ago the place was a sleepy Persian town: it is now a thriving city, owning more shipping than Cronstadt or Odessa, and the centre of a vast and rapidly increasing trade. But even in the thirteenth century the "sacred element" was so far robbed of its sanctity that the crude petroleum was extensively exported into various parts of Asia. In "The Book of Ser Marco Polo, the Venetian," edited by Colonel Yule, we read that—

"On the confines towards Georgine there is a fountain from which oil springs in great abundance, inasmuch as a hundred shiploads might be taken from it at one time. This oil is not good to use with food, but 'tis good to burn, and is also used to anoint camels that have the mange. People come from vast distances to fetch it, for in all countries round there is no other oil."

Jonas Hanway, to whom Englishmen must be for ever grateful for the introduction of the umbrella to this country, visited Baku about the middle of the eighteenth century in the interest of one of the powerful trading companies of the time; and in 1754 he published a very complete account of the district and of the uses to which its naphtha or petroleum was put. The oil was then, as now, mainly employed for light and fuel, but we are also told that—

"The Russians drink it both as a cordial and medicine; but it does not intoxicate. If taken internally, it is said to be good for the stone as also for disorders of the breast. . . . Externally applied it is of great use in scorbutic pains, gouts, cramps, &c., but it must be put to the part affected only; it penetrates instantaneously into the blood, and is apt for a short time to create pain. It has also the property of spirits of wine to take out greasy spots in silks or woollens, but the remedy is worse than the disease, for it leaves an abominable odour. They say it is carried into India as a great rarity, and being prepared as a japan is the most beautiful and lasting of any that has yet been found."

Since that time Baku and its wonders have been frequently described, and the importance of the place with respect to the Central Asian question has been repeatedly pointed out by such travellers as Marsh, Valentine Baker, O'Donovan, and Arnold. Up to 1872 the extraction of the oil was a monopoly, but in the following year it was thrown open to the world, and hundreds of wells have since been sunk, mainly by the energy of Swedes and Russians. Geologically speaking, practically nothing is known about this extraordinary district, and even the engineers who bore for the oil and work the wells are ignorant of the conditions which affect the supply of petroleum. At the present time there must be at least five hundred wells and fountains situated close together on less than a thousand acres of ground, but the sources seem to be absolutely independent of each other. The supply is simply (to use Dominie Sampson's word) "prodigious"; and every year, as the borings get deeper, the fountains become more prolific. These borings are nothing like so deep as in America: not a single Baku well has yet approached a depth of 1000 feet. In 1883 two flowing wells each sent out nearly 30,000,000 gallons in less than a month from a depth of 700 feet. In America there are said to be 25,000 drilled petroleum wells, but a single Baku well has thrown up as much oil in a day as nearly the whole of the 25,000 in America put together. Mr. Marvin thus describes one of these "spouting" wells:—

"'In Pennsylvania that fountain would have made its owner's fortune; there's £5000 worth of oil flowing out of the well every day. [The actual value was at least £11,200 a day.] Here it has made the owner a bankrupt.' These words were addressed to me by an American petroleum engineer, as I stood alongside a well that had burst the previous morning, and out of which the oil was flying twice the height of the Great Geyser in Iceland, with a roar that could be heard several miles round. The fountain was a splendid spectacle—it was the largest ever known at Baku. . . . The derrick itself was 70 feet high, and the oil and sand, after bursting through the roof and sides, flowed fully three times higher, forming a greyish-black fountain, the column clearly defined on the southern side, but merging into a cloud of spray 30 yards broad on the other. . . . The diameter of the tube up which the oil was rushing was 10 inches. On issuing from this the fountain formed a clearly-defined stem, about 18 inches thick, and shot up to the top of the derrick, where, in striking against the beam, which was already worn half through by the friction, it got broadened out a little. Thence, continuing its course more than 200 feet high, it curled over and fell in a dense cloud to the ground on the north side, forming a sand-bank [from the amount of admixed sand], over which the olive-coloured oil ran in innumerable channels towards the lakes of petroleum that had been formed on the surrounding estates. . . . Standing on the top of the sand-shoal, we could see where the oil, after flowing through a score of channels from the ooze, formed in the distance, on lower ground, a whole series of oil lakes, some broad enough and deep enough to row a boat in. Beyond this, the oil could be seen flowing away in a broad channel towards the sea."

Flowing wells yielding from 40,000 to 160,000 gallons of oil daily are common in Baku, and the ordinary yield obtained by pumping is from 10,000 to 25,000 gallons daily; and many of these pumping wells have been worked for years without any diminution in the supply. A well belonging to Gospodin Kokereff had up to the

date of Mr. Marvin's book produced 60,000,000 gallons of oil, and the supply showed no sign of decreasing. The waste occasioned by "spouting" is at times enormous; millions of gallons of oil being lost from the want of any storage accommodation. Occasionally the neighbouring proprietors who happen to have reservoirs empty may thus obtain the oil at a nominal price. On one occasion 2,000,000 gallons were sold at about 7½*d.* per ton. When the Droojba fountain "spouted," the crude article, we are told, altogether lost its value for the moment.

"Fedoroff filled his reservoirs with 2,800,000 gallons of oil for 300 roubles, or £30. . . . Thousands of tons were burnt outside the district to get rid of it; thousands were led towards the Caspian; huge lakes of oil were formed near the well, and on one occasion the liquid suddenly flowed into a distant engine-house, and but for the promptness of the engineer in extinguishing his petroleum furnace the whole locality would have been ablaze. Houses were completely buried by the sand cast up by the oil; all efforts to stop the fountain on the part of Baku experts were fruitless."

After great exertions on the part of the well owners of the district, the fountain was eventually gagged, but not before 500,000 tons of oil had "spouted," equal to a loss at the current value of American petroleum of upwards of £1,000,000 sterling. But the record of the Droojba fountain was beaten in 1886, when a single well "spouted" as much as 11,000 tons of petroleum per diem; an amount equal to the aggregate daily yield of the 25,000 wells of America, the thousands of wells in Galicia, Roumania, and Burmah, and the shale oil distilleries of Scotland and New South Wales. As a result the market is now glutted, and the crude oil has been selling at times at the rate of fifty gallons for a penny!

We have not space to indicate all the many points of Mr. Marvin's interesting narrative, or to do justice to his account of the economic results which he thinks must inevitably follow from the prodigious source of wealth which Russia possesses in this wonderful district. It must be remembered that petroleum ton for ton is more potent than coal as a source of power. Hundreds of immense floating cisterns driven by petroleum furnaces are carrying this fuel across the Caspian and up the Volga, to be spread throughout Russia and Germany, and along the Baltic coasts. We learn from a recent Consular Report that pipe lines are being laid from Baku to Batoum: the Caspian and Black Sea Naphtha Conduit Company has now been formed, and the line is to be laid within the next four years. The conduit is to have a forked line on the Black Sea, reaching Batoum and Poti, and the capacity of the line is such as to admit of the daily passage of 1,200,000 gallons of naphtha. In a few years, therefore, this petroleum fuel will be scattered along the Mediterranean coasts and through Southern Europe. Possibly we may have it burning in our own Underground Railway before long. Indeed, as Mr. Marvin tells us, we shall surely see the Parsee back again at Baku, not to worship the Everlasting Fire, but for the purpose of buying lamp oil for the bazaars of India. What the effect of this intercourse will be on the future of India time will show. Meanwhile Russia is steadily making her way towards the gates of India, and Tchernayeff's road to Central Asia will be an accomplished fact before many years are past; and since the discovery of the new springs near the Mervi Kultuk Bay, the railway to Khiva will possess its own supply of fuel. A few days ago Mr. G. Curzon read an interesting paper to the Royal Geographical Society on the Transcaspian Railway, which must have opened many people's eyes to the development of Russia's power in Central Asia. In the meantime what are we doing with the sources of wealth in petroleum which we possess in Upper Burmah? Along the valley of the Irrawadi, and within 60 miles of the Rangoon-Prome railway, are enormous deposits of petroleum, probably as copious as those of America, if not so rich as those of Baku, and certainly capable of supplying the whole of India with light and fuel. Perhaps those capitalists who are so eager to rush into the ruby mines of Burmah might more profitably devote their wealth to exploiting the petroleum springs of that country, for it needs not the gift of prophecy to assert that Burmese petroleum in the long run will be certainly more precious than Burmese rubies.

We can heartily commend Mr. Marvin's book to all who are interested in the Central Asian question, for, as he says in the outset, petroleum is bound to become an important factor in that problem. Hannibal was said to have dissolved the Alps by vinegar. It is far more likely that petroleum will dissolve the sort of Chinese wall that our Governments are feebly setting up to keep the Russian trader and the *tchinovnik* out of India.

T. E. THORPE.

A TEXT-BOOK OF ELEMENTARY BIOLOGY.

A Text-book of Elementary Biology. By R. J. Harvey Gibson, M.A., F.R.S.E., Lecturer on Botany, University College, Liverpool. (London: Longmans, Green, and Co., 1889.)

THE above-named work is one of those which, as has been remarked in these pages (vol. xxxviii. p. 52), "the system of examining the whole world on a limited schedule . . . is bound to produce," and the essence of it is devoted to a consideration of those type-organisms which the examining body have set down for study. It contains 345 pages small octavo, and is divided into eight chapters, with an introduction. The first three chapters are devoted to generalities, and the last one to a "history of biology."

The author decries the "evils of the cram system," and proceeds at once to assert that "this must be my apology . . . for the introduction of so many speculations and explanations of casual relationship," while he claims for his treatise the special distinction that it deals "with the relationship of botany to zoology, and of both to the fundamental sciences of physics and chemistry." In fulfilling this determination the author gives, at the outset, a physico-chemical *résumé*. We regard the whole of this as out of place and superfluous, inasmuch as University students (for whom the book is written) will, if properly trained, have received the same information in a more tangible and authoritative form, at the hands of Professors of the special subjects. We strongly deprecate this growing tendency towards usurpation of the functions of others, especially when it

is seen that the sole object in view has here been that of incorporating tall-talk about that modern bogey "anabolism,"[1] with its antithesis, and about other heresies, which neither the pure physicist nor chemist would tolerate. Much that has been written of late under these and similar heads is now, by common consent, tabooed, as a mere garbling with ill-defined terms. As originally presented, it is, to say the least, over-reaching and often childish in its ambiguity: as diluted in the work before us, it bodes mischief whereby it becomes unendurable. It cannot be denied that for many a raw student such phantasies have an especial charm. In this work they are so interwoven with the more solid portions of the text as to bias and distort the intellect.

The "conditions of the environment necessary for the maintenance of life" and the "balance of Nature" are discussed and dismissed before the student is made familiar (in any but misleadingly general terms) with the constitution of the living organism. This we regard as a fatal error, revolting alike to common-sense and to established precedent, and we can only surmise that the adoption of so extraordinary a course has resulted from the influence of a wrong-headedness, at work upon the author's elementary training.

It will be seen that the author has, in our opinion, failed (and that, most probably, from faults not entirely his own) in the mode of treatment of his leading novelty. When first we realized the extent to which he had wandered into subjects not professionally his own, our suspicions were aroused as to whether he might not have erred proportionally within the limits of his recognized domain. The volume abounds in inaccuracies and misstatements. The methods of expression are frequently loose and contradictory: for example, on p. 293 we read that, in the frog, "the air is sucked into the interior of the body to the blood," and on p. 294 that the frog "forces the air into the lungs." On p. 145 a fair description is given of the bulb of the lily, whilst on p. 174 the same plant is "termed an annual." Things are too frequently declared to be "obviously," "naturally," or "clearly" so and so, and the author has yet to realize that with elementary students *nothing* must be taken for granted; while he has, on most points, grossly violated the inductive method (cf. the statements concerning the differentiation and structure of the nervous system, as successively presented on pp. 231, 232, 245).

The author's selection of types is unprecedentedly capricious. On the animal side, the Arthropod and Mollusk are omitted; while on the vegetable side, the description (p. 78) of an imaginary apical cell in *Spirogyra* implies complete ignorance of the type chosen for study. Nor must we disguise the fact that while the author tolerates those types now in vogue, he loses no opportunity of depreciating their educational value (pp. 219, 233, 264). We would remind him that these have served exceedingly well in the past, and that it is the manner of their manipulation by a certain class of teachers, rather than their constitution, which the unsuccessful student has cause to lament.

We deem detailed criticism superfluous, as there are no six pages in this book free from error, and, for a long succession, no two without inaccuracy. The following extracts will suffice. On pp. 265-66 we read that, in the frog, the alimentary system has become differentiated into "a buccal cavity, where the food is torn in pieces, or masticated; an œsophagus, or tube for the carriage of the triturated food (*sic*)," &c.; on p. 301 we are told that the occipital region of the skull, in the same animal, "consists of a floor and two side walls of bone (the basi- and two ex-occipitals)"; on p. 327, the oviduct of the frog is said to contain, when ready for oviposition, fertilized ova. Now as to the botanical side. *Penicillium* is selected as the type of Fungi, but the descriptions and figures apply throughout to *Eurotium*. In describing *Polytrichum*, his type of the Mosses, the author informs us (p. 103) that the leaves are "composed of almost undifferentiated parenchyma." A ridiculous attempt is made, three pages further on, to show homology between the archegonium of a moss and the conceptacle of *Fucus;* and the diagrammatic figure illustrative of the same can only bewilder the student, and mislead him as to the real structure and mode of development of the organs in question. Under the head of "cell-fusions," the statement is made (p. 149) that "the adjacent walls may have become completely broken down, as in tracheides": no well-tutored beginner needs to be reminded that this is in direct contradiction to the usually accepted definition of these structures. Finally, on p. 152, the *Duckweed* is referred to, and that in the most unfortunate manner conceivable, as a Dicotyledon. Misstatements such as these show the author to be ignorant of some of the most elementary truths dealt with in the most didactic handbooks in contemporary English literature. More the pity that the author should parade his indebtedness to the works of foreign writers.

One of the most conspicuous features of the book is the employment of a new nomenclature. The author was struck, early in his career, with the shortcomings of our conventional terminology; and, bolder than his fellows, he forthwith resolved to revolutionize the same. Order appears to dawn with the correlatives "Protozoa and Protophyta," "Metazoa and Metaphyta," but, when examined in detail, most of the author's substitutes are seen to be no better than their predecessors, and they consequently only complicate matters unnecessarily. We protest against this reckless use of new words. New and comprehensive terms are only to be accepted as landmarks in general advancement. Attempts to uproot a classical and time-honoured nomenclature, which are, like those before us, begotten only of youthful ambition, deserve no encouragement.

There would appear to be something seriously wrong in connection with the system which repeatedly produces books like that before us. Catering, as it does, for a prescribed curriculum, this one, the latest of its kind, will be eagerly sought by the examinees; and in their interests, if in none higher, it is time that something should be done to stem the tide. Similar complaints reach us from other sources, and it has been suggested in the pages of this journal (vol. xxxvii. p. 268) that the difficulty might be met by the establishment of "an Association to prevent the further publication of elementary works other than such as had been carefully revised and

[1] Defined by the author (pp. 336–40) as *consisting*, in the animal, of the processes of mastication, digestion, absorption, circulation, and assimilation.

approved of by a Publication Committee of the Association." No body of men have any such right to interfere with private enterprise; and the remedy proposed is wholly unscientific in principle, inasmuch as it would lay a sure foundation for systems of cliquism and popery, whose issue would be fatal to legitimate progress. Others there are who would seek the solution of the difficulty in an occasional substitution of the types chosen for teaching, and, in fact, such a change is already premeditated. This proposal cannot fail to meet with general approval, but it does not solve the problem; for, while no doubt it may, at the outset, insure to the examinee manuals of the better class, it will only prolong the evil day of publication of yet other inferior ones. The fault appears to us to lie not in systems, but in the individual. We are not yet rid of the old delusion that anybody can keep the children quiet. The infant-class is too often entrusted to the care of a novice, and with what results past systems of training have shown. "*Qu'est-ce qu'une grande vie?*" wrote de Vigny, with the rejoinder, "*Une pensée de la jeunesse exécutée par l'âge mûr.*" No one knows better than the English student that the production of an elementary text-book may constitute a leading feature in a great life. Such a work should be other than a medium in which the author airs his knowledge of fads and phantasies (most of which are sure to be wrong in the end) to the exclusion of fact and common-sense, and we hold its construction to be one of the most arduous of all possible tasks. It is, moreover, one for which a man is not fitted until ripened by long experience and meditation, and to none but the most experienced teacher would we intrust that awakening of the "thought of youth," which, if distorted at the outset, leads to certain failure. Here, to our thinking, lies the clue to the whole position. The matter is one for individual consideration. Upon the mind of the author of this work there has dawned the *pensée de la jeunesse*; in following it up, he has acted prematurely. Had he kept his ideas well in hand, others would have intersected them in the course of time, as his knowledge of (elementary) fact increased and as his experience ripened. He has done otherwise, and, in his eagerness for notoriety, has piled up, upon a flimsy foundation of words, a scant superstructure, the materials of which are ill-chosen and defective, and badly put together. G. B. H.

UNITED STATES GEOLOGICAL SURVEY.

Monographs of the United States Geological Survey. Vol. XII. *Geology and Mining Industry in Leadville, Colorado.* By S. F. Emmons. Pp. 747, with Atlas of 35 folio Plates. (Washington Government Printing Office, 1886.)

THE operations of the United States Geological Survey, under the charge of Mr. S. F. Emmons, in the Leadville mining district, have become known to some extent to many geologists in Europe by personal examination on the ground, and more particularly from the valuable summary of their results which appeared in the Report of the Director of the Survey a few years back. But even those most familiar with the thorough manner in which work is done in the office of Mr. Emmons's division at Denver can scarcely have been prepared for the mass of information which is presented to them in the present volume. Although the actual productive area of Leadville at the date of the survey was estimated at about one square mile, the study of a considerable part of the adjacent mountain districts was necessary in order to arrive at any general conclusions likely to be of value for practical purposes in regard to the mineral deposits; and therefore a district of about 15 to 20 miles of the western or Musquito Range of the Rocky Mountains has been surveyed, and mapped in very full detail on a scale of 2 inches to a mile. The interior parts of the mining region proper are treated more minutely on a scale of about 6 inches to a mile, and the geology and mine works on the three districts of Iron Hill, Carbonate Hill, and Fryer Hill are given on a scale of 1 to 1920.

From the maps and the sections which accompany each set, and which, in accordance with the excellent custom of the founder of the Geological Survey of Great Britain, the late Sir H. De la Beche, are constructed to the same scale both for heights and distances, it appears that the country described consists essentially of a series of ridges and furrows of sedimentary rocks resting upon an Archæan foundation forming the central mass of the Rocky Mountains. The most important member of this sedimentary series, the blue or metalliferous limestone, is a blue-gray dolomite of Lower Carboniferous age, which, at or near its contact with an overlying igneous sheet, known as the white or Leadville porphyry, is changed over considerable areas, but in an extremely irregular fashion, into a mass of clay and quartz charged with carbonate and sulphide of lead, chloride and bromide of silver, manganese and iron ores, which are obviously of secondary origin, and derived from the alteration of metallic sulphides. The upper surface of the deposit, being formed by the base of the porphyry sheet, is comparatively regular; but below, the boundary is exceedingly ill defined, the metalliferous mass—which in the principal mines resembles a brown garden-mould, mottled with dark-coloured patches in places—shading off into the unchanged limestone; it being, in fact, a pseudomorphous change of the latter rock by infiltration of metalliferous salts from the weathering of the overlying porphyry subsequently to the intrusion of the latter, and before the elevation of the Musquito Range—events which have been placed, as the results of detailed geological study, about the close of the Cretaceous period.

Since the year 1881, when the present Report was substantially completed, the ores of the Leadville district have changed very considerably, the more tractable carbonates and chlorides originally met with having given place to unchanged sulphides, with the result of complicating the processes of reduction. This circumstance detracts a little from the interest of the last section of the work, which is devoted to a very detailed description of the smelting processes as carried on at and near Leadville in 1880. This is due to the labour of M. A. Guyard, of the École des Mines, and for some time an assistant to Messrs. Johnson, Matthey, and Co. Unfortunately, he did not live to see the result of his work in print. Subsequently to the date of the Report, some of the larger smelting establishments were removed to localities closer to the fuel-supplies on the eastern side of the Rocky Mountains, and con-

siderable improvement has been made in the character of the smelting appliances. Some curious points are, however, brought out by M. Guyard's researches, especially as regards the speiss or arsenical regulus formed in the lead furnaces, which he finds collect by preference nickel and molybdenum from the ores, while cobalt, if present, is carried off by the lead, and may be found in the skimmings taken from the bath before casting it into pigs. Another point of interest is the occurrence of chlorine, bromine, and iodine in notable quantities in the furnace fume, which are due to the corresponding silver salts of the ores. The general chemical problems arising in the study of the ores and the containing rocks have been treated in a separate section by Mr. W. F. Hillebrand. The mass of analytical material contained in these sections is very large and important, but in some instances their value is diminished by an unnecessary striving after accuracy. Analyses reported to six decimal places seem to be scarcely suitable for practical purposes. The petrography of the district has been studied by Mr. Whitman Cross, his results being illustrated by heliotype prints of microscopic sections which though good in their way are decidedly inferior to the excellent drawings given by Prof. Irving and others in the earlier volumes of the same series before photographic illustrations were used. In his preface Mr. Emmons very handsomely acknowledges the "continuous and unwearied service" rendered by Mr. Ernest Jacob, an old student of the Royal School of Mines, who, we are sorry to say, has been compelled by reasons of health to retire from a service in which in a comparatively short time he was able to do a large amount of excellent work.

H. B.

OUR BOOK SHELF.

Practical Inorganic Chemistry: the Detection and Properties of some of the more Important Organic Compounds. By Samuel Rideal, D.Sc. (Lond.), F.I.C., F.C.S., F.G.S., Fellow of University College, London. (London: H. K. Lewis, 1889.)

THIS little book, as we learn from the preface, is designed to meet the wants of the medical student in his higher examinations, and we may say at once that it fulfils that purpose admirably. The syllabus of the University of London has been duly considered; all the substances therein mentioned are discussed at length, and their reactions fully given: and not only this, but Dr. Rideal has helpfully distinguished in each case the most characteristic reaction by an asterisk. With the aid of this book, and with ordinary application, the average candidate may fearlessly confront the Sphinx of Burlington Gardens (and *a fortiori* all minor Sphinxes), and attempt her riddles without risk of being torn in pieces.

All this is excellently done, and only one regret crosses the mind of the reviewer. Of course, a medical student is not intended to be an organic chemist, or, necessarily, a specialist of any kind; and it would be absurd to expect from him the knowledge of a specialist. But the training of a medical student is calculated to make him regard himself as the depositary of universal scientific knowledge—a belief which he frequently carries with him through life. Would it not be possible to convey the salutary notion that all this testing for organic substances has about as much relation to real practical organic chemistry as, say, the "use of the globes" to practical navigation?

Scottish Moors and Indian Jungles. By Captain J. T. Newall. (London; Hurst and Blackett, 1889.)

MANY years ago, in India, Captain Newall was unfortunate enough to suffer from an accident by which the spine was fractured. To some extent he recovered his health, but he has never since been able to walk or even to stand. Yet he has contrived—by an ingenious device which enables him to be carried about in a chair, in an easy position, by several men—to obtain a good deal of wholesome exercise in the open air. In the year 1880, in conjunction with his brother, he took the little shooting of Scaliscro, in Lewis; and in the first part of this volume he describes the incidents of sport and out-door life there during the seasons of the following four years. The second part of the volume is devoted to a record of more or less exciting sporting experiences in India at a time when the writer had full use of his limbs. The book may be read with pleasure not only by sportsmen but by others, for it is written in a bright and attractive style, and Captain Newall is always careful to give as vivid a picture as possible of the surroundings in the midst of which the incidents of his narrative took place. His account of autumn life in Lewis is particularly fresh and interesting. There are twelve very good illustrations from sketches by the author.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Inheritance of Acquired Characters.

WILL you allow me to say, in reference to Prof. Hartog's interesting letter, that there is no ground for regarding the word "Lamarckism" as a nick-name? There can be no desire to "nick" him or anyone else, should it appear that the views they advocate are to be classified with those of Lamarck. Lamarckism is as reputable a denomination as Darwinism, and no reasonable man can possibly regard with anything but respect and sympathy the attempt to bring forward solid evidence in support of Lamarck's fundamental assumption, viz. that acquired characters are transmitted by heredity.

It is not unusual for children to rest the head on the left forearm or hand when writing, and I doubt whether much value can be attached to the case described by Prof. Hartog. The kind of observation which his letter suggests is, however, likely to lead to results either for or against the hypothesis of transmission of acquired characters. An old friend of mine lost his right arm when a school-boy, and has ever since written with his left. He has a large family and grandchildren, but I have not heard of any of them showing a disposition to left-handedness.

E. RAY LANKESTER.

45 Grove End Road, N.W.

IT would be difficult to overrate the importance of the instance given by my friend Prof. Hartog in the last number of NATURE (p. 462) of the inheritance of a character acquired by habit; but the explanation which he offers of the non-inheritance of characters produced by mutilation, so far from being flat Lamarckism, appears to me to flavour of ultra-Darwinism, and the following hypothesis, resting more directly on mechanical principles, might be suggested. It is well known that many of the lower animals possess a remarkable power of regenerating lost parts. The garden snail offers a familiar instance: if the eyes be snipped off from their tentacles, they are in a short time reproduced, usually with a structure as perfect as that of their predecessors, as may be proved by a histological examination of thin slices. This power appears to be possessed to an unlimited extent, for one of my former pupils, Mr. Trevor Evans, performed the experiment twenty times in succession on the same snail, and the last eye was as perfect as the first; he then relinquished the research, being persuaded that the power of regeneration would

only terminate with the life of the unfortunate subject. This power of growing afresh so complex and specialized an organ as an eye is certainly at first sight not a little astonishing, but it appears to be capable of a very simple explanation: the cells terminating the cut stump of the tentacle are the ancestors of those which were removed; a fresh series of descendants are derived from them, similarly related to the ancestral cells as their predecessors which they replace; the first generation of descendants become in turn ancestors to a second generation, similarly related to them as were the second tier of extirpated cells; and this process of descent being repeated, the completed organ will at length be rebuilt. The possibility of this arises from the fact that in the snail the embryological course of development is capable of being repeated by the adult structure. In higher organisms this possibility does not as a rule exist, and mutilation is not followed by regeneration; but even in their case the ancestral cells remain, and when the embryological development is repeated their representatives in the embryo are present to give rise to descendants of the normal type in the normal fashion. It follows from this view, which leaves pangenesis out of account, that mutilations cannot possibly be inherited, and this for the reason that the cells forming the organism at each stage of its development must be regarded as the ancestors of those of the next stage; thus finally we are brought round to something which looks very like Weismannism.

W. J. SOLLAS.

Trinity College, Dublin, March 15.

P.S.—The foregoing completely accounts for the non-inheritance so often referred to of the character produced by circumcision. In the case of a snail it might be presumed that circumcision could not produce any persistent result; in the human subject what is remarkable is not the reappearance of the prepuce in the descendant, but that no regrowth beyond healing takes place in the subject.

MR. MARCUS M. HARTOG's letter of March 6 inserted in last week's number (p. 462), is a very valuable contribution to the growing evidence that acquired characters may be inherited. I have long held the view that such is often the case, and that I have myself observed several instances of the, at least I may say, apparent fact.

Many years ago there was a very fine male of the *Capra megaceros* in the gardens of the Zoological Society. To restrain this animal from jumping over the fence of the inclosure in which he was confined, a long and heavy chain was attached to a collar round his neck. He was constantly in the habit of taking this chain up by his horns and moving it from one side to another over his back; in doing this he threw his head very much back, his horns being placed in a line with the back: the habit had become quite chronic with him, and was very tiresome to look at. I was very much astonished to observe that his offspring inherited the habit; and although it was not necessary to attach a chain to their necks, I have often seen a young male throwing his horns over his back and shifting from side to side an imaginary chain. The action was exactly the same as that of his ancestor. The case of the kid of this goat appears to me to be parallel to that of child and parent given by Mr. Hartog. I think at the time I made this observation I informed the late Mr. Darwin of the fact by letter, and he did not accuse me of "flat Lamarckism."

Hertz's Equations in the Field of a Rectilinear Vibrator.

IN Dr. Oliver Lodge's valuable communication to NATURE of the 21st ult. (p. 402), giving Hertz's equations for the field of a rectilinear vibrator, may I suggest the following very slight change, in order to bring the formulæ into complete accord with those of the Maxwellian theory.

Hertz has, with $A^2 = \mu K$,

$$A\frac{dL}{dt} = \frac{dZ}{dy} - \frac{dY}{dz}, \quad A\frac{dM}{dt} = \frac{dX}{dz} - \frac{dZ}{dx}, \quad A\frac{dN}{dt} = \frac{dY}{dx} - \frac{dX}{dy},$$

$$A\frac{dX}{dt} = \frac{dM}{dz} - \frac{dN}{dy}, \text{ \&c.},$$

whence he obtains the suitable solutions—

$$X = -\frac{d^2\Pi}{dxdz}, \quad Y = -\frac{d^2\Pi}{dydz}, \quad Z = \nabla^2\Pi - \frac{d^2\Pi}{dz^2},$$

$$L = A\frac{d^2\Pi}{dydt}, \quad M = -A\frac{d^2\Pi}{dzdt}, \quad N = 0,$$

where Π satisfies the equation—

$$\nabla^2\Pi = A^2\frac{d^2\Pi}{dt^2}.$$

The corresponding Maxwellian equations would be—

$$\frac{dL}{dt} = \frac{dZ}{dy} - \frac{dY}{dz}, \quad \frac{dM}{dt} = \frac{dX}{dz} - \frac{dZ}{dx}, \quad \frac{dN}{dt} = \frac{dY}{dz} - \frac{dX}{dy},$$

$$A^2\frac{dX}{dt} = \frac{dM}{dz} - \frac{dN}{dy}, \text{ \&c.},$$

with the solutions, X, Y, Z, as before, and

$$L = A^2\frac{d^2\Pi}{dydt}, \quad M = -A^2\frac{d^2\Pi}{dzdt}, \quad N = 0.$$

The more general solutions of the field equations would be—

$$X = \frac{d}{dy}\left(\mu\frac{d}{dx} - \lambda\frac{d}{dy}\right)\Pi + \frac{d}{dz}\left(\nu\frac{d}{dx} - \lambda\frac{d}{dz}\right)\Pi;$$

$$L = A^2\frac{d}{dt}\left(\nu\frac{d}{dy} - \mu\frac{d}{dz}\right)\Pi;$$

with corresponding expressions, *mutatis mutandis*, for Y, Z, M, N; where λ, μ, ν, are arbitrary constants, coinciding with Hertz's results when $\lambda = 0$, $\mu = 0$, $\nu = -1$.

H. W. WATSON.

Alternative Path Leyden Jar Experiments.

IN your issue of Feb. 14 (p. 380) there is an "Electrical Note" which is very misleading. You will perhaps allow me to say, therefore, that Mr. Acheson's photographs show no evidence of oscillation whatever; that his experiments are aimed at practical questions connected with lightning protectors, and confessedly were not made in such a way as to have any theoretical importance; that in so far as Mr. Acheson thinks he is expounding a new theory by calling self-induction "extra currents" he is, in my opinion, mistaken; and finally, that the author of the note, in speaking about "the errors due to charging which vitiated Prof. Lodge's early experiments," is talking about something which has no existence. OLIVER J. LODGE.

The Celluloid Slide-Rule.

CELLULOID has been applied to so many purposes, that one is never surprised to see one or other of its many valuable properties turned to account in some new way. A slide-rule is now made, in which the surfaces on which the divisions are engraved consist of thin sheets or veneers of dead white celluloid. The divisions are beautifully sharp and distinct. If these veneers do not come unfastened, and the rule does not lose its dead white surface with use and exposure, this new application of celluloid will be found a most valuable one. The rule examined is one almost identical in pattern with the well-known Gravet instrument, and, if one may judge by the scale, the accuracy of the divisions, and the smoothness of the motions, it is made by the same machinery. The differences are mere differences of detail. Mahogany takes the place of boxwood. The cursor runs on an improved form of slide. Chisel-edges, instead of cross-lines, on the cursor are used to transfer readings. There is only one opening at the back, so tangents cannot be read without reversing the slide. The millimetre scales at the two edges are replaced by scales of inches. It is a pity that one of the scales of millimetres has not been left. The agents are John Davis and Son, of Derby and 118 Newgate Street, and the price is rather less than that at which the ordinary Gravet can be obtained in this country.

C. V. BOYS.

The Philosophical Transactions.

YOUR correspondent "S." seems to be unaware that what he asks for has been already done. The abridgment of the Philosophical Transactions, which was brought down to the year 1800 by Charles Hutton, George Shaw, and Richard Pearson, was continued in octavo form, by order of the President and Council of the Royal Society, under the title of "Abstracts of the Papers printed in the Philosophical Transactions of the Royal Society of London." This series extended to six volumes, bringing the abridgment down to the year 1854. At the seventh volume the title was changed to "Proceedings of the Royal Society of London," a publication which still exists, and which contains abstracts of all the papers in the Philosophical Transactions and a good deal besides. H. R.

Japanese "Koji."

IN the current number of NATURE (p. 469) is a note upon the preparation of Japanese *koji*, taken from the American Consular Reports.

In NATURE, vol. xxiv. p. 468, will be found a report of a paper read before the British Association on this subject, supplemented in the following number (p. 509) by a letter from the author giving more details. The whole subject was exhaustively treated in a paper on "The Diastase of Koji," read before the Royal Society in 1881, and also in a memoir on "*Sake*-brewing," published by the University of Tokio in the same year. Further, an abstract of the latter appeared in the *Chemical News*, November 11, 1881, p. 230.

I shall feel obliged if you will insert this letter, as most people, on reading the note in NATURE, would be led to think that Prof. Georgeson had made observations which were previously unknown. This is not the case. R. W. ATKINSON.

44 Loudoun Square, Cardiff, March 18.

THE TOTAL SOLAR ECLIPSE OF JANUARY 1.

BY the kindness of Mr. Todd we are enabled to give a drawing summarizing in a general way the phenomena observed during the last total eclipse. A comparison of this with the records at the two preceding sun-spot minima indicates very clearly that we have now very definite information concerning the corona of the sun as observed at the minimum period of sun-spots.

Everything written relating to the form of the corona in 1878 is now strengthened by still another critical observation at the succeeding minimum. It remains to be seen whether the same marked absence of bright lines in the coronal spectrum has been noted.

Here is an extract from what I wrote in 1878:—

"The utter disappearance of the large bright red corona of former years in favour of a smaller and white one in this year of minimum, struck everybody. Indeed it is a remarkable thing that after all our past study of eclipses, this last one should have exhibited phenomena the least anticipated. It isolates the matter that gives us a continuous spectrum from the other known gaseous constituents. The present eclipse has accomplished, if nothing else, the excellent result of intensifying our knowledge concerning the running down of the solar energy. With the reduction of the number of spots or prominences for the last four years, the terrestrial magnetism has been less energetic than it has been for the preceding forty years, while at both ends of this period we have had famines in India and China.

"As the sun is the great prime mover of earth, and as every cloud, every air current depends upon it, its present quiet condition is worthy of the most minute study.

"The absence of lines from the corona spectrum shows a great reduction in the temperature of the sun, and such a marked change in the sun should produce a corresponding change on the earth, so that the associated terrestrial phenomena should be carefully observed. Hence I regard this eclipse as the most important that has been observed for many years, as it throws much-

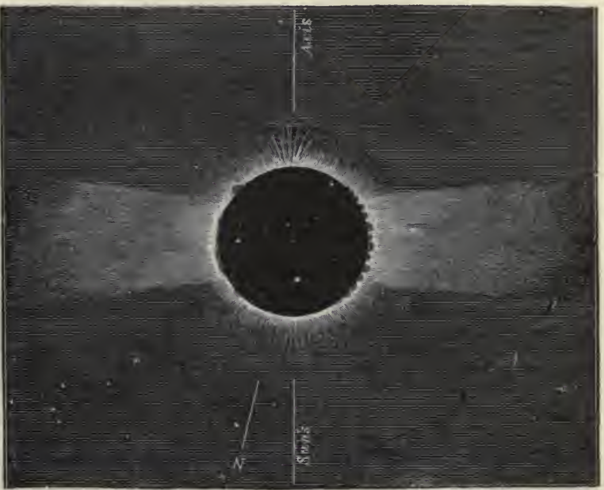

FIG. 1.—The equatorial extension and Polar tracery observed at the minimum of 1867.

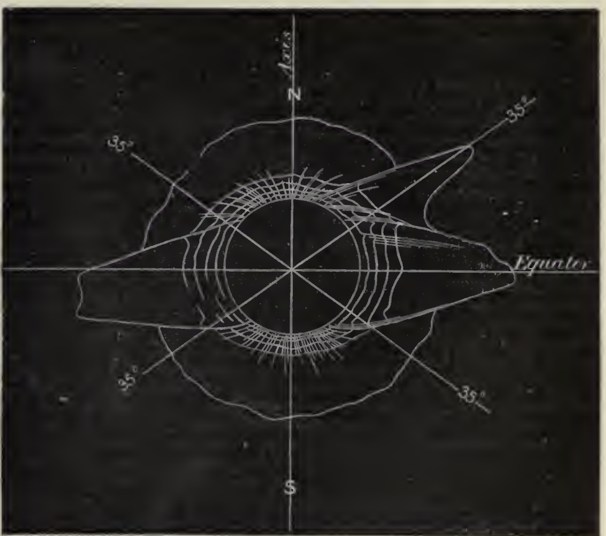

FIG. 2.—Tracing of the results obtained by the cameras in 1878, showing inner portion of equatorial extension, and how the surfaces of it cut the concentric atmosphere in lat. 35° N. and S., or thereabouts.

needed light on many points hitherto obscured in doubt."

The similarity of the coronas of 1867 and 1878 was one of the points relied upon when I subsequently discussed (see "Chemistry of the Sun") the possible meteoric origin of many solar phenomena, and pointed out that if this were so, there must be an equatorial ring to produce them. The recent development of the meteoric theory suggests that

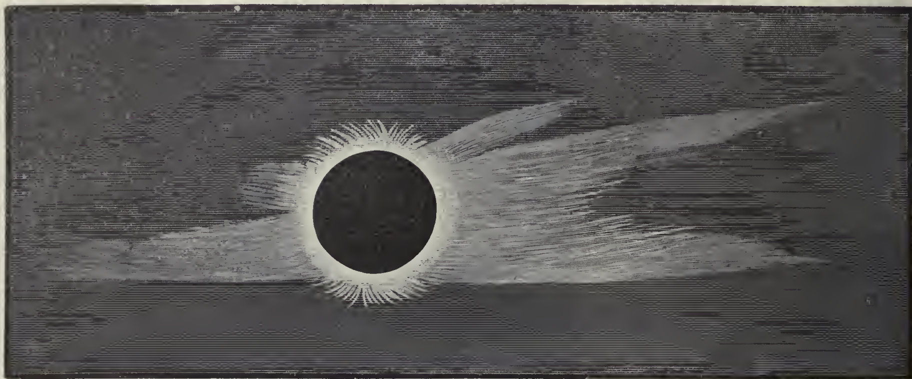

FIG. 3.—Phenomena observed during the total solar eclipse of January 1, 1889 (see NATURE, March 7, p. 436).

among the most important observations to be made at future eclipses will be a direct comparison of the spectrum of the corona with the low temperature spectrum of meteoritic dust. It may be that some of the photographs taken during the last eclipse may give us some information on this point, but so far nothing is known.

J. NORMAN LOCKYER.

ON THE GRADUAL RISING OF THE LAND IN SWEDEN.

ALTHOUGH we find in a work by Urban Hjärne, printed in 1702, some remarks on the level of the sea in the Baltic, and the old shore-lines of the island of Gothland, the honour of having for the first time raised this question seriously, and of having subjected it to scientific investigation, belongs to Emanuel Swedenborg, who, in 1719, published a work entitled "On Proofs from Sweden of the Level of the Sea, and the Past World's Strong Flood and Ebb." From the condition of the rocks in West Gothia; from fossils in horizontal chalk and marl beds; from shell-banks situated high above the actual level of the sea; from skeletons of whales and wrecks of ships found far inland; from the structure of the sand-hills and from the round stones found therein; from erratic blocks (or, as Swedenborg calls them, "stones that are spread all over the world"); from giants' bowls; from the shore-lines on Halle and Hunneberg (mountains in West Gothia); from the species of fishes existing in lakes at great elevations; and, finally, from the many proofs of the fall of the sea-level in the Baltic,—from all this, Swedenborg drew the conclusion that the former level of the sea in Sweden was some 400 feet above the present one. These changes he attributed in part to an alteration in the velocity of the earth's rotation and the period of rotation of the moon, whereby the water at the Pole is forced towards the equator. He also assumed that as the Baltic lies at a higher level than the Western Sea, the water therein gradually decreases.

Swedenborg's work, which suggested many points respecting the history of the world that have been hotly debated to the present day, was at first not understood, and continued to be almost ignored by the scientific world. But it was the immediate cause of analogous researches begun by Prof. Anders Celsius, in 1724, along the coast of the Baltic, the results of which he embodied in a paper published, in 1743, in the Proceedings of the Royal Academy of Sciences, entitled "Remarks on the Decrease of the Water in the Baltic, as well as in the Western Sea."

Setting aside all other periods dealt with by Swedenborg, Celsius devotes himself exclusively to the changes in the sea-level which have taken place in historical times. He adduces several examples, tending to show that harbours and roadsteads on our shores have become shallow, and that rocks have gradually risen above sea-level; that ample depth for seine-fishing existed where there is now a shallow; that the appellations "island" and "holm" are frequently used on the coast for uplands surrounded by lowlands, the name "sound" for bights or dry land; that flat rocks at the level of the sea, formerly valuable on account of seals gathering therein, have become valueless by having risen too high above the sea; and that anchors and wrecks have been found in inland peat-bogs. He further compares measurements of the rising of the land extending over 168 years, and comes to the conclusion that at Gefle (on the Baltic), during 100 years, the land rose from 41 to $47\frac{1}{2}$ inches, and, on the opposite side of the Bothnia Sea, from 41 to 50 inches, being an average of 45 inches. Celsius also proves a similar rising on the west coast, and from these facts he infers that the entire Scandinavian peninsula is gradually rising. Celsius further calculates the area of the land thus won from the sea since the days of Pytheas, and finally, for the benefit and instruction of coming generations, has a rock at Löfgrundet, off Gefle, carefully marked, this being the first scientific water-marking of the rising of the land in Sweden. As regards the fall of the sea, Celsius is of opinion that it is partly due to the transformation of water into earth through plants, and partly to the flowing

of water into "abysses" in the earth. It may be pointed out that the former theory could hardly be considered absurd at a time when most physicists believed that water could be transformed into earth; and as to the latter, we are still discussing the possibility of water being "absorbed by underlying strata."

Celsius found an ardent supporter in Linnæus, who, returning to Swedenborg's theory, connected the decrease of water with the presence of mussel-shells and *petrificata marina* in strata now situated high above the sea. Linnæus wholly rejected the theory that their presence was due to the Flood. He also held that "endless ages" must have elapsed since the earth began to be inhabited by plants and animals.

The views of these two great naturalists were at first accepted and defended by a number of distinguished scholars. But from 1755 they met with the warmest opposition, especially from the Bishop Johan Browallius, who, from the theological point of view, in a celebrated and learned work refuted and condemned the theories of Swedenborg, Celsius, and Linnæus. When some years later Colonel Carl Fredrik Nordenskiöld presented a paper to the Academy further elucidating the question, four years elapsed before it was published, and even then a "note of apology" for its appearance was appended.

But with the opening of the present century a new controversy arose. The theory of the structure and history of the earth had, during the preceding era, not only become developed into a special science, but students had already, by different opinions on certain fundamental scientific points, become divided into two schools, the followers of which, under a fierce, but to science beneficial, contest, each attempted to prove their views by searching old and collecting new records. Hardly had this strife begun when it became evident of what importance the old question of the rising of the land or the fall of the sea would be for the determination of the matters in dispute. One of the founders of the plutonic school, John Playfair, in 1802 advanced the theory of a connection between the rising of the land in Sweden and the volcanic forces in the interior of the earth, and some years later this view was further developed by the most ardent and gifted champion of plutonism, Leopold von Buch, who himself had had the opportunity during a journey in Scandinavia, 1805–6, by personal observations and by intercourse with Swedish men of science, of learning that at all events most of the observations on which the assumption of a change in the sea-level of the Baltic were founded had been carried out with the greatest care and conscientiousness.

Some of the opposite views, on the contrary, were revived, after a careful study of the literature appertaining thereto, by K. E. A. von Hoff, in an excellent work printed in 1822, entitled "Geschichte der durch Ueberlieferung nachgewiesenen natürlichen Veränderungen der Erdoberfläche"; but it should be added that the views defended in this work were retracted, twelve years later, after a careful discussion of the researches respecting the land-rising carried out in 1820–21 by Herr N. Bruncrona, Director of the Swedish Pilot Service, and the observations of Lieut.-Colonel C. P. Hällström, recorded in the Proceedings of the Academy in 1822. Hoff then acknowledged that the theory of the rising of the land formed one of the most important and instructive parts of modern geological science. Hällström, by the way, demonstrated that a considerable rising of the land takes place on the east as well as the west coast of Sweden, that the rising differs in magnitude in various localities, and that no rising exists on the coasts of Halland and Scania in the extreme south.

At this stage of the discussion, the closing word was spoken by the famous English geologist Lyell. He had at first doubted the assertion of the rising of the Scandinavian peninsula, but having, in the summer of 1834, paid a visit to Sweden for the purpose of investigating the question, having examined many of the statements bearing upon it, and having obtained valuable information from Berzelius and others, he published, in the following year, a paper in the Transactions of the Philosophical Society, entitled "On the Proofs of the Gradual Rising of the Land in Certain Parts of Sweden." In this paper Lyell accepts unhesitatingly the views held by the Swedish men of science. He especially points out the theoretically important and instructive fact (already, however, demonstrated by Hällström) that the rising varies much in different localities, and even that in some places in Southern Sweden no rise has taken place within historical times. Lyell's paper remained the final word upon this question for a long time, during which no opposition was raised to the fundamental principle. Efforts, however, were made by fresh measurements on the Swedish coast, to obtain fuller material for research, valuable contributions being rendered by Sven Nilson, P. A. Siljeström, A. Erdmann, Sven Lovén, J. G. Forshammar, G. Lindström, Lord Selkirk, A. G. Nathorst, and others. From these new researches it became evident that it was often difficult to establish harmony between observations made in places very close to each other, a circumstance which indicated that the phenomenon was far more complicated than at first supposed, and which again threw some doubt upon the matter, and caused fresh opposition. Even Lyell himself, in the eleventh edition of his "Principles of Geology," published in 1872, speaks with far less confidence of the land rising; and in a newly published important work the celebrated Austrian Professor, Suess, wholly denies the rising as well as local changes of the shore-lines. The old view of Urban Hjärne is adopted, viz. that the Baltic may be considered a lake, in which the height of the water chiefly depends upon the proportion between the water conveyed into it and the water lost by evaporation and outflow. Space does not permit me to enter further into the ingenious arguments of the eminent Austrian geologist. Hardly had his work left the press before the views advanced were refuted by Dr. Holmström in an elaborate paper, published in the Transactions of the Royal Swedish Academy.

Holmström's researches were begun in 1867 at the instigation of Prof. Otto Torell, so that his paper is founded upon studies extending over a period of thirty years. During that time Dr. Holmström, partly at the expense of the Pilot Service, visited and re-measured most of the old water-marks along the coast of Sweden. New ones have also been cut in the rocks, and for the guidance of future researches the old as well as the new markings have been carefully drawn and described.

The following important synopsis is the result of Dr. Holmström's prolonged studies.

The twenty-four hydrographical rock-marks along the *west* coast of Sweden show that the land in that part has risen about 0·5 centimetre during the last half-century. The rising is incontestable, but varies in different localities, amounting, for instance, at Nordkoster, to almost nothing, but at the Väderö to more than 1 metre in the century.

This result of the west coast researches is very important, inasmuch as no doubt can be entertained that the average water-level there corresponds with that of the North Sea, and that the rising of the land thus demonstrated cannot possibly be caused by a gradual fall of the water in the Baltic.

The two rock-marks on the south coast also indicate a rising during recent years, but as the time between the registration and the cutting of the marks is hardly twenty years, this proof cannot be accepted with certainty.

On the east coast of Sweden, as far as Stockholm, some twenty water-marks have been examined, and here, too, a rising is perceptible in most places, but at Säfvö

and Rödskär, and some other places, a *sinking* has taken place during the last twenty years, amounting to 0·7 centimetre a year. This sinking is, however, at all events at Säfvö, as far as can be ascertained from personal observation, of a quite local nature. At Calmar, on the other hand, as already shown by Dr. Siljeström, no change whatever has taken place since the beginning of the century.

From Stockholm northwards there are about thirty water-marks, and here, too, the rising predominates, although it varies often in localities very near each other; but a careful discussion of the observations seems to have established that the rising has been on the decrease during the last century. During the last period it amounted at Stockholm to 0·5 centimetre a year; at Celsius's old water-mark, at Löfgrundet, off Gefle, to 0·9 centimetre; at Chydenius's mark at Ratan to nearly 1 centimetre; at Bergö, on the Finnish side of the Gulf, to 1 centimetre; and at the mark cut by Augustin Ehrensvärd, August 21, 1754, on a rock at Hangö (Finland), to 0·6 centimetre. Therefore, a considerable rising, varying from 0·5 to 1·1 metre per century has taken place in this part of the Baltic.

The above facts, gathered by Dr. Holmström, form the last contribution to our practical knowledge of the old water decrease problem, and many decades must now elapse before fresh data can be obtained for further observations upon these changes in the earth's crust—changes which appear to us to take a long time, but which, geologically reckoned, are very rapid.

If the problem of the land-rising is taken in the same extent in which it was first raised by Swedenborg, it may be divided in two problems, certainly related, but widely separated, and both of pre-eminent importance to the geological history of the earth, viz. (1) the question of the changes of level to which the sea or the hydrosphere of the earth has been subjected in historical times; (2) the question of changes in the level of the sea during the immense length of the geological ages.

As regards the first, it must be considered fully demonstrated, to the student free from preconceived opinions, (1) that in several places along the coast of Sweden, during the lapse of a few generations, a considerable rising of the land has taken place, not only in the Baltic, but also on the west coast; (2) that this rising varies in different localities, and is in some places entirely wanting.

These facts cannot possibly be explained, as some students have attempted, simply by maintaining that the sea-level of the Baltic lies above that of the seas beyond, and that a gradual levelling takes place; as in that case no rising could take place on the west coast. If we, therefore, as is always advisable in natural researches, take the actual observations as basis for our theories, we are compelled to assume that in some places on the Swedish coast a gradual upheaval of the solid fundamental rock really takes place, although some portion of the apparent rising may no doubt be ascribed to a decrease of the water in the Baltic. That such a decrease does occur is probable, but when the student of science refers to it, he should bear in mind that it is only an hypothesis, as yet far from being proved.

Several circumstances seem certainly to speak against the trustworthiness of the observations founded on the water-marks. Prof. P. A. Gadd, for instance, remarks that often there have been found, close to a mark indicating a rising of the land from 3 to 4 feet in a century, trees 300 years old standing close by the water's edge—*i.e.* in places which, when the tree was only a shoot, would have been several feet under water, and this argument has been repeated without contradiction by Lyell, Erdmann, Suess, and others. But it is forgotten, when this is used as an argument against the land-rising theory, that the tree during a period comprising centuries may have sunk through its own weight and through the washing away by rain of the earth at its roots, peculiarities which cannot be unknown to the horticulturist who has planted trees on earthy eminences in parks. Indeed it is self-evident that among the thousands of trees by our shores there must be some which could strike their roots and thrive just in such a spot. Viking mounds, memorial stones, and buildings by the shore might be subjected to similar sinking, the water-marks carved in the solid crystalline rock only being trustworthy as evidence in questions about secular changes in the earth's strata.

Another argument against these observations on the coasts of Scandinavia is that these changes of level, if they do really take place, cannot possibly be confined to this country alone, but must be observable in other parts of the world. But any certain counterpart to the land-rising in Sweden is not known anywhere, not even on the North Sea coast of Norway, nor along the Atlantic border, where foundations of monuments dating from the time of Cæsar still remain intact. The weight of the latter argument is, however, greatly reduced when we bear in mind that observations such as those made in Sweden could not possibly be effected on a coast exposed to the ocean, where, in consequence of the tide, the level of the sea varies diurnally and alters with the direction and force of the wind—changes which so far exceed the land-rising here referred to that they would entirely obscure it. Besides, as regards old buildings, only those built carefully of granite and resting on the solid rock can be taken into account in this discussion. It is, moreover, possible that such an elevation of the land as that in Scandinavia takes place only in districts where the rocks consist of granite or crystalline schist. The Mediterranean being a sea with a mouth far more narrow than that of the Baltic, is unsuitable for the settlement of such questions. On the west coast of Europe, again, the tide is so great that similar observations there would be very difficult. Neither are the sandy shores of Holland and Germany suited for such observations, and the east coast of America has hardly a history long enough for such researches. This applies in a still greater degree to the west coast of America and the coast of Australasia. The volcanic shores of the Pacific Ocean are but little suited for the observation of such changes of the level of the sea. That no rising of the land along the coasts of the oceans has been observed is therefore capable of explanation.

But even accepting the theory that a slow secular disturbance of the level of the shore-line does take place in some localities we are obliged to confess that the geologists at present cannot advance any certain proof of a general change in the level of the sea having occurred in historical times. Any general decrease or increase of the volume of water in the sea in historical times has not been proved. The case is, however, different when it is a question of changes during ages not measured by those of man, but by those of the earth, *i.e.* by the measure of time, which no doubt bears the same proportion to our years and centuries as our terrestrial measures bear to astronomical distances. For in all parts of the globe, as well at the equator as near the Poles, we find rocks which incontestably have, during former geological ages, been formed below the sea, although now lying above it. There is not a shade of doubt about this. And one of the reasons why the geologist has with such great interest studied the question of land-rising in Sweden is that he hopes to derive from the small changes that take place before our eyes an insight into the causes of the great ones. With regret, however, we must confess that our success has yet been very slight. There does not yet exist any satisfactory theory of the origin of the beds of chalk and clay, a thousand feet in thickness, containing fossils of unmistakable sea animals, which are found high

up on the slopes of the Alps and far in the interior of high continents.

The marine deposits which are encountered all over the globe high above the present sea-level are stratigraphically of two very different kinds: viz. marine layers which have been greatly disturbed from their original horizontal position, upheaved and thrust up by the side rocks; and marine layers which, lying perfectly horizontally, form the upper strata of the high plateaus, or of the table-mountains.

That the former, after having been deposited as mud below the level of the sea, and afterwards hardened into more or less solid rock, have been dislocated from their original position by mechanical forces, and raised high above the level at which they were formed, pressed together, and thrown above each other,—about this all geologists agree. Formerly the opinion prevailed that the volcanic forces in the interior of the earth had accomplished all this, but we may assume that most geologists are now inclined to seek the cause of the changes indicated in *side pressure*, dependent upon various causes—a theory advocated by me twenty years ago, but then little heeded.

However, this explanation is no longer applicable to marine layers which have not been disturbed in the least degree from their original horizontal position, although they at present form high plateaus several thousand feet in depth and several thousand square kilometres in area. Such formations are, as is generally known, found in all parts of the globe, and from all geological ages. On the west coast of Norway, where no such rising of the land in historical time as in Sweden has been observed, one finds in many places, particularly in the north, terraces or ledges which run perfectly horizontally, irrespective of the geological structure of the coast, for miles along the shore. Since attention was first drawn to these terraces by Urban Hjärne in Sweden, and by Keilhau and Bravais in Norway, they have been the subject of careful study, and of a literature as voluminous as that relating to the land-rising question. No geologist will now venture to deny that we have here before us old shore-lines, indicating that the sea even during the very last geological epoch, but still long before, very long before, historical times, stood far above its present level; whilst the horizontal position observed everywhere, apart from purely local exceptions, appears to contradict the view that this is due to local upheavals. Similar formations are also found in other parts of the world, as for instance at the Cape and the southern part of South America, proving that even there great changes in the level of the sea have taken place since the beginning or middle of the last geological epoch.

Of layers from the Tertiary period we have, in consequence of the erosion during the Glacial age, only traces in Scandinavia; but further north, in Spitzbergen, we find Tertiary strata thousands of feet in thickness. Near the west coast they are much disturbed, but further inland they form almost horizontal strata of sand and clay, here and there containing small coal-seams and schists, rich in splendid fossil remains, bearing witness not only to a magnificent vegetation having once existed in these parts, now ice-covered, but to the fact that the sea at Spitzbergen when they began to form hardly stood higher than at present. When therefore Prof. Nathorst, during one of his expeditions to Spitzbergen, on the highest plateaus of one of these high but horizontal Tertiary beds, found a mighty layer of marine fossils, we obtained proof that during the Tertiary period, geologically speaking so near us, the level of the sea had varied to the extent of several thousand feet. Even here the perfect horizontal position of the strata from Advent Bay by the Ice Fjord across the Storfjord to Franz Joseph's Land, excludes the possibility of these Tertiary marine beds being raised to their present level by volcanic forces. And if we proceed from the Tertiary beds of the Arctic regions to those on which Paris rests, or to those of the United States or of Patagonia, we encounter everywhere proof that the level of the sea has changed many times during the Tertiary period. Analogous observations may be made about the strata from the Trias, the Jura, and the Chalk periods in different parts of the globe. Again, the geologist finds that the level of the sea for some reason or another during those epochs has changed by many thousands of feet, in most places without its being possible to connect this change with the oft-adduced reaction on the earth's crust of the supposed red-hot interior; and the same applies also to layers from the Palæozoic period, from the period during which the rocks of West Gothia, referred to by Swedenborg, were formed.

Independent of all observations on the land-rising in Sweden, and independent of all theories, the fact remains that since the earth became an abode for animals and plants, the level of the sea has changed many times.

But we must confess that up to the present no acceptable theory explaining the *cause* of these changes has been proposed. Some have re-adopted Swedenborg's ancient idea that a change in the rotation of the earth caused a change in the form of the hydrosphere; others have discussed the great influence exercised by heavy mountains on the water-level of the adjacent seas, calculating that under favourable conditions this may amount to a great deal, *i.e.* that the sea-level on coasts that are engirdled by great mountain ridges is several hundred metres above the main level of the ocean in the same latitude; others, again, have sought the explanation in the hypothetical, and to those who are familiar with the Arctic regions wholly arbitrary, assumption, that huge masses of ice are periodically heaped up at one or another of the Poles, and by their attraction cause notable changes in the sea-level; and, finally, some maintain that the rising of the level depends on dust and *débris* being either blown or washed into the sea, and that the sinking depends on water being absorbed by strata in the interior. But to the student reckoning with figures, and who bases his researches on actual observations and not on assumptions, none of these causes explains fully and satisfactorily the great and probably simultaneous changes of the sea-level. To my mind the simplest explanation, and nearest at hand, has never been duly considered.

No doubt this neglect in some degree springs from the still prevailing belief in the quantitative unchangeableness of the heavenly bodies, which with the Aristotelian philosophy has penetrated the intellect of natural philosophers. Kepler, on account of the sun being obscured during three consecutive days in April 1547, most probably by cosmic dust, opposed this principle, declaring expressly, *Cœli materiam esse alterabilem;* but the belief in the old dogma was so little shaken thereby that the scientific ban went forth from more than one quarter against Chladni when he attempted to demonstrate that cosmic matter does really fall upon the earth. Now Chladni's doctrine is everywhere accepted, but even at the present day few geologists will assign to the cosmic matter that falls on the earth an important influence in the formation of new strata. Only a few quantitative studies of the phenomenon itself, and an unprejudiced estimation of the length of the geological epochs, are needed to convince anyone how unjustifiable this is. To my mind it seems fully proved that solid matter, as well as gaseous, and fluid at a temperature above 0°, is daily in great quantities brought to the earth, and that through this fall, and by the masses of *débris* carried by rivers and wind into the sea, the latter must during geological ages have become filled, and its level raised in a manner which would be totally opposed to actual facts, if there were not other causes to counteract it.

Such a cause might be found in the circumstance that,

just as fresh matter is hourly brought to the earth by meteors, it steadily loses during its orbit in the solar system some of its gaseous constituents; and the near maintenance of a *status quo* during ages partly depends upon the circumstance that gain and loss balance each other, and partly also upon the gain and loss, during the record of mankind, being so infinitesimally small in proportion to the gaseous and fluid matter surrounding the lithosphere of the earth. But during the geological ages even this "little" may be appreciable: long periods may have passed when the gain has been in excess, which has caused a rise in the volume of the sea; whilst at others the loss has predominated, whereby a gradual fall of the sea-level has taken place.

That the atmosphere sometimes decreases through loss in space it is of course impossible to demonstrate by direct observation; but as we at present know fairly well the forces acting upon a gas or dust molecule in the outer strata of the atmosphere, it seems that we may, from a theoretical point of view, be able to obtain an answer to the question raised here. However, we must, to avoid erroneous and hasty conclusions, here take into consideration so many factors difficult to estimate that the definite answer probably for a long time will give rise to much controversy.

Therefore, although the problem of the rising of the land on the coasts of Sweden and Finland may now be said to have, in the main, been decided, the old question about the diminishing of the sea-level, and that just in the general form in which it was presented by Swedenborg and Linnæus, still remains an unsolved riddle of immense importance to the history of our earth.

A. E. NORDENSKIÖLD.

VARIABLE STARS AND THE CONSTITUTION OF THE SUN.

VARIABLE STARS.—The theory of variable stars set forth by Dr. Brester in a recent essay[1] somewhat resembles those suggested by Zöllner in 1865,[2] and by Dr. Lohse in 1877.[3] Briefly, Zöllner's theory regards variability as being due to the formation of scoriæ on the photospheres of the stars and their subsequent dispersion by the heat due to chemical combinations which take place in virtue of reduced temperature. Dr. Lohse substitutes absorption by the cooled atmospheres of the stars for the reduction of light by scoriæ as in Zöllner's theory, although both agree as to the cause of the removal of the light-obstructing agencies. The theory suggested by Dr. Brester is a little more ambitious than either of these, and, to give a translation of his own statement, "All the phenomena that variable stars present to us are the varied effects of one cause—the intermittent chemical combination at the cool external layers of that which had previously been dissociated by heat" (p. 1). All the explanations are based on the assumption that the stars are stratified spherical agglomerations of gaseous matter, the different layers having different compositions according to their distances from the centre.

Most stars are too hot to allow of the formation of compounds as we know them, but the stars most subject to variability (the red stars) are sufficiently cool, in their outer layers at least, for the formation of such compounds as hydrocarbons. It is in the obstruction of light by these compound vapours that Dr. Brester finds his explanation of variability. He aptly compares the cooling of a star to the running down of a clock-spring, and the intermittent chemical combination to the escapement which regulates it. These changes pass unnoticed in the hottest stars, because the periods elapsing between the coolings is very great, and the combinations formed exert no very great absorbing influence; but in the cooler stars only small changes of temperature are necessary, and the periods are correspondingly short.

Again, although the temperature may be low enough for a combination to take place, the combining substances may be so diluted by other matter that the combination is impossible, just as a mixture of oxygen and hydrogen will not explode if admixed with more than 7½ volumes of air (Bunsen). This condition Dr. Brester describes as a state of *surdissociation*. This state does not last long, because, as the combining molecules get nearer the centre, they get more concentrated, while the substances which prevent their union diminish in proportion. When the combination does take place, there is an "eruption of heat" and the clouds in the outer cool layers are dispersed, the brightness of the star consequently increasing.

So much for the general theory, which Dr. Brester believes to be competent to explain every description of variable star, even such diverse ones as Algol and β Lyræ. He rejects the eclipse explanation of the Algol type on the ground that it is impossible to conceive such large obscure bodies to travel at such an enormous rate, and that it is in contradiction to the recent work of Chandler and Sawyer, showing irregularities in the periods, especially in the case of U Ophiuchi.

Secondary maxima, such as occur in β Lyræ, he believes to be due to double combinations: the first substances which combine by the fall of temperature do not produce sufficient heat to reproduce the first maximum, whereas the next combination does, and these taking place alternately, the β Lyræ type receives explanation. Irregularities in the variability are, according to this theory, due to disturbances brought about by very rapid rotations.

"New stars" are believed by Dr. Brester to be produced by the sudden dispersion of the obscuring clouds which formerly surrounded the star, by heat due to a new chemical combination. On this supposition they must be at a very low temperature before they burst out. It is not easy to understand, however, how any such action as this could raise a star from the ninth to the second magnitude, as was the case with T Coronæ. The spectroscopic difficulty is a still greater one. How the spectrum of a new star just before its disappearance could, on Dr. Brester's view, be like that of a planetary nebula, is not easy to explain. For the present it seems more consistent with the facts to regard "new stars" as being due to the clashing together of two meteor-swarms in space.

In this theory Dr. Brester has attempted too much. Most astronomers are agreed that more than one cause of variability is at work, and it is certainly too much to expect one theory to explain all the various types. Dr. Brester does not seem to be aware that Algol is one of the hottest stars in the heavens, and that a recent photograph by Prof. Pickering shows the spectrum to be the same at maximum as at minimum. If one hot star be variable, why not all? Again, if variability is only manifest in the cooler stars, why does not every cool star give indications of variability? Further, the theory assumes that all variable stars are cooling, whereas Mr. Lockyer's recent work has shown that those of the Mira type are increasing in temperature. Dr. Brester's only objection to Mr. Lockyer's theory of variability is its limited application, but it was not set forth as being universally applicable. If Dr. Brester's theory had been limited to the variables of Group VI. (Vogel's Class III*b*), it would be more reasonable, but even then it would not be easy to understand why all the stars of the group do not exhibit variability.

The Sun.—The second part of the essay attempts to explain the various phenomena presented to us by the

[1] "Essai d'une Théorie du Soleil et des Étoiles variables," par A. Brester, D.Sc. (Delft: J. Waltman, 1889).
[2] "Photometrische Untersuchungen." p. 252.
[3] *Monatsber. der Akad. der Wissenschaften*, p. 826.

sun. The first great departure from prevailing opinions is the view that the sun is in a tranquil state, and is in no way subject to the violent storms which are commonly believed to disturb it. The stratified character of the solar atmosphere is set forth as evidence of this tranquil state. Dr. Brester believes that the apparent motions of the protuberances are not real, but simply indicate the displacement of the luminous condition brought about by chemical combinations in tranquil matter. This he believes to be quite consistent with the observed displacements of the prominence lines, and we see no reason to differ with him.

The next important divergence from prevailing ideas is the suggestion that pores, spots, and faculæ are all at exactly the same temperature because they are at the same level. The experiments of Spoerer and Langley have shown that the spots emit less heat than the other parts of the photosphere; but Dr. Brester states that this is not due to a difference in temperature, but to a difference of emissive power. He believes that spots are formed by the vaporization of the photospheric matter in the regions where they are formed, the luminosity being reduced, whilst the temperature remains the same. On this supposition, the photosphere bears the same thermal relation to the spot that ice does to the water formed as it melts.

The forms of the spots he believes to be due to the increase of pressure caused by the volatilization of the photospheric matter, the conical form being due to the fact that the nearer the centre the greater the resistance to the expansion.

That faculæ should precede spots Dr. Brester states to be essential to his hypothesis. They indicate the places where increased condensations are taking place prior to the "eruptions of heat" which will produce spots.

For an explanation of the periodical phenomena, and the increased angular velocities of spots near the equator, Dr. Brester assumes that, while the photospheric surface which we see is spherical, the different layers of the atmosphere must be ellipsoidal, owing to the rotation of the sun. He admits that this state of things is not easy to explain, but states that it is sufficient to know that the fact exists. This being taken for granted, the varying periods of rotation in different latitudes is not difficult to explain. For since the photospheric matter is formed by the condensation of the vapours of the ellipsoidal layers, the particles in equatorial regions have to descend a greater distance towards the centre than those in the same layers near the Polar regions; and since the linear velocity remains the same during the descent, the angular velocity is increased, and is increased more at the equator than away from it. Since the spots lie in the photosphere, they thus indicate an increased angular velocity in equatorial regions. It will be seen that this explanation is much akin to that suggested by Mr. Lockyer,[1] differing from it mainly in giving the whole photosphere the additional velocity, whereas, according to Mr. Lockyer's view, only the spot-forming material partakes of the added angular velocity.

The relation of spot spectra to the eleven-yearly period observed by Mr. Lockyer is also partially explained. According to Dr. Brester's view of the solar economy, the photosphere must have a special composition in each latitude, and since the latitudes of the spots vary with the period, the spectra would also vary with the period. The exact nature of the change—namely, from lines of iron and other known substances at minimum to unknown lines at maximum—is not explained.

The similarity of the spot zones on both sides of the equator, according to Dr. Brester's view, is due to the fact that the same atmospheric layer meets the photosphere in equal latitudes on opposite sides of the equator. The slight differences which do exist are regarded as simply the effect of chance, since an "eruption of heat" may either produce one large spot or several smaller ones.

[1] "Chemistry of the Sun," p. 424.

Dr. Brester also attempts to explain the cause of the eleven-yearly period, but his explanation is difficult to follow. Broadly speaking, his idea is that during eleven years the integrated effects of the various chemical combinations which have taken place are such as to very nearly restore the conditions which had existed at the commencement of the period. Slight differences would be produced each time, so that after a long interval, well-marked differences might be expected.

Although the theory explains many of the phenomena observed, an explanation of many more is still required. Thus, although it is not difficult to understand the absence of spots at the equator, the cooler layers there being at the greatest distance from the photosphere, we should be led to expect the greatest number of spots in polar regions, where the atmosphere in the neighbourhood of the photosphere is coolest, and where, therefore, chemical combinations would be most likely to take place. The question of the corona is reserved for a future essay, but Dr. Brester is confident that it will present no great difficulty. He also hopes to satisfactorily explain the phenomena of comets' tails, the zodiacal light, and the variability of Jupiter and his satellites.

In conclusion, Dr. Brester states that his theory, so far from being at variance with the laws of chemistry and physics, really strengthens them, and that it is not discordant with the observed facts. At the same time he admits that the difficulty of comprehending it in detail will prove a great drawback to its acceptance.

A. FOWLER.

THE RABBIT PEST.

MR. W. RODIER, of Tambua, Cobar, New South Wales, has forwarded to this Society a printed sheet, containing, as it appears to me, by far the best suggestion yet made for the extermination of rabbits—a subject to which my attention has been repeatedly called by various correspondents in the Australian colonies, where, as is well known, the damage done by these animals is enormous. Mr. Rodier states that his plan has been in operation at his station in New South Wales for about eight months "with the utmost possible success," and has cleared the country of rabbits. It is a very simple plan. Ferrets and nets are used in the usual way to capture the rabbits, but while all the females taken are destroyed, the males are turned out again uninjured.

The results of this mode of operation are that the male rabbits, as soon as they begin to predominate in numbers, persecute the females with their attentions, and prevent them from breeding. They also kill the young rabbits that happen to be born; and even, as Mr. Rodier asserts, when they largely predominate in numbers, "worry the remaining does to death."

This is all strictly in accordance with what we know takes place under similar circumstances in the case of other animals, so that we can readily believe it to be likely to happen.

The ordinary mode of trapping, as Mr. Rodier points out, is more likely to increase the number of rabbits than to diminish them. For reasons which he clearly explains, more buck rabbits are always killed by the trappers than does. Thus the does predominate in numbers, and, a few bucks being sufficient for a large number of does, are perpetually breeding and increasing the stock.

The plan advocated by Mr. Rodier is so simple and easy that I cannot doubt it will be widely followed when known. No disease that might otherwise cause injury is introduced, no other noxious animal is proposed to be

imported, but advantage is taken of the well-known natural laws which regulate the increase of life to effect in this instance a salutary decrease.

P. L. SCLATER.

Zoological Society of London,
3, Hanover Square, W., March 18, 1889.

NOTES.

THE number of candidates for the Fellowship of the Royal Society this year is seventy-one, being about a dozen above the average number.

THE contributions hitherto paid or promised in this country towards the intended statue of G. S. Ohm amount to £95 14s. 6d. from ninety-four subscribers. It is proposed that the subscription-list shall be closed at the end of the present month, and we are desired by the Committee to ask intending subscribers to send their contributions as early as convenient to the Treasurer, Dr. Hugo Müller, F.R.S., 13 Park Square, N.W.

A COMMITTEE was formed some time ago at Limoges for the purpose of securing the erection of a statue of the great French physicist and chemist, Gay-Lussac. The preliminary arrangements have now been made, and the task of preparing the statue has been intrusted to M. Millet, who expects to be able to exhibit it at the *Salon* next year.

WE have to congratulate the Fishery Board for Scotland upon the acquirement of the services of Dr. J. Beard, who for some years has been working on the Continent. Dr. Beard's researches into the development of fishes take rank among the leading recent contributions to the subject, and they augur well for the future work of the Board. We are pleased to see that the members of this body are now issuing their scientific Bulletins independently of their official Reports.

MR. W. E. HOYLE, late of the *Challenger* Office, has been appointed to the Curatorship of the Manchester Museum in the Owens College. The Museum Committee is fortunate in having secured the services of so competent a man.

A VALUABLE collection of photographs, representing Alpine and Caucasian scenery, taken by the late Mr. W. F. Donkin, is now being exhibited at the Gainsborough Gallery, 25 Old Bond Street.

WE regret to have to record the death, at a very early age, of Mr. J. Reynolds Vaizey, a promising member of the younger school of botanists at Cambridge. His best-known contributions to botanical science are his papers in the first volume of the *Annals of Botany*, on "The Transpiration of the Sporophore of the Musci," and on "The Absorption of Water, and its Relation to the Constitution of the Cell-wall in Mosses." Mr. Vaizey was subject to epileptic fits, and, during one of these, received fatal injuries from falling into the fire.

THE oldest botanical journal of Germany, *Flora*, hitherto published at Regensburg, under the auspices of the Bavarian Botanical Society, appears now, in its seventy-second year, under a new form, issued at Marburg, under the editorship of Prof. K. Goebel. In addition to original papers, it will contain a *résumé* of botanical work during the year in different departments. The first part under the new *régime*, for March, contains important papers by Goebel, Pfeffer, Ludwig, J. Müller, and others.

IN the March number of the *Kew Bulletin* there are papers on fibre industry at the Bahamas, hardy species of Eucalyptus, yam bean, West African rubbers, Phylloxera in Asia Minor, botanical station at Lagos, and Chiga bread.

AT the meeting of the Scientific Committee of the Royal Horticultural Society on March 12, corroborative information was received from Mr. Plowright, of Lynn, regarding the occurrence, described at the previous meeting, of boughs of various trees being broken off by the extraordinary growth of crystals of rime upon them. As no snow had fallen during the period, it was impossible to attribute the results to such a cause. There had been excessive fog before January 7; the rime forming upon the telephone wires was so great that they were broken down. The ice was deposited unilaterally like flat sheets of glass, 1½ to 2 inches in width on the south side. On the 8th was a thaw. The result of the frost was that a birch had a branch amounting to one-third of the tree broken off; the smaller branches particularly suffered. The elms were most injured, branches of all sizes being broken off, even large arms, one measuring 5 feet 6 inches in circumference and 1 foot 10 inches in diameter. To such an extent was the roadway covered with *débris*, that the market carts were greatly impeded. Oaks, willows, and poplars also suffered; but ashes and Scotch firs escaped. Mr. Plowright noticed that fracture without falling was a distinct feature of rime-injuries to trees, excepting to willows and poplars, the vast majority of whose branches fell to the ground.

THE Society established some months ago under the name of the Gesellschaft Urania has already issued the sixth monthly number of its excellent magazine, *Himmel und Erde*, which is edited by Dr. W. M. Meyer. The main object of the Society is to popularize the accurate knowledge of scientific matters, by practical demonstrations at the head-quarters in Berlin, and through the medium of its magazine. Astronomy, as it always did and always must, leads the way in this attempt to interest the general public in science. Since it is expounded by such authorities as Prof. Schiaparelli, whose illustrated article on Mars runs through the first three numbers, it is evident that the Society does not mean to sacrifice genuineness for the sake of popularity. Dr. Scheiner, of the Potsdam Observatory, contributed an admirable article to the January number, on the principles of spectrum analysis and their application to celestial physics. Astronomical articles have also been contributed by Prof. Foerster, Prof. Seeliger, F. K. Ginzel, and others. Other subjects, however, have not been neglected. A clear exposition of the proofs of subsidence and elevation afforded by the pillars of the Temple of Jupiter Serapis was given by Dr. Brauns in the November number. The January number also contains an excellent article on the aurora, by Dr. Weinstein. The magazine is got up in an attractive style, and is admirably illustrated. The Society has purchased a 13-inch refractor, several microscopes, and other apparatus for the demonstrations; and it is their intention to have models constructed to illustrate eclipses and other phenomena.

THE Educational Society of Japan has, says the *Japan Weekly Mail*, published and circulated a little volume containing its programme, organization, and a list of its members. It is worthy of note that, in the artistic device on the cover, women are conspicuous, and the fact that women are carrying on their studies side by side with men would seem to indicate that the Society is desirous of recognizing the equality of the sexes. No fewer than 5000 members have joined the ranks of the Association, and a kind of committee or parliament is elected by these for purposes of discussion and deliberation, consisting of 200 deliberative members, seven councillors, seven sectional presidents, and one president.

AN interesting step has been taken in Japan by the organization of a branch of the Anthropological Society of Tokio, to be called the "Maine Club," after the late Sir Henry S. Maine, having for its object the investigation of the ancient laws and

customs of Japan, and all matters connected with the development and progress of civilization in that country. Its members are chiefly members of the parent Society, but membership is not confined to these. It is proposed that there shall be monthly meetings at which papers will be read, and discussions held. Well-known scholars are to be invited to attend the meetings, and contribute to the discussions. Essays or speeches which are considered to be of sufficient importance will be printed either separately or in the volume of Transactions of the Anthropological Society.

AT the meeting of the French Meteorological Society on February 5, M. Lemoine communicated the information he had collected upon the rising of the Upper Rhone from the 3rd to the 5th of October last. The maximum rise was on the 5th at Lyons, where it reached 14 feet. The cause of the rise was a severe thunderstorm which broke out at 2 a.m. on October 2, with incessant rain over a large area lasting until the evening of the 5th.

THE Pilot Chart of the North Atlantic Ocean, issued by the Washington Hydrographic Office, for March, shows that gales were experienced in the western part of the Atlantic during the first three weeks of February. The most noteworthy was one which originated on the 10th, just north of the Bahamas; on the 12th its influence was felt, noticeably from Newfoundland to the West Indies, and from the American coast to the 45th meridian. More fog was experienced than is usual during February. The southward movement of ice was very backward, no field ice or bergs having been reported till February 6, in lat. 45° 35′ N., and long. 48° W. The chart contains brief rules for the use of oil at sea.

THE "Administration Report" of the Surveyor-General of Ceylon, for the year 1887, contains meteorological summaries for sixteen observatories, and monthly rainfall values for seventy-one stations. The mean temperature of the year was below the average at almost every station, and a comparison of the records since 1882 proves that there has been a fall of temperature throughout the island up to the present time. A map is given, showing the mean annual rainfall of the various districts, and a table showing the monthly means during different periods. The returns from Ceylon have been regularly published since 1869.

Two shocks of earthquake occurred at Bologna on March 9, but no damage was done. A severe shock was noticed at Aquila on March 10.

THE vapour-density of aluminium methide, $[Al(CH_3)_3]n$, has formed the subject of an important series of experiments by Dr. Quincke, of Göttingen, with the view of further elucidating the question of the valency of aluminium. A few months ago, Messrs. Louïse and Roux published an account of their experiments upon the same substance, from which they conclude that molecules of the constitution $Al_2(CH_3)_6$ are capable of existence. This result was in direct contradiction to the earlier observations of Messrs. Buckton and Odling, who showed that, even at the boiling-point itself, 130° C., the density was considerably lower than that required for this double formula; from the boiling-point upwards the density gradually diminished, until, at the temperature at which this organo-metallic body unfortunately commences to decompose, it had almost reached that required for $Al(CH_3)_3$. Hence a revision of the subject has been undertaken by Dr. Quincke at the request of Prof. Victor Meyer. The aluminium methide employed was a very pure specimen, of constant boiling-point, and solidifying, on cooling, in the form of magnificent tabular crystals. Analyses gave practically theoretical numbers. The vapour-density was determined in a Victor Meyer apparatus in an atmosphere of hydrogen. Of course, the all-important point to decide was the nature of molecular grouping just above the boiling-point, and, if such molecules were found to exist at all, to ascertain whether the value required for $Al_2(CH_3)_6$ remained constant for a sufficient interval of temperature. The experiments were therefore performed at the temperature of boiling xylene (140°), only 10° higher than the boiling-point of the methide. The mean value for the density, obtained from ten consecutive determinations, was 3·92; $Al_2(CH_3)_6$ requires 4·98, and $Al(CH_3)_3$ corresponds to 2·49. Hence it can no longer be doubted that molecules of the double formula are incapable of existence. Aluminium methide must therefore be represented by $Al(CH_3)_3$. Readers of NATURE will remember that only a fortnight ago an account was given in these columns (p. 447) of an analogous series of experiments by M. Alphonse Combes, upon a new organic aluminium compound, $Al(C_5H_7O_2)_3$, aluminium acetyl acetonate. It is supremely satisfactory that in this case the density, at a temperature only 45° above the boiling-point, was found to actually correspond precisely with that required by the triad formula, precluding again the possibility of the existence of molecules of the type Al_2R_6. Taking the mass of evidence now before us, it may fairly be granted that the stable molecules of aluminium salts are constructed upon the type AlR_3; and aluminium in this respect thus completely resembles iron, chromium, indium, and gallium.

A REPORT of Mr. D. Hooper, the Government Quinologist in the Nilgiris, says that efflorescent salts occur in nearly every district of India. When the salt is alkaline in its nature, the surface of the soil on which it collects is known as dhobies' earth, which has for ages been used in various manufactures, and for washing and dyeing. A large quantity of the efflorescence of Northern India, which is sold in the bazaars as *sajji mati*, is a mixture of salts, where the sulphate and chloride of sodium preponderate over the carbonate. Dhobies' earth consists principally of sodium carbonate and sand; the other ingredients are organic matters and sodium chloride, with traces of sulphate of clay, oxide of iron, and lime.

IN the Report on the Blue-book of 1887, the Colonial Secretary for Ceylon says that the operations of the Survey Department during the year were most important and varied. Not only was the ordinary work of surveying Crown land for sale carried on, but a large amount of surveying was undertaken in connection with irrigation schemes and forest reservation. The minor triangulation of the island was continued, and thirty new stations were established. The great triangulation of the northern part of the island, for the purpose of connecting the Ceylon system with the Madras coast series of the great Trigonometrical Survey of India, was completed, as described in these columns some time ago. Considerable advance was also made with the surveys of roads, streams, and lakes in all the provinces; and a vast amount of other work, including surveys of the coast-line, surveys of villages for forest reservation purposes, &c., was satisfactorily completed.

A RECENT American Consular Report contains a long account of the industrial school at Reichenberg, which was founded by the Imperial and Royal Ministry of Public Instruction as a technical school of the middle grade, with the object of educating young men for important industrial and manufacturing positions. The institution is divided into a high school and a workmaster's school, and each of these is subdivided into branches for architecture, mechanical arts, and chemistry. In the high school a very high standard of general education is maintained, and the students are prepared, by systematic courses of lectures, for practical work. The workmasters' school is open to persons who have already worked in architecture, or in some mechanical art, or in chemistry. Besides these

schools there is one at night for the benefit of persons who are compelled to work during the day, the instruction given relating chiefly to drawing and modelling. This institution is now being taken as a model for other schools which are in course of establishment by the Russian Government.

In the report, to the Foreign Office, of Sir A. Nicholson on the agriculture of Hungary during the past year, it is said that in November last a new agricultural school was opened in the Torontáler country, and at the end of the year there existed an academy of forestry at Chemnitz, a veterinary school at Buda-Pesth, an agricultural school in Hungarian Altenburg, four other agricultural academies in various parts of the country, and six schools. There were eight institutions for giving instruction in viticulture, three of which were in receipt of a fixed subvention. A proposal made to establish a high school for forestry and agriculture at Buda-Pesth has, for the present, fallen through. A Director-General has been appointed for all the agricultural schools; and a staff of travelling teachers for certain branches of agriculture has been formed. This staff, however, needs organization similar to that in Austria and France. Up to the present the members of the staff seem to have devoted themselves chiefly to instructing in agriculture and viticulture. Some years ago a body of engineers was formed under the control of the Ministry for Agriculture, with the object of assisting proprietors and farmers in irrigation, drainage, and other similar works, and of watching over water rights and fisheries. At present the number of these engineers is too small for the needs of the country.

A new stalactite cave has lately been discovered by accident near the little village of Erlach, in Lower Austria. It is about 60 metres long, and contains a shaft filled with water. The floor and walls are covered with stalactites and stalagmites picturesquely grouped, varying in colour from brown and green to white.

At the annual general meeting of the Linnean Society of New South Wales, on January 30, Prof. W. J. Stephens, in his Presidential Address, took occasion to discuss Dr. Waagen's ideas as to the supposed Upper Carboniferous glacial period, and its assumed bearing upon the correlation of various Upper Palæozoic and Mesozoic formations in India, South Africa, and Australia. Prof. Stephens's object was to show that no general glaciation had ever taken place in the temperate regions of the southern hemisphere, and that evidences of local glaciation, as of glaciers, floating ice, whether of icebergs or river ice-rafts, cannot be regarded as of any value in the determination of the question of the relative ages of members of geographically distant formations.

The new number of the *Mineralogical Magazine* contains, besides Mr. L. Fletcher's address on the renaissance of British mineralogy, the following papers: a mangano-magnesian magnetite, by Prof. A. H. Chester; on the zeolites of Rye Water, Ayrshire, and the minerals of the Treshinish Islands, by Prof. M. F. Heddle; elaterite, a mineral-tar in Old Red Sandstone, Ross-shire, by Mr. W. Morrison; analyses of various mineral substances, by Prof. I. Macadam; on the supposed fall of a meteoric stone at Chartres, Eure-et-Loir, France, in September 1810, by Mr. L. Fletcher; calcites from the neighbourhood of Egremont, Cumberland, by Mr. H. A. Miers; on the large porphyritic crystals of felspar in certain basalts of the Isle of Mull, by Mr. T. H. Holland. Mr. Allan Dick has a paper in which he describes a new form of microscope.

The United States Geological Survey has published the fifth volume of the series entitled "Mineral Resources of the United States," by David T. Hay, Chief of Division of Mining Statistics and Technology. This volume contains a summary statement of the mineral substances produced in the United States in the year 1887, and chapters showing the features of the principal mining industries during that period.

Several valuable Bulletins of the United States Geological Survey (Nos. 40–47) have just been issued. One of them (No. 44) consists of a bibliography of North American geology for 1886.

Vol. iii., Part 1, of the *Folk-Lore Journal* contains, amongst other interesting matter, papers on African folk-lore, by Edward Clodd; on Wexford folk-lore; and on superstitions of Scottish fishermen, by E. E. Guthrie. This volume also contains the Annual Report of the Council of the Folk-Lore Society, in which it is said that many new members have joined the Society. Amongst the losses by death during the past year have been Sir H. S. Maine, Mr. J. C. Morison, Mr. R. Proctor, and Mr. Gifford Palgrave.

The Geneva Society of Physics and Natural History has issued the first part of vol. xxx. of its Memoirs. It opens with an address by the President, M. Victor Fatio, giving an account of the work done by the members of the Society in the course of the year 1887.

Mr. John Anderson has compiled an interesting "History of the Belfast Library and Society for promoting Knowledge, commonly known as the Linen Hall Library" (Belfast: M'Caw, Stevenson, and Orr). It has been published in connection with the hundredth anniversary of the institution. Some valuable old maps of Belfast are reproduced in the volume.

Part 5 of Cassell's excellent "New Popular Educator" has been issued. Like the preceding parts, it is carefully illustrated.

Dr. A. B. Griffiths's "Treatise on Manures" will be published, in a few days, by Messrs. Whittaker and Co., of Paternoster Square.

Messrs. William Wesley and Son have issued No. 94 of their "Natural History and Scientific Book Circular." It contains a catalogue of works relating to the various branches of physical science.

The additions to the Zoological Society's Gardens during the past week include a Fruit Bat (*Cynonycteris*, sp. inc.) from India, presented by Mr. W. Jamrach; two Pine Grosbeaks (*Pinicola enucleator*), two Waxwings (*Ampelis garrulus*), a Nightingale (*Daulias luscinia*), British, presented by Mr. J. Young; a Great Eagle Owl (*Bubo maximus*), European, presented by Mrs. Morant; a Cactus Conure (*Conurus cactorum*) from Brazil, presented by Mr. W. H. St. Quintin; a Common Moorhen (*Gallinula chloropus*), British, presented by Mr. G. Hayward; a Rhesus Monkey (*Macacus rhesus* ♀) from India, two Nicobar Pigeons (*Calœnas nicobarica*) from the Indian Archipelago, deposited; a Buffon's Touracou (*Corythaix buffoni*) from West Africa, purchased.

OUR ASTRONOMICAL COLUMN.

Rowland's Photographic Map of the Normal Solar Spectrum.—Prof. Rowland has been engaged since the publication in 1886 of his first photograph of the spectrum, in endeavouring to perfect it, and has now completed a new map, which he considers much superior to the former. The entire work has been gone over again; a new dividing-engine has been constructed, and several concave gratings ruled by its means, some of which give especially fine definition. Much greater attention has been paid to the photographic manipulation, and the prints are, it is said, much finer and more perfect than those of the first series, which, however admirable as representations of the spectrum, as photographic works of art

left much to be desired. The present issue comprises ten plates, each 3 feet by 2 feet, and includes the entire spectrum, from λ 6950 in the B group up to the extreme limit of the ultra-violet. Of these, all but the first plate, which contains the most refrangible portion of the ultra-violet, are now ready, though plate *i*, λ 6050 to λ 6550, is not quite satisfactory, and may have to be replaced. The original negatives for this new edition show as distinct doubles, not only E, but even finer lines, such as those at λ 5276·1 and 5914·3, but it has not been found possible to exhibit all these as divided on the map.

THE CLINTON CATALOGUE.—We learn that the ownership of this most important work, which embraces the positions of over 35,000 stars, is in dispute; Mr. Borst, who with his sisters performed the principal part of the reductions, and prepared the manuscript of the completed Catalogue, having laid claim to it, whilst Dr. C. H. F. Peters, the Director of the Litchfield Observatory, of Hamilton College, Clinton, New York, at which Observatory Mr. Borst was an assistant, has instituted an action against him in order to regain possession of the Catalogue. The manuscript in question contains 3572 pages, 900 of which are of nearly double folio size, and shows more than 7,000,000 of figures.

SATURN'S RING.—Prof. Krueger telegraphs from Kiel that Dr. Terby, of Louvain, announces the appearance of "a white region on Saturn's ring, opposite the shadow of the globe" (*Dun Echt Circular*, No. 169).

THE O'GYALLA OBSERVATORY.—The tenth volume of the observations of Dr. N. de Konkoly's private observatory has just been published, in which he gives the results of the work done during the year 1887. The principal observations made were those of the sun, and of meteor-showers. In the former department, 137 drawings were made, showing 187 groups of spots. The relative spot number for the year was deduced as R = 10·35. The meteor-showers watched were those of the Aquarids principally, on July 25–27, the Perseids on August 8–12, and the Leonids on November 17. Some experiments with hydroxylamine as a developer, and the trial of a couple of object-glass prisms, with two or three observations of comets, complete the volume.

MOON-CULMINATING STARS, 1889.—M. Lœwy has prepared a comprehensive Catalogue of moon-culminating stars for 1889, which has recently been issued by the Bureau des Longitudes. Stars down to the seventh magnitude, 366 in number, have been taken and arranged in the order of their right ascensions. The R.A. of each star is given for every ten days during its period of visibility, the mean declination and sec D and tan D being also given. The Catalogue forms a valuable supplement to the tables already published in the *Connaissance des Temps* and the *Nautical Almanac*.

The ephemerides of eight Polar stars for 1889, all within 9° of the Pole, and none below the sixth magnitude, are given in the first part of the memoir.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 *MARCH* 24–30.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on March 24

Sun rises, 5h. 54m.; souths, 12h. 6m. 16·5s.; sets, 18h. 18m.: right asc. on meridian, 0h. 14·9m.; decl. 1° 37′ N. Sidereal Time at Sunset, 6h. 28m.

Moon (at Last Quarter on March 24, 7h.) rises, 2h. 3m.; souths, 6h. 7m.; sets, 10h. 9m.: right asc. on meridian, 18h. 14·6m.; decl. 22° 8′ S.

GEOGRAPHICAL NOTES.

AT the last meeting of the Paris Geographical Society, M. Ed. Blanc made a communication giving the results of his four years' researches among the oases on the south of Tunis. Referring to the question of the desiccation of the Sahara, and to the obliteration of formerly existing oases by the sand, M. Blanc said he did not believe it was due to the destruction of the irrigation works which had been established by the Romans, nor to any alternation of periods of drought with periods of humidity. Nor did he attribute it to the disafforestation or the depasturage of the country; forests, he believes, have very little if any influence on rainfall. The desiccation of the Sahara M. Blanc attributes to general geographical causes, resulting from modifications in the contour of the continents, such as the emersion of the steppes of Central Asia, the gradual disappearance of the snows which existed during the Glacial period in certain mountain masses of Europe and even of Africa, and perhaps also the elevation of a part of the depressions of the Western Sahara. These various causes, according to M. Blanc, have led to a deficiency of moisture in the air-currents which prevail over that part of Africa, and the equilibrium once broken between rainfall and evaporation, there results a progressive desiccation, more and more marked, and irremediable with the means at present at our disposal. The spread of the sand is a natural result of the exhaustion of the desiccated soil under the action of the winds. It is therefore a consequence of the above conditions, and could only be arrested by an alteration in the rainfall. Still, M. Blanc thinks that though one cannot alter existing conditions it is quite possible to palliate them, and especially by tapping underground supplies increase the number of oases, and restore to fertility others which have existed in former times, but are now overrun with sand.

MR. F. ARNOT, the young missionary who has spent seven years in South Central Africa, returns to Loanda in a few days. Mr. Arnot intends to proceed again to the Garanganze country to resume his labours. He means, however, to travel about the region of which Lake Bangweolo is the centre. The contour and position of that lake he will endeavour to settle, and also lay down as far as possible the courses of the various rivers that contribute their waters to the Congo. Mr. Arnot has during his stay at home been qualifying himself for taking exact observations, so that we may expect important contributions from him to the geography of Central Africa.

THE immense terrestrial globe which is being constructed for the forthcoming Paris Exhibition will have many points of

interest. It will be one-millionth the size of the earth; a millimetre on the globe will represent a kilometre on the surface of the earth. The globe will be about 30 metres (nearly 100 feet) in diameter. On this scale it will be possible in most cases to give geographical details their true dimensions; Paris will occupy just about 1 centimetre, and may serve as a unit with which to compare the dimensions of other features. All the great lines of communication by land or by sea can be shown in detail. In the enormous cupola under which the globe will be placed, it will be possible by means of a clock-work arrangement to turn the globe on its axis and convey a precise notion of the diurnal rotation of the earth. A point on the equator will move at the rate of half a millimetre per second. The many educational uses to which such a globe could be put are evident. The globe, we understand, is well advanced towards completion.

In the most recent number of the *Bulletin de la Société de Géographie*, M. Jules Marcou continues and concludes an account of his investigations into the origin of the name America. He rejects, for very many reasons, which will be found in the contribution in question, the ordinary derivation—that is, from the Christian name of Vespucci, the Italian navigator. Vespucci, he says, never took the name Amerrigo, or Amerigo, till after America was discovered, and, through vanity, he kept up the proud title. The name is an indigenous one, M. Marcou thinks, and means the country of the wind, or the land rich in gold. Four-fifths of the storms which are met with in the Atlantic come from America, and the gold put in circulation by Columbus's discovery explains the second meaning of the term. Between Lake Nicaragua and the Mosquito Coast is a range of mountains called the American Mountains, inhabited by a tribe of Indians, now very few in numbers, who bear the name, "Los Amerriques," and who have been, according to the President of the Nicaraguan Republic, who supports this view, continually in communication with the whole of the Mosquito Coast. Columbus, and not Vespucci, was the discoverer of America, and the country was named from this place and these people, and not from Vespucci, who was a man of no importance, until he either took the name of Amerrigo, or until it was given him.

Captain Cecchi, Italian Consul at Aden, sends to the *Bollettino* of the Italian Geographical Society some further particulars of Count Teleki's expedition to the north of Masai Land, and his discovery of the two lakes Samburu (Upper and Lower Narok) in that region. The explorer, who was accompanied by Lieut. L. von Höhnel, of the Austrian Navy, after ascending Mount Kenia, reached the Niems territory on November 21, 1887, and was detained there till the following February. On the 10th of that month the party continued their journey in a northerly direction, and on March 6 arrived on the southern shore of the large lake Samburu (Upper Narok), to which Count Teleki gave the name of his intimate friend, the late Crown Prince Rudolph. The much smaller basin of the Lower Narok, which was also re-named Stephania, in honour of the Crown Princess, was reached on April 4, after which the Expedition returned to the coast at Mombasa. At the northernmost point to which they penetrated (nearly 6° N. lat.) they were within about seventy miles of the Kaffa country, and they describe the two rivers flowing thence southward to the northern extremity of Lake Rudolph as "very important streams." This agrees with the results of Sig. Borelli's explorations in the region south of Shoa, and makes it highly probable that one of these two rivers is the Omo (Ghibieh), which in that case would be an affluent, not of the Juba or of the White Nile, but of the inland Samburn basin, lying between those two water-systems. To the same basin belongs Lake Stephania, which communicates with the northern extremity of Lake Rudolph, about lat. 4° 20′ N. The expenses of this important expedition were entirely borne by Count Teleki, who is a wealthy Hungarian nobleman. Captain Cecchi's letter is accompanied by a map of the two new lakes prepared from Lieut. von Höhnel's original sketch.

SIXTH ANNUAL REPORT OF THE FISHERY BOARD FOR SCOTLAND.

THE Report for 1887 is published in three separate parts—a plan which will be found convenient in many ways. Part I. contains the General Report; Part II., Report on Salmon Fisheries; and Part III., the Scientific Investigations. The product of the sea-fisheries of Scotland continues to be very large, but in 1887 the prices of most kinds of fish were much lower than they had been for a great many years previously; the fishermen only received a very small return for their capital and labour, and many of them were reduced to a state of extreme poverty. Of the different fisheries of Scotland, that of the herring continues to be by far the most productive and valuable. The fishing of 1887 was less so than that of 1886, but, owing to the great depression in the herring trade, it was not entered into nor carried on with the spirit and industry of more prosperous times. The summer's catches of herring were, speaking generally, much inferior to those of 1886, but the winter herring fishery was the most productive ever known. With yearly fluctuations, the yield of the herring fishery on the Scottish coast has, since the beginning of the century, gone on increasing in an extraordinary degree. The total quantity of white fish landed and sold for consumption fresh showed a large increase compared with 1886, being the largest landed in any year during which returns have been collected; whilst the shell-fish showed a considerable decrease. The total gross value of the sea-fisheries of Scotland for 1887 was £1,915,602 10*s*. The Board are much impressed with the beneficial results to fishermen and curers arising from increased telegraphic communication, which, when further developed, will be of immense value for the promotion of the fishing industry. It is satisfactory that thirteen new telegraph stations are to be opened in remote districts; also that a number of harbours are being improved or constructed. The marine police and fishery superintendence was carried on by H.M.SS. *Jackal*, *Vigilant*, *Firm*, and *Active*.

The inference from Mr. Young's Report on the oyster and mussel fisheries on the south-west coast of Scotland is that there are many places where the cultivation of these mollusks might be renewed or established, but that, to make this of any permanent use, such nurseries should be the property of someone whose interest it would be to make the concern profitable to the public and himself, of course under proper legislation. In the salmon fisheries, owing to the dryness of the season, the angling was very poor, but the nets, especially those in the tide-ways, were very successful. The total value was £282,523 10*s*.

The third part of the Report, consisting of 400 pages and 17 plates, contains the results of the scientific work. The text is divided into three sections, and is preceded by a general statement, which touches upon the scientific work done in 1887, and draws attention to the matters requiring special attention in the immediate future—viz. (1) how adequate supplies of bait for the line fishermen may be best provided. (2) What measures should be taken to improve certain exhausted fisheries of the shores and in-shore waters, such as mussels, lobsters, oysters, &c., by artificial cultivation, or otherwise. (3) The collection of all possible information bearing upon the influence of different modes of fishing, especially in the territorial waters, and in relation to the destruction of young fish. (4) The study, by means of the *Garland* and otherwise, of the distribution, migrations, and spawning periods of the edible fishes, and of the distribution and movements of the floating organisms which form a large portion of their food. (5) The extension of our knowledge regarding the physical conditions of the fishing-grounds and of the waters around the coast. (6) The collection of special statistics in relation to the fisheries of particular districts. The value and utility of such investigations and inquiries is manifest. It is very desirable that some measures should be taken with the object of providing a plentiful supply of bait for the line fishermen. The condition of certain of the shore fisheries is also a subject of considerable gravity. The oyster, as an article of commerce, is becoming slowly but surely extinct in Scotland, the total value of the yield for 1887 being only £965. The diminution in the numbers and in the size of the lobster has been referred to, and it will be an unfortunate circumstance if, for the want of active steps being taken, this important branch of the Scottish fisheries, now rapidly falling off, is allowed to follow the oyster in the process of practical extinction.

Section A of the appendixes contains the general scientific reports, the longest of which is that on "The Trawling Experiments of the *Garland*, and the Statistics of the East Coast Fisheries," Part 2, by Prof. Cossar Ewart and Sir J. R. G. Maitland, illustrated by three admirable charts, a map showing the chief areas investigated by the *Garland*, and about 130 pages of elaborate and accurate statistical tables. The influence of

excessive beam-trawling in the in-shore waters has formed the subject of several Parliamentary inquiries; but from want of trustworthy statistics or scientific evidence the conclusions arrived at have not always been in agreement. The result of the *Garland* experiments and the statistics collected shows that in those areas where trawling is prohibited, the fish, especially the flat-fish, have largely increased and the number of young fish is greater than formerly. The results of the *Garland's* investigations as to the distribution of edible fishes, their numerical variations at different seasons, and the proportional abundance of young and adults are also given, and the scientific statistics collected are discussed in detail. It is evident that by the systematic collection of scientific statistics regarding the productiveness of the fisheries and the relative influence of special modes of fishing, the migration, the spawning processes, and the general life-history of the fishes themselves, a great deal will be accomplished for the promotion of the fishery industries of Scotland. In this connection it will be seen that the investigations carried on by the *Garland* are calculated to have a high value, since the data thus collected are wide in their scope, systematic, and trustworthy. Without the use of a vessel specially adapted for the purpose such investigations would be impossible.

Section B contains the biological investigations. The paper on "The Scottish Lobster Fishery," by Prof. Ewart and T. Wemyss Fulton, M.B., discusses at due length the interesting question as to the best means of restoring this fishery to its old place in our seas and in our markets. Slowly but surely lobsters have been diminishing in size and number and rising in price; and our once famous home lobster market has to be supplemented by supplanting foreign supplies, simply because Scotch lobsters cannot be got in sufficient numbers of a marketable size. The older and most valuable lobsters have been cleared out, and the less mature forms are being drawn upon. Unfortunately also, the female lobster being much more valuable for cooking purposes, the "coral" is sometimes collected alone, and so, by the systematic destruction of its ova, the lobster is seriously handicapped in the struggle for existence. The use of "creels" or "pots," instead of the older-fashioned "rings," has been also an important factor in bringing about the "over-fishing." The legislation of lobster-fisheries is a very difficult matter, and in Canada, where the restrictions are very severe, they have failed in their aim. It is impossible to set one fixed close-time all over Scotland, as there is no general agreement among fishermen as to which time would be most serviceable. The institution of a minimum legal size is a regulation generally adopted, and it is proposed that the gauge of 8 inches should be raised to 9 inches. Further, that, as in Norway and the United States, artificial culture should be resorted to. By artificially hatching the eggs and rearing the young through the larval stages till they have reached a certain size, they are protected from their natural enemies, and if then transferred to the sea would be better able to take care of themselves. That the process is feasible has been shown both in Norway and the United States. A complete lobster-hatchery could be established for a comparatively small sum at some suitable point on the west coast. Unless some steps be taken, the lobster fishery of Scotland is likely to become the memory of a pleasant and profitable past. Mr. Thomas Scott gives in interesting detail, a "Revised List of the Crustacea of the Firth of Forth," which records 230 species, including 41 of Ostracoda, 42 of Copepoda, and 13 Schizopods. Of these species many are new to the district, and two Copepods—*Aztrotrogus papillatus* and *Cyclops ewarti*—new to science. This list is a valuable addition to our knowledge of the Crustacean fauna of this region, previously studied by Leslie, Herdman, Henderson, and others. Mr. Scott also supplies notes on the contents of the stomachs of herring and haddock, and on interesting fishes, &c., sent to the University of Edinburgh. The nature of "red cod," a fungoid condition sometimes met with in the preserved fish, is described by Prof. Ewart; Dr. Edington furnishing and figuring the results of a bacteriological investigation as to the nature of the organisms present, and the cause of the red coloration. Red cod was first noticed in America, but has since been observed in various places, including two as far apart as Algiers and the Hebrides. Used as food in this state, the results may be disagreeable or even dangerous. It was generally referred to the presence of a minute Fungus (*Clathrocytis roseo-persicina*), but Dr. Edington ascribes it to a special Bacillus (*Bacillus rubescens*), which also existed in the salt used for curing, and thus infected the fish. Mr. W. L. Hoyle reports on biological investigations in the sea to the west of Lewis during July and August 1887, and gives a list of the various forms obtained. Prof. McIntosh, F.R.S., gives Reports from the Marine Station at St. Andrews. These deal chiefly with the stages of development in several of the food-fishes, and with the Annelids and other forms used as bait. Mr. Calderwood furnishes notes on an intra-uterine specimen of the porbeagle (*Lamna cornubica*); and Mr. J. Murray on the fishing-grounds of the Stonehaven district, of which he is officer. A new and edifying feature of the Report is furnished by Dr. Wemyss Fulton's account of contemporary work relating to the scientific and economic aspects of the fisheries. The contemporary work carried on in England and Ireland, United States, Germany, Norway, Denmark, Holland, Italy, and Japan is also summarized.

Section C, which is devoted to the physical investigations, contains three papers: on the apparatus required for carrying on physical observations in connection with the fisheries, and on a physical and chemical examination of the water in the Moray Firth and the Firths of Inverness, Cromarty, and Dornoch, by Dr. John Gibson and Dr. H. R. Mills, the latter also reporting on the physical observations on the sea to the west of Lewis, taken during the cruise of the *Jackal*, as described previously by Mr. Hoyle. These papers are illustrated by ten graphic plates, with tables, charts, &c.

As may be seen from the foregoing abstract of the Report, the Scottish Fishery Board is doing good and trustworthy work in many directions, and, from a scientific and commercial point of view, it deserves every encouragement from the Government and the public. It would be an important aid if, by interchange of publications, the Board could be kept in touch with the important fishery organizations abroad. Unfortunately, at present the number of copies of the Report placed at the disposal of the Board renders this impossible. This should be remedied speedily, as, from an economical point of view, there should be the freest circulation of knowledge on questions touching such an important industry.

SCIENTIFIC SERIALS.

Revue d'Anthropologie, troisième série, tome iv. (Paris, 1889).—The Hottentots in the Paris Garden of Acclimatization, by M. Deniker. As the group consists of only six men, five women, and two children, the observations and anthropometric measurements made by the author cannot be regarded as contributing any very important facts to general ethnological inquiry. To French readers the subject has, however, the interest of novelty, since it would appear that the physical conformation of these South Africans has not hitherto been often made the subject of careful study among French ethnologists owing to their lack of opportunity for examining the living subject or measuring the cranial remains of the people, since the Museums of France contain scarcely more than thirty skulls in all, including both Hottentots and Bushmen. The observations of M. Deniker agree generally with those of Profs. Flower, Virchow, and Davis; and like them he believes that we must regard the Hottentot as belonging to the dolichocephalic type, while the Bushmen must be included under the mesocephalic group, the cephalic index being, however, nearly the same, 73, for both. The women of the party all presented the well-developed steatopygia, which is generally admitted to be a national characteristic of the sex, this condition being specially marked even in one of the elder women whose body was almost emaciated in all its other parts. A curious abnormality was noted in two of the men, and in one woman, who presented an interdigital membrane between the second and third toes, affecting both feet in one case.—M. S. Reinach in an article on the museum of the Emperor Augustus, whose collection of bones and arms is referred to by Suetonius, points out that owing to inexact interpretations the precise meaning of the writer has gradually been more and more distorted. M. Reinach thinks that we must seek for the site of this so-called museum at Capri, and not on the Roman Palatine, as M. Nadaillac supposes; while he believes that the "*gigantum ossa*" spoken of by Suetonius were fossil bones, popularly characterized as "*arma heroum*." This opinion, the author thinks, derives support from the story of Samson slaying the Philistines with a jaw-bone; animal bones having been found by primitive peoples to be more readily available as weapons than implements of stone, which required labour for their fabrication. There is no doubt, moreover, from a reference in the Vedic

hymns to the weapons of Indra, that animal bones were used among the early peoples of the East for purposes of offence and defence.—Continuation of Dr. Seeland's notes on Kashgaria and the passes of the Tian-shan. The author's description of the city of Kashgar, which lies on an extensive elevated plateau 3750 feet above the level of the sea, shows that the spot described in such glowing terms by Marco Polo is now nothing more than a confused network of foul, narrow, and tortuous streets, the houses of which lack every requirement of comfort, and almost of decency, as judged by our notions. The dwellings of the richer people have indeed large gardens filled with luxuriant fruit-trees, but the modern traveller would seek in vain for the shady groves, sparkling fountains, splendid mosques, spacious baths, rich bazaars, and lovely women, spoken of by the old Venetian writer. The ethnic type of the Kashgarians is clearly that of a deteriorated mixed race, in which the original Aryan or Turkish character has been nearly obliterated by repeated admixture with different Mongol races. The Chinese officials, under whose rule the people have long languished, effectually prevent all improvement in the country or the people, as is sufficiently shown by Dr. Seeland's account of the mode in which they govern this once fertile region. Indeed, nothing can be more deplorable than the account given of the personal appearance, character, and sociology of the Kashgarians, who exhibit the most marked slovenliness and incapacity, with a melancholy and passive temperament; and whose only pleasures are derived from an excessive abuse of narcotics, accompanied by a marked degree of sexual depravity, which they have possibly acquired through their intimate association with the Chinese. It fact, honesty seems to be the only virtue left to the Kashgarian. The account given by the author of the effect of Chinese rule in this part of Asia Minor agrees with the views of the late M. Prjevalsky, and certainly seems to warrant the conviction cherished by these travellers that the only apparent chance of ameliorating the condition of the people would depend upon the annexation of Kashgaria to the Russian Empire.—The race of Lagoa Santa of Brazil, by Dr. Soren Hansen. The bones found by M. Lund in the caves of Lagoa Santa were mostly deposited in one of these numerous recesses. These human remains were not associated with any animal bones, from which it could be determined with absolute certainty whether they were contemporaneous with a Tertiary or a Quaternary fauna, while the absence of every kind of implement left the antiquity of the race equally uncertain. These remains, which include fifteen more or less entire skulls, besides a very large number of bone fragments belonging to persons of all ages, are preserved in the Zoological Museum of Copenhagen. All the crania present remarkable uniformity with two skulls, respectively preserved in the British Museum and at Rio, which have been referred by M. Quatrefages to a Papuan type, and they appear to give support to his opinion of the existence over the greater part of South America of a primitive dolichocephalic race, which was subsequently intermingled with peoples presenting a brachycephalic character.

Notes from the Leyden Museum, vol. xi. No. 1, January 1889, contains twenty articles, chiefly descriptions of new genera and species of insects. The more important entomological papers are: Dytiscidæ et Gyrinidæ nouveaux ou rares, par M. Régimbart; Neue Coleopteren, beschrieben von E. Reitter; and a note on *Macronota apicalis*, G. and P., by J. R. H. Neervoort van de Poll.—There are two interesting papers by Dr. R. Horst, on a remarkable Syllis bud, with extrudible segmental organs (plate 1); and contributions towards a knowledge of the Annelida Polychæta (plate 2). This latter note, treats about the species of the genus Arenicola found at Naples: these are *A. claparedi*, Levinsen, possibly peculiar to the Mediterranean, but should be looked for on our southern coasts; *A. cristata*, Stimpson, originally described from South Carolina, but now found at Naples; *A. grubii*, Claparède, very common in the Gulf of Naples.—Dr. F. A. Jentink gives notes on a collection of mammals from East Sumatra, based on the collections made by Dr. B. Hagen. The orang-utan is to be found along the coasts of the northern half of East and West Sumatra, and among the other mammals, hitherto not recorded from Sumatra, though known to occur in Borneo, are *Arctogale stigmatica*, *Hemigalea derbyana*, *Herpestes brachyurus*, *Cynogale bennetti*, *Ptilocercus lowii*, and *Rhizomys dekan*.—Mr. J. Büttikofer gives notes on a new collection of birds from South-Western Africa (plate 4). The collection was made at Gambos, in the Upper Cunene region; it contained 267 skins, representing 103 species, of which number 49 were not mentioned in Mr. Büttikofer's previous list; two species are new, *Lophocercs alboterminatus* and *Francolinus jugularis*.

THE longer papers in the *Nuovo Giornale Botanico Italiano* for January are almost entirely floristic, relating to the phanerogamic or cryptogamic flora of particular districts of Italy.—Signor G. Arcangeli describes a remarkable monstrosity of *Narcissus Tazzetta*, in which the "corona" is divided into six petaloid leaves.—In the Reports of the meetings of the Societa Botanica Italiana, the same botanist follows up his account of the structure of the seed of *Euryale ferox* by a description of those of our common water-lilies, *Nymphæa alba* and *Nuphar luteum*. They all agree in the occurrence of a scanty endosperm, consisting of from one to four layers of cells, and a very copious perisperm.—Signor R. Pirotta describes the mode of fertilization of *Amorphophallus Rivieri*, which is effected almost entirely by a number of different species of Coleoptera.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 15, 1888.—"Observations upon the Electromotive Changes in the Mammalian Spinal Cord following Electrical Excitation of the Cortex Cerebri. Preliminary Notice." By Francis Gotch, Hon. M.A. Oxon., B.A., B.Sc. Lond., and Victor Horsley, B.S., F.R.S., Professor of Pathology, University College, London. (From the Physiological Laboratory of the University of Oxford.)

Hitherto pathologists have attempted the analysis of the epileptic convulsion by the graphic method—that is, by recording the spasmodic contractions of the muscles involved. Recent investigations of this kind have shown that the excitation of the cortex cerebri, whether by electrical or chemical means, or by the presence of certain pathological states, neoplasms, inflammation, &c., is invariably followed in the higher mammals by a definite and characteristic sequence of movements in the muscles. It is, however, obvious that such investigations have up to the present succeeded in determining the characters of the neural disturbance only when this has reached the peripheral terminations of the efferent nerves. Now since the excitatory processes originating in the cortex are conducted by the efferent channels in the spinal cord, presumably the pyramidal tracts, the problem of their relationship to the centres of the bulbo-spinal system cannot be determined by experiments which record the mechanical changes in the muscles. In order to ascertain what share respectively the centres in the cortex and those in the spinal cord have in the production of the characteristic epileptic sequence, the action of the latter must be eliminated. This can be done by investigating the nature of the excitatory processes in the cord when the efferent channels in the dorsal region for the lower limbs are made the subject of observation.

For this purpose we determined to obtain, if possible, evidence as to the nature of the excitatory processes of the epileptic convulsion in the spinal cord, as shown by "tapping" the cord and noting the electromotive changes which, as is well known, accompany functional activity in nerves. The results we have already obtained are so harmonious and demonstrative, that we venture to make this preliminary communication, reserving full details for a subsequent account.

PART I. *The Electromotive Change following a Single Excitation of the Mammalian Nerve.*

Our first experiments were made for the purpose of ascertaining to what extent we could detect an electromotive change following a single excitation of a mammalian nerve. Since the discovery by du Bois-Reymond of the fact that the excitatory process in nerve is accompanied by an electromotive change, the characters and time relations of this change have been investigated by various observers, notably by Bernstein, Hermann, Hering, and Head. The general result of their observations is to show that the change following a single stimulus is of very short duration, so short that the galvanometer gives little evidence of its presence, and the observers referred to were compelled to adopt the device first employed by Bernstein, which involves repeated excitation and consequent summation of effect, a method well known to physiologists as that of the repeating differential rheotome. For our purpose it was essential to obtain evidence of the effect following one stimulus only, and this we were fortunately able to do by using a sensitive Lippmann's capillary electrometer of quick reaction, made by Mr. G. F. Burch, and

belonging to Dr. Burdon Sanderson, who kindly placed it at our disposal. This instrument, when the capillary was magnified 400 times by the observing microscope, gave a perceptible response when connected through a resistance of 10,000 ohms for one-thousandth of a second with an electromotive difference of only 0·003 D. The amount of movement of the mercury was estimated by the divisions of a micrometer eye-piece, one division of which indicated an actual movement of $\frac{1}{160}$ of a millimetre. After we had found that the electrometer, when connected with the transverse and longitudinal surfaces of the sciatic nerve of the toad, showed a response of one division following the application of a single stimulus, whether electrical or mechanical, we proceeded to the examination of the sciatic nerve in the rabbit, cat, and monkey. For these experiments the animal was in every case kept under the influence of ether, which was maintained throughout the whole experiment, and the animal was killed before recovery. The sciatic nerve seemed for many reasons the most suitable of the mammalian nerves. It can be quickly prepared for 7 or 8 cm. of its length, its nutrition is well preserved, since the *arteria comes nervi ischiadici* can be left uninjured, and its diameter lessens the dangers of drying.

The nerve, having been rapidly prepared and bathed in warm saline solution, 0·6 per cent., was ligatured low down in the thigh, the ligature including the popliteal trunks. It was then divided on the peripheral side of the knot, and raised in air so as to be at right angles to the limb. One kaolin pad of a non-polarizable electrode was applied to the cut end, and another to the longitudinal surface at a distance of 1·5 cm. A pair of sheathed exciting platinum electrodes, 2 mm. apart, was then applied to the trunk of the nerve 6 cm. centrally from the nearest leading-off electrode, *i.e.* opposite the sciatic notch. The exciting stimulus was obtained by the break of the current of a single Callaud cell supplying the primary coil of a du Bois-Reymond inductorium graduated by Kronecker. The break shock produced in the secondary coil by this means was so feeble as to be barely perceptible on the tip of the tongue when the secondary coil completely covered the primary. The break was effected by the spring rheotome, which opened a fixed key at a definite point in its course. The electrometer was connected with the non-polarizable electrodes by a circuit which included the usual compensator. By means of a switch the electrometer could be cut out, and the circuit made to include a high resistance galvanometer, which also revealed the single variation. The two instruments could be thus readily compared. The excursion of the mercury of the electrometer was ascertained both by direct observation in terms of the divisions of the micrometer eye-piece, and by photographing the projected capillary upon a moving sensitive plate; in the latter case the capillary was magnified 100 times. The results of our observations are briefly as follows:—

The mammalian nerve showed a well-marked difference or demarcation current—that is to say, the electrode upon the longitudinal surface was notably positive to that on the cut end. The movement of the mercury corresponding to this difference amounted in some cases to 60 divisions of the micrometer, and was produced by an electromotive force which was estimated as from about 0·01 to 0·015 D. The passage of the single break induction shock through the platinum electrodes in either direction was followed by a small quick movement of the mercury, which was invariably in the opposite direction to that produced by the demarcation current. Its amount varied in different animals from 1 to 2·5 divisions of the micrometer eye-piece, and was photographed. After severing the nerve from the bulbo-spinal system above the exciting electrodes, the same effect was obtained; its character, as shown by the movement of the mercury, was, however, different, being as we believe much shorter in duration and less in amount. But, our experiments not being directed to the elucidation of this point, we will not speak positively with regard to it. After a time, varying in different cases from twenty minutes to three-quarters of an hour, the effect was no longer visible. We convinced ourselves that the movement we obtained and photographed was due to the electromotive change which accompanies the propagation of an excitatory state along the mammalian nerve when this state is evoked by the application of a single stimulus.

PART II. *Excitation of the Cortex Cerebri.*

A. *Mixed Spinal Nerve connected with the Electrometer.*—In two cases we have connected in the manner described in Part I. the sciatic nerve with the electrometer, and have then exposed by a small trephine opening the so-called motor cortical centre for the lower limb. This we then excited by a very weak but adequate faradic current. So far, however, we have not been able to detect any movement in the mercury, although the muscles of the investigated limb supplied by the anterior crural nerve were thrown into a state of active convulsion. It is probable that the character of the neural disturbances in the mixed nerve may be best studied by investigations which we shall shortly undertake upon the electromotive changes in the muscles.

B. *The Spinal Cord connected with the Electrometer.*—The experiments, the results of which are now to be briefly detailed, were made in the following manner:—

The spinal cord of the etherized animal (cat and monkey) was exposed in the lower dorsal region for about 4 cm., and as low down as the upper end of the lumbar enlargement. Great care was taken by bathing with warm saline to guard as much as possible against the dangers of error due to cooling and drying. The dura mater having been split longitudinally, a strong thread was passed round the spinal cord at the lower limit of the part exposed. It was tied firmly and the cord divided below the knot. By successive division of the two or three roots exposed in the intervertebral foramina, the cord was easily raised from the neural canal and suspended in the air without any great interference with the circulation in the longitudinal vessels.

One of the non-polarizable electrodes was then brought into contact with the cut end of the cord and the knotted ligature, while the other was connected with the longitudinal surface of the cord 2 cm. from the cut end by means of soft thread cables soaked in saline solution and tied loosely round the cord. In one experiment the connection was with one lateral column only. Mass movements of the electrodes upon the spinal cord were suitably guarded against, though it was found that the cord might be shaken without producing any effect in the electrometer.

On connecting these electrodes with the electrometer a considerable electromotive difference was found to exist between the contacts, the excursion of the mercury being so great, *i.e.* beyond the field of the microscope, that its amount could not be estimated in terms of the micrometer eye-piece. The cut surface was always negative to the longitudinal surface, and the amount of the difference as estimated by the compensation method was about 0·02 D. It appeared to be highest when the section passed through the dorsal region without involving the lumbar enlargement. A difference between the surfaces of the cord has been previously observed by du Bois-Reymond.

The cortex cerebri was now exposed and the exciting circuit prepared. The inductorium previously employed was again used with one Daniell cell in connection with the interrupter of primary coil and the Helmholtz side wire. The exciting electrodes had platinum points 2 mm. apart.

The demarcation current having been compensated, and the electrometer placed in connection with the non-polarizable electrodes, the motor area for the lower limb was excited. The results of the observations made upon four monkeys and several cats may be summed up as follows:—

(1) The application of the exciting electrodes to the cortex was without exception only followed by a movement in the electrometer when the area of representation of the lower limb was touched, and this even when owing to prolonged excitation of the arm area the upper limb was in violent epileptic convulsion. We found that when the exciting electrodes were moved over the surface of the brain the observer at the electrometer only gave notice of a movement in the instrument when the person exciting had crossed the margin of representation of the limbs. This shows that electromotive changes in the cord sufficient to affect our instrument occurred only when the motor area of the lower limb was excited. All error due to escape is thus set on one side, while at the same time this remarkable fact confirms the localization of function.

(2) The excitation of the motor area for the lower limb was accompanied and followed by characteristic movements of the mercury. The excitation by means of the interrupted current usually lasted for three seconds—that is, about 300 equal and alternately directed induction currents passed through the excited tissue. During this period the mercury showed an excursion opposed in direction to that of the difference between the longitudinal surface and cut end of the cord. This excursion persisted as long as the excitation lasted, and ceased when this was left off. Then after an interval of from one to three seconds there ensued a rhythmical succession of excursions each opposed

in direction to the resting difference, some apparently single and others multiple. These lasted from twenty to thirty seconds and suddenly ceased.

We have repeated this observation thirty or forty times, and feel ourselves justified in concluding that we have obtained evidence that during a cortical epileptiform discharge the electromotive changes in the spinal cord are exactly parallel as regards the character of their sequence to the convulsions of the muscles as recorded by the graphic method. It remains to be stated that after removal of the cortex we have obtained an effect in the electrometer when the corona radiata was stimulated. This effect was only present during the period of excitation, no rhythmical after effect ever being observed. Its character was prolonged, and resembled the first persistent stage referred to above.

In conclusion, we consider that, since by the method we have adopted the influence of the lumbar bulbo-spinal centres is excluded, the existence of the epileptic rhythm in the dorsal regions of the spinal cord points to its being almost entirely of cortical origin.

Physical Society, February 23.—Prof. Reinold, President, in the chair.—Dr. J. W. Waghorne read a note on the measurement of electrical resistance, showing that two resistances may be compared by joining them in series with a battery, and observing the deflections of a galvanometer connected successively with their terminals. The resistances are proportional to the currents which pass through the galvanometer in the two cases, provided they are large compared with that of the battery, or are not very different from each other. By using a rocking key, the method is rendered expeditious, and the galvanometer resistance need not be known.—On a new polarimeter, by Prof. S. P. Thompson. The author gave a *résumé* of the ordinary methods of determining the position of the plane of polarization, pointing out their advantages and disadvantages; and exhibited his new polarimeter, in which two black glass mirrors, placed at a small angle (about $2\frac{1}{2}°$), are used to polarize the light in two different planes. By using a modified Nicol as analyzer, the plane can be determined to one-tenth of a degree, when the substance examined does not absorb much light; but, for dark-coloured liquids, the author prefers to use one of his "twin prisms," described before the British Association in 1887, as polarizer, in which the planes of polarization are 90° apart. A method of dividing a polarized beam into two parts inclined at a variable angle, by means of a combination of quarter-wave plates of mica, was described, in which the two halves of the field are similarly coloured. Mr. Glazebrook considered Poynting's glass cell, with different thicknesses of active solution, a very convenient means of obtaining two beams polarized at a small angle, as, by altering the strength of the solution, the angle may be varied at will.—Prof. Thompson also read a note on the formation of a cross in certain crystal structures. Several specimens (including benzoic acid, stalactite, Eno's salt, &c.), which exhibit a radial structure, and show a cross when examined by polarized light, were thrown upon the screen, and the fact that the cross remains stationary when the specimens are rotated demonstrated. Similar effects were produced by mica sectors arranged radially, thus showing the stationary cross to be caused by the light not being analyzed in those directions.—On electrical measurement, by Prof. W. E. Ayrton, F.R.S., and Prof. J. Perry, F.R.S. In a paper on winding voltmeters, read before the Society in 1885, the authors showed, on the assumption that the thickness of insulating covering on wires was proportional to their diameter, that instruments wound with copper wire gave a less heating error than similar ones wound with German silver. Since then, platinoid has been introduced, and the electrical constants of phosphor-bronze determined. Further, a remarkably simple relation between the volts corresponding to a given deflection on a given type of instrument, and the resistance per unit length of the wire used in winding it, has been suggested by Mr. Crawley. Suppose F = number of ampere turns required to produce the deflection P, and U the half area of section and volume of the coil respectively, and d and D the diameters of the bare and covered wires, then—

$$A = \frac{F}{n},\ n = \frac{P}{D^2},\ r = \frac{4l\rho}{\pi d^2},\ \text{and}\ l = \frac{U}{D^2};$$

from these we get—

$$V = Ar = \frac{FU}{P} \cdot \frac{4\rho}{\pi d^2} = K \cdot \frac{4\rho}{\pi d^2},$$

(say) where K is a constant depending on the type of instrument. Since $\frac{4\rho}{\pi d^2}$ is the resistance per unit length, *the volts required to produce a given deflection are proportional to the resistance per unit length of the wire used, whatever be the material of the wire or thickness of the insulation.* Taking this into account, and using a more accurate value for the thickness of the covering, it is shown that the four metals above referred to arrange themselves in the following order of merit when used for high-reading voltmeters—platinoid, phosphor bronze, german silver, and copper; and for comparatively low-reading instruments, the last two change places. As a standard ammeter of great range, a circuit containing a Depretz D'Arsonval galvanometer is shunted by a wide sheet of thin platinoid, and by altering the resistance in the galvanometer circuit, the sensibility may be varied in known proportions. An instrument on this plan has been arranged to measure any current from 0·1 to 800 amperes to one-quarter per cent., and the same galvanometer in series with various resistance coils is used as a standard voltmeter of practically unlimited range. Whilst arranging these standards it has been found that the deflections are not generally proportional to the currents, and the discrepancy traced to the centre of gravity of the swinging coil not being in the line of suspension. By replacing the bottom torsion wire by a long thin spring the defect may be remedied. As relating to calibration curves of instruments, it was mentioned that in "Siemens's dynamometer" the "square law" is not correct, probably owing to distortion of the spring. Referring to "hot wire voltmeters," in which the sag of a wire heated by the current is measured by a magnifying spring, the authors remark that, in their original paper on the subject, they neglected the change of length due to change of stress in the wire, and subsequently their assistant, Mr. Bourne, found that maximum sensibility was never co-existent with minimum sag. The sag which gives maximum sensibility depends on the initial stress in the wire, and by altering the initial sag the instruments may be compensated for changes of temperature of the room. In the present paper the mathematical treatment is more rigorous, and the results are in accordance with experiment. A voltmeter intended for use with "electric welders," which deflects about 300° for 2 volts (direct or alternating), and is graduated to 1/100 of a volt, was exhibited, and used to measure the resistance of a storage cell. Dr. Thompson suggested that the want of proportionality of D'Arsonval galvanometers might be due to lateral displacement of the coil caused by the current in the torsion wires crossing a magnetic field, but from experiments with pivoted coils the authors thought this improbable.—Prof. Rücker read a note on the dimensions of electro-magnetic units, by Prof. G. F. Fitzgerald, F.R.S., which suggests that specific inductive capacity and permeability be *assumed* to be of dimensions $\left[\frac{T}{L}\right]$ (slowness); if this be done the dimensions of quantities expressed in electrostatic and electro-magnetic measure become identical. The author also states that it seems most likely that inductive capacities are related to the reciprocal of the square root of the mean energy of turbulence of the ether. Prof. Rücker remarked that in his recent paper on the subject he considered it important to retain K and μ as secondary fundamental units, and Mr. Blakesley did not concur with Prof. Fitzgerald's suggestion.—A photograph of crystal models, by Mr. R. T. Anderson, of Belfast, was exhibited at the meeting.

Chemical Society, February 21.—Mr. W. Crookes, F.R.S., in the chair.—The following papers were read:—Note on the decomposition of potassic chlorate by heat in the presence of manganic peroxide, by Prof. H. McLeod, F.R.S. The author concludes from his experiments that the reaction which ensues when potassic chlorate is heated with manganic peroxide most probably consists in the formation of potassium permanganate chlorine, and oxygen in the first instance; that the permanganate as rapidly as it is produced is decomposed by the heat into potassic manganate, manganic peroxide, and oxygen; and that the resulting potassic manganate is acted on by chlorine generated by the action of the peroxide on some fresh chlorate, forming potassic chloride, manganic peroxide, and oxygen, so that the peroxide is being continually reproduced. The quantity of chlorine evolved corresponds to only a very small proportion of the manganic peroxide present, so, if the first action really takes place, the chlorine must be absorbed and employed in converting the potassium into chloride.—The vapour-density of hydrogen

fluoride, by Prof. T. E. Thorpe, F.R.S., and Mr. F. J. Hambly. Gaseous hydrogen fluoride, on being heated from a few degrees above the boiling-point of the liquid, shows a rapid decrease in density, owing to the dissociation of H_xF_x molecules ultimately into HF molecules, the course of the dissociation being similar to that observed in the case of nitrogen peroxide and acetic acid. The density of the gas at about 32° corresponds with that required for a molecule H_2F_2, but a careful study of the molecular breaking down of the vapour as it is effected by changes of temperature and pressure shows that there is no evidence for the existence of such a molecule. At a temperature of 26°·4, the lowest temperature observed, the density of the gas corresponds with a molecular weight of 51·2 ($H_3F_3 = 60$), and from this point the process of dissociation is perfectly continuous until the temperature increases to about 60°, when the density corresponds with that of a vapour consisting wholly of HF molecules. In the discussion which followed the reading of the paper, Prof. Ramsay said that Prof. Thorpe, in speaking of the analogy of the results obtained in the case of hydrogen fluoride with those of the brothers Natanson for nitric peroxide, had pointed out that these latter afforded insufficient proof of the higher limiting value of n in the formula N_nO_{2n}; and that this limiting value was also unknown in the case of acetic acid, of which the vapour-density also increased with fall of temperature. Now there were three separate lines of argument leading to a knowledge of the higher limiting formulæ of these bodies which had been pointed out by himself and Dr. Young, and of which the data were to be found in papers published in the Philosophical Transactions, in the *Philosophical Magazine*, and in the Chemical Society's Transactions. The first of these has reference to the alteration of density of the saturated vapour with fall of temperature and corresponding fall of pressure. It is argued that the density of the vapour of a substance must necessarily, at any given temperature, be higher when the vapour is on the point of condensation than when it is unsaturated. Hence, if it can be proved that the density of the saturated vapour of bodies like nitric peroxide and acetic acid shows no signs of increasing beyond those required for the respective formulæ N_2O_4 and $C_4H_8O_4$, such formulæ must denote the limit of complexity of the molecules, in the gaseous state at least. To ascertain such a limit, Dr. Young and the speaker constructed from the Natansons' data for the relations of volume, pressure, and temperature of nitric peroxide, and their own data for the vapour-pressure of that body, isothermal curves in which pressures formed ordinates and vapour-densities abscissæ. The terminal points of such curves are characterized by rapid increase of density without rise of pressure, and, in fact, denote that the substance is no longer in the gaseous state, the vapour-pressure of the liquid having been reached. The densities of the saturated vapour therefore will correspond with the angles of union of the isothermal curves with horizontal straight lines representing condensation to liquid under vapour-pressures constant for each temperature. By joining with each other such angles of union for each temperature a curve is obtained expressing the densities of the *saturated* vapour in relation to pressure. It is evident from inspection of such a curve for acetic acid, shown in a plate in the Transactions of the Chemical Society, 1886, 806, that the line of zero-pressure would be cut at the density 60, corresponding with the formula $C_4H_8O_4$; a similar curve can be constructed from the Natansons' results and Ramsay and Young's determinations of the vapour-pressures of nitric peroxide, and this intersects the line of zero-pressure at a point corresponding with the vapour-density 92, equivalent to the formula N_2O_4. The second argument is as follows: Representing the relations of temperature and pressure of a "perfect" gas for any given constant volume, $p = c \cdot t$, where c is a constant and t absolute temperature. This is the equation to a straight line; such a line is termed an *isochoric line* or *isochor*; its point of origin for a perfect gas is absolute zero of pressure and temperature. If a different volume be chosen, the slope of the line is different. Now it is clear that if a given volume of gas contains $2n$ molecules, pressure will rise with rise of temperature at twice the rate that it would if the given volume of gas contained n molecules. Constructing for nitric peroxide and for acetic acid, on the assumption that they are perfect gases, diagrams showing the relations of pressure and temperature for the formulæ NO_2 and $C_2H_4O_2$ at such volumes that 1 gramme occupies, say, 1000 c.c. in each case, the resulting straight lines will manifestly differ in slope from those corresponding to the respective formulæ N_2O_4 and $C_4H_8O_4$, the pressure in the latter case not rising so rapidly with rise of temperature owing to the smaller number of molecules in that volume. But we know that the actual behaviour of these bodies is not that of perfect gases. The line representing the relations of pressure and temperature, should at high temperatures, when the substances exist in the molecular states NO_2 and $C_2H_4O_2$, nearly coincide with the theoretical line for these molecular states; and at low pressures and temperatures with the line denoting the molecular condition N_2O_4 and $C_4H_8O_4$. The data of actual experiment show that such is the case. The S-shaped isochoric curve trends so that it is probable that it would become tangential with that expressing the behaviour of molecules of the higher formulæ, showing no signs of cutting it as it must needs do were still more complex molecules capable of existence. The third line of argument is derived from the application of Raoult's method to a solution of nitric peroxide in acetic acid, and the results obtained show that the molecular weight corresponds closely with the formula N_2O_4.—Contributions to the chemistry of lignification: the constitution of the jute fibre substance, by Messrs. C. F. Cross and E. J. Bevan. The authors describe the results of a fuller study of the lignocelluloses (cf. Chem. Soc. Trans., 1882, 90; 1883, 18).—The atomic weight of chromium, by Mr. S. G. Rawson. The atomic weight of chromium, as determined by converting a known weight of ammonium bichromate into chromic oxide, is found to be 52·061.

Linnean Society, March 7.—Mr. Carruthers, F.R.S., President, in the chair.—Mr. J. E. Harting exhibited specimens of a South American Bat (*Noctilio leporinus*) alleged to be of piscivorous habits, and which, through the kindness of Sir William Robinson, the Governor of Trinidad, had been forwarded from that island by Prof. McCarthy, together with a Report on the subject. From this Report, it appeared that the stomach of one specimen, opened within half-an-hour after it had been shot on the evening of December 29, "contained much fish in a finely-divided and partially-digested state." In three others procured at 6 a.m. the following morning, the stomachs were empty. On the morning of December 31, at 3 a.m., numbers of these bats were observed returning to their caves: two were shot, and "both contained considerable quantities of fish." Prof. McCarthy added that in the stomachs of other specimens examined by him fish scales were undoubtedly present. Of the specimens forwarded in spirits to this country, two had been skinned and the stomachs and intestines examined by Mr. Harting. The sac-like stomach was much less muscular than might be expected in a fish-eating mammal; but in one of them (the other being empty) fragments of a finely-striated and iridescent substance resembling fish-scales were found. A discussion followed, in which Prof. Howes and Mr. W. P. Sladen took part, the conclusion being that, although there was no *a priori* improbability in the alleged piscivorous habits of this bat, it could hardly be accepted as a fact until the fragments, supposed to be of fish, were really proved to be so by careful microscopical and chemical examination.—A paper was then read by the Rev. Prof. Henslow on the vascular systems of floral organs, and their importance in the interpretation of the morphology of flowers. The author drew attention to the importance of this class of observations, as supplementing development and teratology; for, by referring all organs back to their "axial traces," their real origins could generally be discovered. Taking the words metaphorically as "floral units," he explained how they can, as it were, give rise to axes as well as to all kinds of floral appendages. Quoting Van Tieghem's definitions of axial and foliar characters, the former was shown to be subject to exceptions. After describing the arrangements of the cords in peduncles and pedicels, in which endogens often have the cords as regularly placed as in exogens, the author explained the different ways by which pedicels and umbels are formed in each class respectively. The "chorism" and union of cords were illustrated and the effects produced. Considerable light was thrown upon the cohesion and adhesion of organs, and the interpretation of the "receptacular tube" and "inferior ovary" was shown to depend upon the undifferentiated state of the organs when in congenital union. The true nature of axile and free central placentas was revealed, so that in the case of the former, with scarcely any exception, the axis takes no part in the structure, all "carpophores," "stylopods," &c., being simply the coherent and hypertrophied margins of carpels. Similarly, the free central placenta of *Primula* received its interpretation as consisting of the coherent and ovuliferous bases

of fine carpels which have the upper parts of their margins coherent in a parietal manner. Illustrative diagrams were exhibited of nearly seventy genera typical of about thirty orders. The paper was favourably criticized by Dr. D. H. Scott, Mr. A. W. Bennett, and Prof. Marshall Ward.

PARIS.

Academy of Sciences, March 11.—M. Des Cloizeaux, President, in the chair.—Fresh experiments with hydrogen peroxide and chromic acid, by M. Berthelot. In previous communications (*Comptes rendus*, vol. cviii. pp. 24 and 157) it was shown that the reactions between chromic acid and hydrogen peroxide also took place with bichromate of potassium, and that this salt has the property of gradually decomposing an unlimited quantity of hydrogen peroxide, remaining itself unchanged. This continuous reaction was attributed to the formation of an intermediate compound incessantly destroyed and renewed throughout the process of decomposition, and the experiments now described tend to confirm this phenomenon.—On the cephaloid organs in the tendons of birds, by M. Ranvier. The organs to which M. Ranvier has given the name of "cephaloid" are here fully described, and their presence determined in the domestic fowl, pigeon, and duck, but not in the lapwing. Where found they invariably present pretty much the same disposition and structure.—Actinometric observations made in 1888 at the Observatory of Montpellier by MM. Houdaille and Mazade, and reported by M. A. Crova. These observations confirm the general laws established by the records of previous years (1883-87), showing that, while the epochs of maximum and minimum intensities vary with the meteorological conditions, the great maximum always occurs in spring, and the secondary in autumn.—On the solar spots, by M. Spoerer. These remarks are made in connection with the author's recent memoir on the periodicity of the solar spots since 1618 (Hallé, 1889), in which the law anticipated by Carrington is definitely demonstrated and formulated. But although the norma for the distribution of spots in heliocentric latitude is established for many past periods, great aberrations are shown to have prevailed during the period between 1672 and 1713. After the reading of the paper, M. Faye pointed out that according to his own theory the spots depended, like the pores, not on irregular eruptions of a volcanic nature, but on the alimentation of the photosphere, an essentially stable process, or at least subject only to infinitesimally slight variations. In the general complexity of the phenomenon, the pores with the faculæ and cloudy protuberances appear to be the more stable elements, and the spots and metallic protuberances more of an accessory character.—On the value of the revolution of the right ascension screw in a meridian instrument, as determined by the observation of the equatorial or circumpolar stars, by M. G. Rayet. This inquiry shows that the determination of the value in question by observing the transit of a circumpolar is not more exact than that resulting from the observation of equatorial stars, and that when practised in the ordinary way, apart from the phenomena of refraction, it leads to systematic errors, that cannot be neglected in researches needing great accuracy.—On the automatic gauging of an artificial feeder, by M. H. Parenty. The method invented by the author, and described by him in the *Comptes rendus*, vol. civ. p. 1427, has been applied with complete success for estimating continuously and automatically the irregular discharge of the Courpalet feeder of the Orleans Canal, all efforts to calculate which had hitherto been baffled by the varying size of the cuttings, its winding course, and almost imperceptible fall.—On transformations and equilibrium in thermodynamics, by M. Gouy. The method already described in the *Comptes rendus* for February 18, 1889, leads to the use in thermodynamics of a new function, which is here described, and which appears to present the advantage of being directly connected with the consideration of cycles.—Relation between magnetic rotatory power and the transmission of luminous waves by ponderable matter, by M. A. Potier. Here an explanation is sought in the views of Fresnel of magnetic rotatory power in reference to Rowland's electromagnetic theory of light.—Employment of sulphite of sodium for developing the picture in photography, by M. Paul Poiré. Numerous experiments carried out by the author with a solution of sulphite of sodium and pyrogallic acid as a developing bath show that the best results are obtained when the sulphite is in the proportion of 25 per cent. with 1·5 gramme of pyrogallic acid added. The development is slower but more intense and clearer than when the sulphite contains carbonate, and the bath may be used repeatedly and preserved for months in corked bottles.—On the monochloracetoacetic ethers α and γ; synthesis of citric acid, by MM. A. Haller and A. Held. It has already been shown that W. James's cyanacetoacetic ether is identical with that obtained by the authors by treating sodium acetoacetic ether with cyanogen chloride. This view is here confirmed by a fresh synthesis of this cyanide, prepared by making acetyl chloride react on sodium cyanacetic ether.—Papers are contributed by MM. Ph. Barbier and J. Hilt, on australene; by M. A. Müntz, on the fertilizing properties of the Nile waters; by M. Aimé Girard, on the cultivation of the potato; by M. I. Straus, on preventive vaccination against glanders; by M. S. Arloing, on the zymotic effects of the soluble substances contained in the cultures of *Bacillus heminecrobiophilus*; and by M. A. Bottarel, on the poisoning apparatus found in certain fishes.

THURSDAY, MARCH 28, 1889.

THE NEW TRAVELLER'S GUIDE TO SCIENTIFIC INQUIRY.

Anleitung zu wissenschaftlichen Beobachtungen auf Reisen. In Einzel-Abhandlungen, herausgegeben von Dr. G. Neumayer. Second Edition, Two Volumes. (Berlin, 1888.)

"TO provide the numerous German travellers and dwellers in foreign lands with a simple introduction to scientific investigation in the various departments of natural science" was, in their own words, the object of the promoters of the present work, and this notice is an endeavour to point out, in the first place, the mode in which it has been carried out; and, in the second, to consider how far the effort has been crowned with success.

In its new shape, the book appears with a somewhat smaller size of page, and the matter is so disposed in two volumes, that the one contains the physical, and the other the biological, articles. Thirty-one collaborators have contributed as many different chapters on the various subdivisions of the subject, and, strictly speaking, each of these ought to have a detailed *critique* to itself. Considerations of space, however, forbid this mode of treatment; and hence it must suffice to enumerate the headings of the articles, and to add a few remarks explanatory of their contents in those cases where it seems advisable, premising that no disparagement is implied regarding any which are passed by without comment.

The first chapter, on "Determination of Geographical Position," by Prof. Tietjen, is eminently practical in tone; the instruments employed are briefly characterized, and instructions given for using and correcting them. The same may also be said regarding Dr. Jordan's "Topographical and Geographical Observations." We are glad to observe that both these authorities advise the traveller to depend less upon the fine graduation of his instruments than upon his ability to estimate divisions: work accomplished by the latter means is incomparably more rapid and decidedly less liable to error than that carried out by the aid of more complicated apparatus.

A most important section is that on "Geology," by Von Richthofen, of which we need only now say that it is an abstract of an independent work by the same author, which was reviewed in these columns a few months ago (NATURE, vol. xxxvii. p. 603).

Prof. H. Wild, of the Central Observatory at St. Petersburg, gives, within the compass of about thirty pages, an adequate summary of the present state of our knowledge regarding "Terrestrial Magnetism," as well as a description of an apparatus suitable for travellers, with directions for its use. Observations upon land only are here discussed, those on board ship being reserved for special treatment in the sequel. The article "Meteorology," by Dr. J. Hann, of Vienna, is commendable, amongst other things, because it informs the traveller what he need not do. A passage of this nature comes upon the traveller, overwhelmed by the multitude of minute instructions, like an oasis in the desert. Nevertheless, the directions regarding what ought to be done are none the less explicit, and the concluding observations are dictated by sound common-sense:—to use only instruments by the most trustworthy makers; to enter in the note-book the *uncorrected* observations; and not to modify, even though it were apparently to improve, a scheme of observations once commenced.

Prof. Weiss treats of the zodiacal light, meteoric showers, refraction, and other "Phenomena which can be observed without the use of Instruments"; but his disquisition seems to us of rather needless length, and the more so because, as the author himself reminds us, "the circle of observations of this kind, which promise a profitable harvest to the traveller, is becoming continually smaller."

Concise, but thoroughly scientific, is the statement of the principles and practice of "Nautical Surveying," by Dr. Hoffmann. We cordially agree, amongst other things, with the dictum that instruments which serve a variety of purposes are always to be distrusted, and that, though they may be taken by land-travellers when considerations of space and weight are paramount, they are quite inexcusable on board ship.

In three succeeding chapters the subject of "Tidal Observations" is treated by Dr. Börgen, and the "Determination of the Amount of Water flowing in Rivers" by Von Lorenz-Liburnau; whilst a very useful general sketch, entitled "Hints for the Observation of the Intercourse of Nations," is contributed by Dr. Moritz Lindeman. A short, but interesting article, entitled "Some Oceanographic Problems," which, by a strange oversight, is omitted from the table of contents, has been written by Dr. O. Krümmel, whose work on the currents of the Falkland Islands is well known, and whose little text-book has been favourably noticed in these columns (NATURE, vol. xxxv. p. 6).

The editor's own contribution to the series is of a very modest character, and consists of a series of supplements to some of the chapters above referred to, showing under what limitations, and with what special precautions, such observations must be carried out on board ship. It is subdivided into two sections, the first of which is hydrographic in its scope, and handles some very interesting topics; for instance, the action of the wind upon the sea, the application of meteorology to navigation, materials carried by currents, and so forth. These are treated with great care and precision; and, as an instance of the way in which the whole is brought up to date, it may be mentioned that the Hon. Ralph Abercromby's invaluable photographic work upon clouds, though only published very shortly before the present volume, is duly noticed. The second subdivision is devoted to magnetic observations, and deals fully with the mode of making these on board ship, and also of determining the appropriate coefficients for their correction.

In the new edition this concludes the physical division of the work, for the chapter on "Earthquakes" has been omitted, on the ground that seismology has now developed into such a special and complex study that the traveller cannot be expected to undertake it. What is essential for him to know on this head has been incorporated in the chapter on "Geology."

The biological volume opens with an introductory essay by Dr. A. Meitzen, headed "General Topography, Political Geography, and Statistics," the bulk of which is

cast in a catechetical mould, furnishing useful hints to the traveller as to the best arrangement of his queries so as to elicit materials for a complete account of a country or district. Dr. A. Gärtner's chapter, on the anatomical, physiological, and medical investigations which may be undertaken by those practitioners who have the opportunity, is much to be commended for its conciseness and completeness. We should like to see it reprinted, and a separate copy placed in the hands of every military and naval surgeon. Agriculture receives the full share of treatment to which it is entitled. Prof. Orth, of Berlin, deals with the subject in general, with special reference to the composition of soils, whilst cultivated plants are separately handled by Dr. L. Wittmack.

The "Geographical Distribution of Plants" is discussed by Dr. O. Drude, upon the same limes as were adopted by Grisebach in the first edition of the work. Fifteen floral regions are recognized, grouped under six larger divisions, and the classification of plants, according to their general biological relationships, is reproduced with certain modifications. The "Geographical Distribution of the Sea-grasses" (which name is here restricted to the marine Phanerogams) is very fully set forth by Dr. Ascherson, all the species being enumerated and defined. The important topic of the modes of "Collecting and Preserving Plants of higher rank (Phanerogams)" has been committed to no less an authority than Dr. G. Schweinfurth. His mode of arranging the matter of his contribution in short numbered paragraphs makes it easy of reference, and the style is a model of terseness and perspicacity. The use of a portfolio in collecting is recommended, instead of the usual vasculum; and the relative merits of preservation in spirit, or by drying and pressing, are carefully considered, the preference being given (rightly, we think) to the former. The three sections just enumerated complete the botanical part of the work, which seems to us in its general arrangement the least satisfactory part of the whole. That such an insignificant group as the marine Phanerogams should have the same number of pages allotted to it as are given to all the rest of the higher plants, whilst the Cryptogams are entirely unnoticed, is hardly in accordance with the relative importance of these different classes of plants.

The editor of the volumes has not forgotten that "the proper study of mankind is man," for no less than four chapters, by as many different authors, treat of the investigation of the phenomena presented by the genus *Homo*. Dr. A. Bastian opens the series byan interesting dissertation upon "The General Scope of Ethnology," wherein a list is drawn up of eighteen different environmental factors, physical and biological, and a number of suggestive remarks are added upon each of them. The difficult subject of "Linguistic Inquiry" is next fully discussed by Dr. Steinthal, and that of "Numeration" by Dr. H. Schubert; whilst from the veteran pen of Prof. Rudolph Virchow, we have a masterly essay upon "Anthropology and Prehistoric Investigation," which is equally remarkable for its attention to practical details and its philosophic co-ordination of results.

The seven succeeding sections are devoted to instructions for the collection and preservation of various forms of animal life. The "Mammalia" have been undertaken by Dr. Hartmann. That this contribution is the work of an expert is obvious from numerous minutiæ, as, for example, when he warns the traveller, in a footnote, not to wear metal or mother-of-pearl buttons, or he will be continually annoyed by the natives begging for them. But though the matter is good, we cannot commend the style of this article: it is too verbose for a work of this character, and not only does the author perpetrate some choice examples of German prose composition, but his enthusiasm at times leads him into descriptive passages of tropical life and scenery. A welcome novelty in this edition is a chapter specially devoted to the "Cetacea," by Dr. H. Bolau, in which we notice with satisfaction that the desiderata of our museums are specially recorded. Dr. Hartlaub's treatment of the "Birds" is very full, and bristles with apt quotations from various authors: one, from the pages of Darwin's "Journal," might very appropriately stand at the head of the whole biological section of the present work: "It is better to send home a few things well preserved than a multitude in bad condition."

The section upon the "Collection of Reptiles, Batrachia, and Fishes," by Dr. Günther, of the British Museum, is quite a model of the way in which work of this kind should be done. The instructions are full and clear, but yet concise, and no extraneous matter is inserted. The "Mollusca," "Marine Invertebrata," and "Arthropoda" are communicated respectively by Dr. Ed. von Martens, Prof. Möbius, and Dr. Gerstaecker, whose names are a sufficient guarantee for the scientific value of the work they have undertaken. The practical nature of the articles, moreover, seems quite on a level with their zoological merit.

Dr. Gustav Fritsch completes the volume by a brief treatise upon two very important subjects—the microscope and photography. This latter has, owing to the perfection of the dry-plate methods, become so easy of practice that no scientific expedition is completely furnished without a photographic outfit; and it is satisfactory to see its various uses brought prominently forward in a work of this kind. Special attention may be called to the mode of recording the topographical features of a country by means of panoramic photographs taken from properly selected points of view, and to its peculiar advantages for the collection of anthropological data.

The editor is to be congratulated on the manner in which his task has been carried out. We have noticed a few, but not many, misprints uncorrected in the errata: "Du Petit-Thonars," for instance, appears in the same place in both editions. Compared with previous works of the same kind, this one is beyond comparison the fullest and most detailed: it contains, for example, about three times as many pages, and these more closely printed, than our own "Admiralty Manual of Scientific Inquiry," so that as regards quantity of information the two works are hardly to be placed in the same category. This, however, may not be altogether advantageous, since the German work, if read by an intending traveller, might not improbably deter him from any inquiries by seeming to exact too much. The English book might be termed a practical hand-book of the subject, whilst the German one is an encyclopædia. In our opinion it would best aid the objects it has in view by being published in the form of small separate works, and we should like to see it adapted into a series of such in the English language. W. E. H.

PLANT LIFE.

Pflanzenleben. Von Anton Kerner von Marilaun. Erster Band. Gestalt und Leben der Pflanze. (Leipzig, 1887.)

THIS is a book which deserves the warmest welcome from all lovers of plants. To give a general and at the same time a full and accurate survey of the natural history of plants, is at the present time a task of immense difficulty, and one which very few botanists could undertake with any hope of success. The task is daily becoming more difficult, as new additions are made to the already huge accumulation of facts, while its efficient performance is now a matter of more importance than ever, if botany is to be saved from becoming a close science, for specialists only. It may be said at once that the author has done his work with remarkable success. The book is a large one; only the first volume is before us, and this contains 734 large octavo pages. Yet it is scarcely an exaggeration to say that there is not a dull page from beginning to end of the bulky volume. On the other hand, inaccuracies are met with here and there, and some of these are serious, but the general excellence of the book is but little affected by these faults.

Before entering on a fuller account of the text, we must say a word about the illustrations, which are among the greatest merits of the book. In the text are 553 figures, many of which are pictures of great beauty. In addition to these there are twenty coloured plates, the first of which is histological, while all the rest represent various aspects of vegetation, both terrestrial and aquatic, in different parts of the world. Many of these plates are accompanied by an outline tracing of the individual plants shown, each figure on the tracing bearing a reference number, while the names are given below. This is an excellent plan (already frequently employed by French zoologists), and adds much to the practical value of the plates.

We will endeavour to give some idea of the plan of the work so far as it extends at present, but only a very cursory view will be possible. The present volume may be said to deal with general organography and physiology, especially of the vegetative organs. Comparatively little space is given to the organs of reproduction, which will no doubt receive full attention in the second volume, dealing with special morphology.

The introduction is headed, "The Investigation of the Vegetable World in Ancient and Modern Times." It contains a general view of the history of the science. This is very well done, and is calculated to rouse the interest of the reader.

Chapter I. is on the living substance of plants ("Das Lebendige in der Pflanze"), and may be described as an outline sketch of histology. The discovery of the cellular structure of plants by the naturalists of the seventeenth century is first narrated, and some of Nehemiah Grew's classical figures are here reproduced. Protoplasm and its movements next receive attention, and in this section there is some room for criticism. Thus the well-known motile granules of Closterium are wrongly described as being embedded in the protoplasm (p. 34), and the difficult question of the movements of Diatoms will scarcely find its solution in the theory here advocated, according to which Diatoms move in much the same way as mussels! In the following section the nucleus and chlorophyll-bodies are treated too much as if they were of the nature of secretions from the protoplasm, like oil-drops or crystals, whereas in all cases of which we have any definite knowledge they originate solely by the division of pre-existing bodies of the same kind. Probably, as regards the chlorophyll-corpuscles, the author wrote under the influence of the somewhat doubtful observations of Mikosch. The division of the nucleus is described by the author later on in the volume, but it would have been well to lay more stress on the process in this place. The remarks on the continuity of protoplasm through the cell-wall are acute and interesting, but it is rashly assumed, in opposition to the most trustworthy investigations on sieve-tubes, that this continuity exists from the first origin of the cell-wall. The author's attempt to identify the intercellular protoplasmic threads with the achromatin fibrils formed during cell-division is equally open to criticism.

The second chapter (pp. 51–246) deals with the absorption of food. This is a striking chapter, and presents in a very attractive manner a part of the science which is too often made to appear excessively dry. Attention may be called to one or two especially good sections, such as those on the nutrition of water-plants and of "stone-plants." The remarks on the correlation between the position of the leaves and the distribution of the roots, as affecting the water-supply of the plant, are of great interest, and are illustrated by excellent figures (pp. 85–92). Saprophytes, insectivorous plants, and parasites are all fully and vividly described. As regards the parasites especially, the account here given is the best general one with which we are acquainted, and the illustrations are as good as the text. Lathræa is reckoned among insectivorous plants as well as among parasites, and the author's peculiar theory as to the nutrition of this plant by means of alleged protoplasmic fibrils projecting from the surface of its glandular hairs, is again brought forward (p. 128). This view must now be regarded as more than doubtful. The section on the absorption of water (pp. 199–223), is perhaps the least satisfactory in the book. The most heterogeneous organs, extra-floral nectaries and chalk-glands among the rest, are classed, on the slightest possible grounds, among organs for the absorption of water, and thus their true functions come to be overlooked. It is difficult to understand how so forced and fanciful a theory can be maintained by any good observer. The short section on symbiosis is clear and satisfactory, and Frank's views on the vexed "Mycorrhiza" question are well put forward.

Chapter III. (pp. 247–343) is on the conduction of food. Root-pressure, transpiration, and the ascent of water through the wood are well discussed, Godlewski's views on the last-mentioned subject being provisionally adopted. The whole question is treated as clearly as is possible, in the present state of our knowledge, in a popular book. The detailed account of the structure of leaves as affecting transpiration is particularly good, and the illustrations here deserve the highest praise. The concluding sections of this chapter are concerned with the fall of the leaf, the relation of transpiring surface to water-conducting tissues, and the conduction of gaseous food-substances.

The subject of Chapter IV. (pp. 344–420) is the formation of organic substances from absorbed inorganic food. Assimilation (in the narrower sense) is fairly described, but the view taken of the action of light on the process has been, perhaps, too much influenced by Pringsheim's "screen-theory" of chlorophyll. Pages 380–393 contain an excellent series of figures to illustrate what is termed "leaf-mosaic," or the relation of the form to the arrangement of leaves, as insuring the exposure of the maximum surface to light. At the end of the chapter the adaptations by means of which assimilating leaves are protected against the attacks of animals are well described.

Chapter V. (pp. 421–475) treats of the metabolism and translocation of food-substances ("Wandlung und Wanderung der Stoffe"). The chapter begins with a few remarks on some of the characteristics of carbon compounds. The usefulness of such a very concise treatment of so vast a subject may be doubted, but the account appears to be good, so far as it goes.

The question of the first product of assimilation in green plants is clearly treated, and then the chief organic substances occurring in plants are described. Under the head of the translocation of food-substances, the structure of the phloëm and of laticiferous tissue is explained, and the anatomical anomalies of climbing plants are shortly described from this point of view. The figures given to illustrate the last-mentioned peculiarities of structure are, as so often happens in such cases, diagrammatic and unsatisfactory. The important subjects of respiration and fermentation are also included in this chapter, and the relation between these two processes is clearly brought out.

In the sixth chapter (pp. 476–544) the growth and construction of the plant are treated of. Under the former head we have an exposition of the mechanics of growth, and of the influence upon it of light and heat. The second part of the chapter includes an account of cell-formation. This section, unlike the rest of the book, seems to us insufficiently illustrated. Nuclear division is represented in a few figures taken from Guignard, but the subject is not treated with any completeness.

Chapter VII. (pp. 545–734), the last in the volume, is devoted to general organography ("Die Pflanzengestalten als vollendete Bauwerke.") The transition from unicellular plants to the most complex forms is first rapidly traced. Then we have sections dealing very fully with the modifications of the leaf, the stem, and the root respectively. In the first of these sections there is an especially good account of the cotyledons, and many interesting facts about germination are described. The section on leaves ends with a short account of the morphology of the flower. It is to be regretted that the author, after severely criticizing the artificial character of some former explanations of the morphology of the ovule, himself makes a laboured attempt to prove that the ovule is always homologous with a leaf or portion of a leaf (p. 603).

As regards the organography of the stem, special attention may be called to the excellent account of the stems of "lianes" (pp. 629–669), and to the clear explanation (founded on Schwendener) of the mechanical construction of upright stems. Here, however, as is usual in such explanations, the thickened stems of Dicotyledons scarcely receive their due share of attention. Under the heading "Hochblattstamm," the special forms of branching characteristic of inflorescences are explained.

The last section is on the construction of the root, and on its movements in response to external stimuli. Full justice is done to this very interesting subject, and the author is quite justified in emphasizing the unsatisfactory nature of those crudely mechanical explanations of these phenomena which are so often given in physiological treatises.

In the rapid survey we have taken it has been difficult to give a correct impression of the volume as a whole. It has been necessary to notice several defects, which have inevitably become more prominent in our review than they are in the book itself. The work is written throughout in a good clear style, and if the concluding portion fulfils the promise of the first volume, the treatise may certainly claim to rank as the best account of the vegetable kingdom, for general readers, which has yet been produced.

D. H. S.

PRACTICAL ELECTRICAL MEASUREMENTS.

Practical Electrical Measurements. By James Swinburne. (London: H. Alabaster, Gatehouse, and Co., 1888.)

THIS is a suggestive little book; and the pity is that the idea of the author, in writing the articles of which it is practically a reprint, has not been a great deal better carried out. The articles were evidently poor in style and excessively incomplete, even taken as newspaper articles; and, when put together in a consecutive form, the "nakedness of the land" becomes too painfully apparent. As it stands, the book consists mainly of remarks on almost every form of instrument known in electric lighting. It has no pretence to be a complete treatise, even of an elementary kind, on practical electrical measurements in general. Many of the most important branches of electric measurement are not even mentioned. What we do find is, partial descriptions of a multitude of instruments and machines, and a good deal of criticism, not always in good taste, and often pretty wide of the mark, of these instruments, and of the ideas of other "engineers."

The author commenced by setting himself the nearly impossible task of writing articles on electric measurement without the use of mathematical symbols. "The pedantic fashion," he says, "of dragging mathematical symbols into all electrical literature, and the respect commanded by an analytical investigation, even on false data, often lead writers to mar work otherwise good, by getting out of their mathematical depths, and writing nonsense to look learned." This, which is not unlike a good deal of the criticism throughout the book, sounds rather like putting on grandfather's spectacles to look sage; but, supposing that others do drag in more mathematical symbols than are absolutely necessary, it seems rather extreme to punish oneself by thrusting them aside altogether. To give really useful information as to the employment of electrical measuring instruments without quoting the formulas which are necessary in connection with them and with their errors and corrections seems to us to be leaving out the very crown of the whole; and as to the "respect commanded by an analytical investigation"

founded on false data, we trust it could never become a temptation to our present author.

But besides the difficulty of writing on electrical measurement without mathematics, there is, in our opinion, an attempt to catalogue and describe far too great a number of instruments and methods. In making this criticism, we cannot support it by mentioning names; but the author knows well, and everyone else knows, that many of the instruments and methods to which space is devoted are absolutely worthless; and it would be infinitely better to omit them, and thus both avoid confusion and save space, which might well be given to those that are of importance.

Altogether, the book requires re-writing, by which it could undoubtedly be made of very considerable value. The style is not good. With a sort of self-consciousness, Mr. Swinburne calls himself "the writer" throughout. Some of the criticisms—for example, that on the "B. A. Committee" (p. 22), and a remark on one of our most highly-valued scientific men (p. 110)—are altogether out of taste, coming from the pen of one who has his reputation still to win.

OUR BOOK SHELF.

Galileo and his Judges. By F. R. Wegg-Prosser. (London: Chapman and Hall, 1889.)

THIS work is a temperate discussion of the vexed question of the treatment of Galileo by the Pope and the Congregation of the Inquisition. The facts are not new; Mr. Prosser puts himself unreservedly in the hands of M. Henri de l'Epinois, whose article in *La Revue des Questions Historiques* is well known, and who has, Mr. Prosser says, gone to the trouble of consulting at first hand all the documents that could be found at the Vatican bearing on the subject. Mr. Prosser, in drawing his conclusions from the facts, adopts a kind of middle ground. He is a Catholic, and though he is too sensible a man to follow many of the Catholic writers in their conclusions, yet he seems to be shocked at the standpoint taken by a few of the Catholic writers who have condemned the treatment of Galileo. Thus he occupies a position between keen controversialists like the late Dr. Ward, on the one hand, who hold that not only did the Congregations act within their rights and their legitimate sphere, but that, looked at from the point of view of the early part of the seventeenth century, they acted wisely and prudently, and Catholic writers like Dr. Mivart, on the other hand, who assert (these are Mr. Prosser's words) "that the Church has no authority to interfere in matters relating to physical science, and that the issue in the Galileo case has proved the fallacy of her attempting to do so; that without entering into the discussion of what ought or what ought not to have been done in former times, we of the present generation have evidence sufficient to show us that scientific investigations should by right be free from the control of ecclesiastical authority." The first step taken by the Church against Galileo was in 1616, in censuring him for his teaching, and warning him of the consequences if he continued to teach the doctrines, first, that the sun was the centre of the universe, and therefore locally immovable; second, that the earth was not the centre of the world, and moved round itself diurnally. The first doctrine was declared by the Qualifiers—that is, the committee appointed from the Congregation of the Inquisition—to be foolish and absurd from a philosophical point of view, and heretical since it contradicted the meaning which had been given to certain passages of Scripture by the Church. Galileo promised to obey the warning, "*ut supra dictam opinionem . . . omnino relinquat, nec eam de cetero quovis modo doceat teneat aut defendat verbo aut scriptis.*" Mr. Prosser enters into a very long argument to show that this decree of 1616, though founded on reasons of doctrine, was merely disciplinary, and not given on a matter *de fide*, in which he is now and then rather casuistical. Galileo after this remained in peace till he was summoned to Rome to answer for the printing and publishing of his "Dialogue" in 1632. The heads of accusation are set out at length in the present work, but substantially they come to this, that he had disobeyed the order of 1616, and had continued to teach the same doctrines as those for which he was then reprimanded. It is impossible not to see that in summoning him to Rome the Pope was to some extent actuated by feelings of pique, for the fool of the "Dialogue," Simplicio, undoubtedly represents His Holiness. Mr. Prosser goes on to show that, having regard to the state of knowledge at the time, the Inquisition could have done nothing else but convict Galileo. The defence of the latter was threefold. In the first place, he said that Bellarmine had informed him that he might hold the Copernican doctrine as an hypothesis. This was undoubtedly the case; but it appears as something more than an hypothesis in the "Dialogue." Galileo answers to this that he had merely put the theory in the mouth of a speaker whose teachings were combated by the other speakers. Secondly, he maintained that he had not contravened the order given to him not to teach or expound that abominable doctrine in any way. This is hardly correct, as the "Dialogue" will show. Thirdly, he declared that he did not remember having been forbidden to teach it. But he could hardly have forgotten the terms of the order of 1616, which have been quoted above, nor the rebuke given him by Bellarmine by order of the Pope.

Observations on the Embryology of Insects and Arachnids. By Adam Todd Bruce, B.A. of Princeton College, Ph.D. of Johns Hopkins University. A Memorial Volume. (1887.)

THE subject-matter of this volume formed the thesis submitted by the author when he presented himself for the degree of Ph.D. at the Johns Hopkins University. After his lamented death, in 1887, the thesis was reprinted, exactly as he wrote it, as a memorial volume. He had made many additions to the work which is here recorded, but as the notes were unaccompanied by drawings it was impossible to make use of them. An account of the life and scientific work of the author is written by Prof. W. K. Brooks. The early death of Dr. Bruce, at the age of twenty-seven, prevented any very extensive amount of scientific research. It will, however, be clear to any reader of the careful and excellent work contained in this paper, that American biological science has lost an investigator of the very highest promise. Dr. Bruce had also very carefully studied, in conjunction with Prof. Brooks, the early stages of the development of Limulus, and it is much to be hoped that these results may be published at no distant date. A thorough study of the earliest stages of this most interesting form by so careful an embryologist would be extremely valuable. Prof. Brooks informs us that the work included "the segmentation of the egg, the formation of the blastoderm and of the germ-layers, and the anatomy of the young larva . . . illustrated by nearly a hundred drawings." I mention this in the hope that some means of publication may be found in this country, if the claims upon the space of the *American Journal of Morphology* are too great to admit of the appearance of a paper on so important a subject in what appears to be its appropriate position.

The volume contains an attempt to settle the most difficult questions concerning the earlier stages of the development of spiders, Lepidoptera, Coleoptera, and Orthoptera, while less complete observations were made

upon Neuroptera and Diptera. Among insects, the Lepidoptera were studied with especial care, the type selected being *Thyridopteryx ephemeraiformis*. The careful account of this embryology, together with the numerous excellent figures, entirely substantiate the author's claim that the study of this type, "if it has brought to light nothing new, has, in the opinion of the writer at least, settled some important points connected with the embryology of this group of insects." In the account of segmentation and the formation of the blastoderm, the author completely confirms Bobretzky's descriptions. The development of *Thyridopteryx* occupies twelve quarto pages: for the details the original must be consulted. The account of the embryology of Orthoptera, represented by *Mantis* and the grasshopper, and of the embryology of spiders, is also very complete.

At the end of the paper many interesting and suggestive conclusions are appended. Among these it is significant that a writer who has done so much work upon the early stages of Limulus should unhesitatingly regard this latter form as an Arachnid. The Trilobites he considers as "possibly the ancestral form of Limulus."

Only a short account of this excellent paper has been given here. All those interested in embryology, and the light shed by it upon morphological science, will, of course, make a careful study of this work. E. B. P.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Satellite of Procyon.

IT is well-known that Procyon, like Sirius, does not travel through space in a straight line, its motion undergoing changes similar to those which would result from the disturbing action of a large satellite. This explanation was advanced by Bessel in 1844, and though the satellite has not yet been *seen*, its existence has been placed beyond reasonable doubt by Dr. Auwers's investigations on the subject.

Does it not seem probable that this interesting body may be revealed by the aid of photography? It is now possible to photograph stars and nebulæ which are beyond the visual range of the most powerful telescopes; and if the companion of Procyon, like that of Sirius, be self-luminous, there would seem to be a good prospect of obtaining its image on the sensitive plate.

As the companion is doubtless in pretty close proximity to its brilliant primary, it will be necessary, for photographic purposes, to intercept the image of the latter by means of a suitable screen. Since the *direction* of the satellite at any time can be found from Dr. Auwers's elements,[1] there would be no uncertainty as to the position in which this eclipsing disk (or wire) ought to be placed, though its proper adjustment would be a somewhat delicate operation. Should the satellite be photographed, its position will become known from its configuration with respect to other stars recorded on the negative.

If a very large telescope were employed, the images of both components, as distinct and separate dots, might be obtained on the plate. For Procyon, a very short exposure would be requisite, and this could be secured by the use of a movable stop or screen, similar to that devised by Prof. Pritchard, and used for parallax work at the Oxford University Observatory.

It is scarcely necessary to dilate upon the interest which would attach to a photograph showing Procyon's companion. As the parallax of Procyon has been satisfactorily determined by Dr. Elkin and others—being 0″·266 according to the Yale College observations—we could ascertain the *actual* as well as the *relative* masses of the two components. And the brightness, or more strictly speaking the photographic magnitude, of the satellite might also be determined with some precision.

[1] At present the position-angle of the satellite is *about* 233°. Its *distance* probably amounts to but a few seconds of arc, and may be within 2″.

It may not be too late to obtain such results during the present season, but exposures of four or five hours, under good conditions, will not be practicable before next winter.

J. M. BARR.

St. Catharine's, Ontario, Canada, March 4.

"Les Tremblements de Terre."

THE issue of NATURE for February 7 (p. 337) contains a review of the little work on earthquakes published for me by Messrs. J. B. Baillière. The anonymous author of the article makes several criticisms on my book to which I desire to reply.

Your critic thinks it a grave fault not to have entered into a detailed description of the seismographs and seismometers at present in use. He reproaches me in particular for having but just mentioned Prof. Ewing's duplex pendulum seismograph; for having omitted to speak of the same inventor's horizontal pendulum seismograph; and especially for seeming to ignore the experiments made with these instruments by Prof. Ewing in Japan. I confess that I had not been struck by the excellence of the instruments in question, and that it was not through an oversight that I omitted to describe Prof. Ewing's observations in Japan, while I quoted in detail those of his *confrères*, Messrs. Milne and Gray, in the same country.

Your critic defends with some acerbity a certain class of seismographs, and wrongly accuses me of failing to appreciate the principles on which their construction is based. The objections which he makes to my treatment of M. Cavalleri's pendulums of unequal length are entirely refuted from a theoretical point of view by the learned note due to M. Poincaré, which is inserted on p. 46 of my book. I need not insist further on this point.

Your critic thinks I have not done sufficient justice to the work of the Italian *savants:* he forgets the limits necessarily imposed on a book destined especially to give to the general public an idea of the present state of an important question.

The writer of the article regards the seismographs of to-day as perfectly sufficient for all scientific needs. I am far from being the only person engaged in the study of earthquakes who does not share this opinion. Finally, he describes, and not very clearly, the experiments which I made with M. Michel Lévy to measure the rate of propagation of disturbances through the soil, and the registering apparatus designed for this purpose. According to the writer, these experiments constitute the only advances we have made in the study of earthquakes. If he had rendered justice to our work on the subject, we should have been content, and I should have raised no objections to his article. But your critic reproaches us with having given results which are masked by inevitable causes of error. A more careful study of the book, and especially of the extracts from our original memoir, published in the *Comptes rendus* for 1885 and 1886, would have preserved him from so inexact an assertion. In fact, he unjustifiably mixes up the *preliminary* experiments, made at Le Creusot by means of an apparatus exactly similar to that used by Mallet and Abbott,[1] with what really constitutes the basis of our work—I mean the determinations made with the aid of photographic registration and explosives. What your critic calls the "personal equation" of the instrument is here nearly negligible[2]; and the merit of our method lies precisely in this point, which distinguishes us from our predecessors.

We would beg the readers of NATURE to verify for themselves the truth of our statement. This verification will enable them to judge of the value of the article laid before them.

F. FOUQUÉ.

Finding Factors.

IT may add interest to Mr. Busk's ingenious method of distinguishing between prime and composite numbers to state the algebraic basis on which it rests.

Let N be any number, and n^2 the next higher square number, and let $N = n^2 - r_0 = (n+1)^2 - r_1 = (n+2)^2 - r_2 =$ &c. r_1, r_2 are formed successively from r_0 by the successive additions of $2n+1$, $2n+3$, . . . the increments being in arithmetic progression, so that $r_m = r_0 + 2mn + m^2$. As soon as r_m becomes a square, N is expressed as the difference of two squares, and its factors are found.

[1] See p. 219 *et seq.*

[2] The only subsisting cause of error is that due to the inertia of the mercury, which we have estimated and introduced into all our calculations (see p. 246).

If N is prime, it is expressible as the difference of two squares in only one way, viz. $\{\frac{1}{2}(N + 1)\}^2 - \{\frac{1}{2}(N - 1)\}^2$. To prove that N is prime by this method, the number of additions required is $\frac{1}{2}(N + 1) - n$, which is $\frac{1}{2}\{(n - 1)^2 - r_0\}$.

It may be noticed that when $n + m$ and r_m have a common measure, it must be a factor of N, and the additions need be continued no further.

For example, $N = 8131$, $n^2 = 8281$.

$$\begin{array}{rr}
n = 91 & r_0 = 150 \\
 & 183 \\
\cline{2-2}
n + 1 = 92 & r_1 = 133 \\
 & 185 \\
\cline{2-2}
n + 2 = 93 & r_2 = 518 \\
 & 187 \\
\cline{2-2}
n + 3 = 94 & r_3 = 705
\end{array}$$

94 and 705 have a common measure, 47; therefore 8131 is is divisible by 47, and the other factor is then found to be 173.

Mr. Busk's method of shortening, exemplified on p. 414 by his proof that $73 = 37^2 - 36^2$, depends upon the following:

Let $r_0 + 2mn + m^2 = (k + m)^2$, then $m = \frac{1}{2}(k^2 - r_0)/(n - k)$: since $k^2 - r_0$ is even, k is even or odd according as r_0 is even or odd; it is necessary only to try values of k descending by differences of 2; the greatest possible number of operations is $\frac{1}{2}(n - 1 - k_0)$, when k_0 is the value of k, with which we begin.

The process may conveniently be arranged as in the following example:

Let $N = 6667$, $n^2 = 6724 = 82^2$, $r_0 = 57$.

k		$82 - k$		$\frac{1}{2}(k^2 - 57)$		Quotient.
15	...	67	...	84	...	a fraction
				32		
17	...	65	...	116	...	,,
				36		
19	...	63	...	152	...	,,
				40		
21	...	61	...	192	...	,,
				44		
23	...	59	...	236	...	4

therefore $6667 = (82 + 4)^2 - (23 + 4)^2 = 113 \times 59$.

If N is composite, this method is not always shorter than the former. It will be shorter whenever $2m > k - k_0$, but it is not easy to see how to determine *a priori* whether this is the case.

The method by decreasing squares is not one of general application. For instance, the factors of 323,171 cannot so be found. It is the difference of two squares, each more than ten times as large as the first square used.

W. H. H. HUDSON.

King's College, London, March 15.

Dolomedes fimbriatus, Clerck, at Killarney.

IT may interest some of your readers to know that this rare and fine aquatic spider occurs on Cromaglaun Mountain, near Killarney Lakes. I first found it when collecting the little shell, *Limnæus involutus*, and though I had it two or three times in my hand, it was so active that it escaped, and I, not knowing its powers of diving, never thought of looking for it under water. The following year I again visited the little lake, which is called Crincaum, with some friends, and this time we fairly captured the spider, which I then easily identified as *Dolomedes fimbriatus*. There is a good account of it in Blackwall's "British Spiders," and also in Andrew Murray's "Economic Entomology—*Aptera*," but I am not aware that it had been observed in Ireland before I found it.

March 18.

BEECH-WOOD.

IT is so characteristic of the science of to-day to find specialists narrowing their field of research, and confining their investigations to a deep narrow channel, that no surprise can be felt that two able men should devote their energies for two years to the examination of the biology and chemistry of the wood of a single tree. It is not so easy to avoid astonishment at the results of the two years' work, however, appearing as they do in the form of a large book[1] of 238 pages of close description and argument, interspersed with long tables of figures, abounding in interesting information when properly read.

The authors have divided their work very fairly, the botanist having set himself the task of elucidating in detail the histology of the wood, the distribution of water, starch, and other contents, the formation of annual rings, and the growth in thickness of the trunk, and a number of other problems throwing light on the growth of the beech in the forest; while the chemist has confined himself to the task of analyzing the timber, so as to discover (1) the quantities of total ash, water, nitrogen, &c., in different parts of the tree; (2) the percentage composition of the ash, and the manner of distribution of the individual constituents; (3) the absolute quantities of each ash-constituent in 1000 parts, and other chosen quantities of dry substance of the wood; (4) the annual in-take and out-put of these constituents on a hectare of beech forest; and (5) similar particulars for the nitrogenous constituents.

The authors have by no means spared their trees. It is enough to make one envious to read of the trees cut down at all ages from 15 to 150 years, and of the specimens selected at all heights from each; how the research was extended to good, bad, and indifferent soils, and how trees in shade and in the open, trees entire and trees pruned, &c., were all laid under contribution as required. More than 100 stems of all ages were thus employed.

The manner of utilizing this enormous mass of material is worth noticing, for every kind of determination was made that would yield practical information.

The height of the trees was found, as the best indication of the value of the situation; the number of stems on a given area, their surface, contents, &c., were also determined; the age of the trees, their physiological condition, &c., were all considered in due course. The selected stems were then cut up as follows: transverse disks were cut at the successive heights of 1·3, 5·5, 10·7, 15·9, 21·1, and 26·3 metres, and separate determinations made of the specific gravity, histological peculiarities, analysis, &c., and these not only for wood and cortex separately, but also for each 30 annual rings of the stem. The thickness, density, &c., of the annual rings were also tabulated, and attention paid to north, south, east, and west sides of the stem.

Not only are all these data given in detail in the tables, but other tables are provided showing the mean densities, cubic contents, &c., &c., of whole trees, or of the trees on given areas; and the patient compilation and ingenious methods here displayed reflect the greatest credit on the authors. It is, in fact, especially in the application of their measurements, &c., to the forest as a whole that the tables will find their greatest practical value. There is also much of more abstract scientific interest to be learnt from the results.

On examining the histology of the wood, several new facts were discovered. The curious dipping in of the annual rings where they cross the broader medullary rays, and the deposits of grains of calcium carbonate on the septa of the vessels, may be mentioned by the way; but the most important results are those relating to the length of the elements, the lumina of the vessels, and the relative numbers and distribution of the latter on a square millimetre of transverse section.

The wood of the beech consists of the usual elements—vessels, tracheides, libriform fibres, and wood parenchyma, with transitional elements difficult to classify under any one of these heads. As was long ago pointed out by

[1] "Das Holz der Rothbuche," by Profs. R. Hartig and R. Weber. (Berlin: Springer, 1888.)

Theodore Hartig, Sanio, and others, the length and breadth of the various elements differ in different parts of certain trees. Prof. R. Hartig has now worked out this subject in the beech for the first time, giving long lists of measurements at various heights, ages, &c., as before.

The recent vessel-segments, tracheides, and fibres in a five-year-old beech-tree are only half as long as those in a tree 120 years old, and this occurs in what at first sight appears a very curious and inexplicable manner.

The length of these organs at first rapidly increases, until the tree is about 60 years old; then they either no longer show increase in length, or do so very slowly, till the tree is about 120 years old. They then exhibit their maximum length. Henceforward the elements formed are shorter each year, and much so if the tree is growing free in the open.

Moreover, in the same tree, the longest elements occur at the base of the trunk, and shorter and shorter ones occur up to a height of about 5·5 metres; then the tracheides and vessel-segments are found to be longer again, until the height of 15·9 metres is attained. The lengths are much less in the crown. The libriform fibres decrease regularly in length all the way up.

Hence, put generally, the elements are short in young trees and in the upper (*i.e.* youngest) parts of older ones; their lengths increase afterwards year by year, but after 120 years only shorter and shorter elements are again found.

The lumina of the vessels also vary with the age of the tree and with the height of the part. Taking, for example, the vessels at a height of 1·3 metres, the average diameter is 0·05 millimetre during the first 30 years, but between 30 and 60 years they are larger (0·064 millimetre), and maintain this average afterwards to the end of the life of the tree. Still more striking are the changes at different heights in the tree: both in very young and in very old trees the vessels in the crown may be very narrow indeed compared with those elsewhere.

As facts of great importance in its bearing on the question of the specific gravity of wood, and the futility of comparing rough weighings, we may select the following. The three elements—vessels, tracheides, and libriform fibres—are distributed very differently on the transverse section of the annual rings according to the age of the tree and the level of the section. The rule is that, at the same level, the number of vessels per square millimetre increases as the tree ages. When it is shown that the numbers may range between about 60 to 80 at 30 years, and 200 to 220 at 100 years or more, the conviction arises that the question of specific gravity may be complicated by many factors.

As regards the level of the section examined, the rule is that the number of vessels per square millimetre increases as we go upwards. But it is found that the number of vessels in any one annual ring remains about the same: it is differences in the breadth of the rings which cause the close packing or otherwise, and the general tendency of the rings to be narrower upwards explains the above.

With respect to tracheides and fibres, it may be said generally that young trees form few tracheides (and chiefly near the vessels) but more are formed later; but again, in old age, in the open, the tracheides are replaced by fibres.

Some interesting observations follow on the micro-chemistry of the wood: vanillin and coniferin occur in the walls of the wood elements, and it is somewhat remarkable that they should show a cellulose reaction quite late. Relatively small quantities of tannin are found in the cells, and drops of "wood-gum" are abundant. It is interesting to note the infiltration of the walls with tannin, and this gives the deeper colour to wood exposed to air, owing to oxidation.

The dark (false) heart of the beech is not due to the presence of much tannin, and Hartig again insists that this wood cannot be divided into heart-wood proper as distinguished from sap-wood. The false heart is a pathological production, and nearly always contains Fungi.

But perhaps the most interesting facts in this connection are those bearing on the starch-grains and their movements.

In an old beech-tree, the quantity of starch diminishes from the periphery to the centre: little or none is found within the last 50 annual rings. In the winter the outer rings will be crowded with starch, every cell of the wood-parenchyma and medullary rays being full.

It is, of course, impossible to go into the details of Hartig's experiments and measurements, but he found that under ordinary circumstances the main mass of stored-up starch does not move at all: contrary to the received opinion that the starch is all, or nearly all, dissolved in early summer, and stored up again in autumn, the astonishing fact comes out that during the development of the current year's annual ring, the cambium only takes starch from the next inner ring (and sometimes the next but one) in June and July, and that before the middle of September it is all restored.

In other words, only the two preceding annual rings yield starch to start the cambium: the completion of the new ring, its stores of starch, and the restoration of the borrowed starch, are at the expense of the work of the leaves of the current year.

Light is thrown on the subject by the following experiment—an admirable instance of the progress which is being made in the study of the physiology of plants. Two trees were completely deprived of branches and leaves, and then allowed to stand otherwise untouched: one was felled at the end of twelve months, the other at the end of two years. In both cases it was found that during the first year after the mutilation a new ring was formed by the cambium, but the mass of wood in this was only about 5 per cent. of the normal increment which would have occurred if the tree had remained intact: no trace of further increment was observable in tree No. 2 during the second year.

This 5 per cent. increment was at the expense of all the starch stored in the medullary rays and wood-parenchyma of the stem; in other words, the quantity of starch held stored in each of these trees was equivalent to the quantity of woody substance in a ring containing 5 per cent. of the normal annual amount: in other experiments the amount rose to 15 per cent. or more, but never approached that of a complete normal ring. It is noteworthy that the cambium only acquires the power to attract the whole of this stored starch under such special conditions of hunger as are induced by stopping its supplies from the leaves.

Some similar experiments, with modifications in the special cases, led to the result that the starch which comes down from the leaves—even when only sufficient to partly fill one layer of wood—is rapidly distributed *over the whole sheet of wood*, both above and below.

The question, What are the stores of starch for, if not to feed the cambium? is answered by the following. Weber's analyses show that the nitrogenous substances decrease from without inwards in the wood, just as does the starch in a normal tree; but the total proteid substances remain practically unaltered (at least they suffer no diminution) because they are not used up in building the cell-walls. Any drain on the proteids by the cambium seems to be paid back in due course by the travelling of the proteids from cell to cell.

Now it is a well-known fact that the beech, like other similar forest trees, only yields seed after attaining an age of 50 to 60 years, and that what are termed good seed-years are separated by considerable pauses. It is also

well known that the production of fruit and seed "exhausts" the plant: in the case of annuals it completely drains their resources, and every apple-grower knows that the trees need "rest" after a good crop. In view of all the facts, then, it is most probable[1] that the stores of starch in the beech are put up in reserve for the enormous drain which the "seed-year" will involve, and we shall see that this idea is fully borne out by the chemical analyses, which show that certain valuable minerals are similarly stored for the seeds.

But this does not fully explain why the stores diminish inwards. Two causes are adduced for this. In the first place, a seed-year having exhausted nearly all the supply of starch, we have seen that succeeding deposits only occur in the outermost rings of wood, and so there is no restoration of the deposits deeper in the tree; secondly, some of the stored starch in the deeper layers gradually undergoes change into the drops of "wood-gum" (*Holzgummi*), of which mention was made above.

Some "practical results" of the above may now be noted, the most important being that the difference in weight between wood felled in summer and that felled in winter is, in effect, *nil*, contradicting a wide-spread assumption, and confirming a doubt which Nördlinger had already put forward. It thus follows that the want of durability in summer wood depends on other causes, and Hartig considers it due to the fact that winter wood has time to dry on the outside before the atmospheric influences are favourable for the development of Fungi, the spores of which are always about, but dormant in the cold of winter. No doubt there are other factors to be considered also, but the importance of the above has been too much overlooked or under-estimated.

Another interesting section of the work is that dealing with the formation of the annual rings. By cutting disks at equal distances apart on simultaneously-felled trees of 50, 100, and 150 years old, and measuring the breadth, &c., of the rings at eight points round the disks, some further discoveries were made. Generally put, it was found that (in the case of beeches near Munich, at any rate) the annual ring commences to form at about the end of May, the tree being already in full leaf; by the middle of June the ring is one-third its normal breadth, and is half finished early in July, attaining its normal complete state before the end of August. Hence the whole period of the activity of the cambium only amounts to about two months and a half.

As regards the parts of the tree, it is found that the active division of the cambium commences first in the twigs and small branches; it is later in the trunk proper, and begins at different parts, according to circumstances.

In the oldest trees (150 years) the cambium was found in an active state at 3 to 4 feet up, while parts above and below were still dormant; whereas in somewhat younger trees the process of ring-formation began simultaneously all up and down the trunk. In still younger trees the cambium was found to awaken first in the higher parts of the trunk. More investigation is still needed here, however, before several dark points can be regarded as explained.

Some generalizations as regards the growth in thickness of the beech deserve notice. In the crown, the annual increment—*i.e.* the quantity of wood produced by the cambium during one period of its activity—increases more or less rapidly as we proceed from the tips of the branches to their point of origin from the trunk; but this is by no means the case in the trunk itself, and several cases have to be considered.

In those trees which, owing to close crowding in the forest, have developed only feeble crowns, the annual increment is greatest just beneath the crown, and diminishes regularly downwards; and in very closely crowded trees the cambium in the lowermost parts of the stem may even *stop dividing altogether:* in such cases the ordinary mode of ascertaining the age of the tree would yield false results, for the number of annual rings at 3 to 4 feet high is less than the number of years of the tree's life. The physiological meaning of the above is, that the small leaf-area does not supply sufficient food-material to provide for the needs of the whole sheet of cambium, and the upper parts take all that is sent down, leaving none for those below.

[1] Hartig has since proved that this explanation is the correct one (*Botanische Zeitung*, December 28, 1888, p. 837).

In those trees which have well-developed leafy crowns, more exposed to light and air, the annual increment follows a rule exactly the converse of the last—the amount of wood formed per annum is greater as we proceed from the upper part of the stem to the lower. If we leave out of account the lowermost 6 to 12 feet, every gradation can be found, and in rare cases the breadth of the annual ring may be constant from above downwards.

Now comes in a remarkable discovery. If such trees as the above are suddenly exposed to full light and air, &c., by cutting down the neighbouring trees, the annual rings *in the lower parts of the stem* suddenly become much broader: no such stimulation of the increment occurs in the upper parts.

Now as to the explanation of these remarkable phenomena. There can be no reasonable doubt that the precedence shown by the upper parts of crowded trees is due to the rapid warming which they receive from the air in the spring sunshine: the lower parts of such trees, however, have to wait until the water which they absorb from the soil raises their temperature to the minimum cardinal point, and by the time the water of the soil is sufficiently warm for this, the cambium in the upper parts is far ahead, and working under such favourable circumstances that the rings maintain their greater breadth to the end. But the chief factor in the process is that the upper cambium gets the first supplies of food-substances, and in larger quantities, because lower down the diminished supplies have to spread over a larger area.

In the case of trees exposed freely to the light and air, the sun's rays warm the thinly covered soil (and its water) around the roots, and so the cambium is enabled to recommence its annual work pretty nearly at the same time over the whole stem: in this case thicker rings in the upper parts of the stem must be due to the nutrition being more abundant. All this still fails to explain the *sudden* stimulus to the annual rings in the lowermost parts of suddenly isolated trees, and Hartig suggests that the probable cause is an increased supply of potassium salts and phosphates, rendered available at the roots. This of course implies the further assumption that such minerals are employed directly, and however probable this may be, it is by no means proved.

The removal of branches from the tree leads to the same results as crowding, *i.e.* the rings formed below are thinner, because the supplies are not sufficient to feed the sheet of cambium equally from above downwards. Moreover, the complementary case may occur: a tree in the open may have *too many leaves*, as is proved by the fact that it may be pruned without any loss of increment. The leaf-area of a tree is by no means always proportional to the supplies of food-materials from the soil: it may be too large or too small to be working economically, or so large that each leaf is sluggish—lazy, so to speak, and not doing anything like the amount of work it is capable of. Not only is this idea interesting and suggestive in itself, but it has important bearings on the question of the thinning and treatment of forests generally.

We must leave this topic, however, and pass to one of a different nature, but no less scientifically important. This is the weight of the wood. Although certain practical ends can be roughly attained by merely weighing equal-sized blocks of any particular kind of timber, at any time or in any state, it is, nevertheless, easy to see that such

weighings are of little or no scientific value: only the weight of the fresh timber immediately it is felled, and the absolute dry weight (after exposure to 105° C. long enough to drive off all moisture) yield results of really scientific value.

If we regard 1 cubic metre as the unit of volume, we may obtain some useful factors by ascertaining the weight of dry woody substance in such a volume, from different parts of the tree, and from trees grown under different conditions, &c. The amount of water driven off, *i.e.* the difference between the fresh weight and the absolute dry weight, is found to vary much, and Hartig some time ago obtained most valuable results, bearing on the difficult question of the ascent of water in tall trees, by comparisons of this kind. Moreover, the real test of quality of wood—its value as fuel, and other technical properties—is given in the absolute dry weight.

Passing over the methods, and other details, it may next be pointed out that the weight of a given volume of wood depends chiefly on the sizes and distribution of the histological elements—vessels, tracheides, fibres, &c.—and in the case of beech-wood, it is especially the sizes and numbers of the vessels that have to be taken into account, and as these stand in direct relation with the magnitude of transpiration, it is clear that the quality of the timber as estimated by its weight depends on the quantity of leaves.

Neglecting the roots, we may regard the tree as consisting of three parts: the stock, the shaft, and the crown. Now, the root-stock and the crown contain wood of the best quality, and some curious results come out on examining why this is.

As is well known, the base of the tree widens at the origins of the main roots, and here the annual rings are broadest: if we bear in mind that the number of vessels in each annual ring remains constant, it is easy to understand why the wood is better—it is simply that the vessels are dispersed over a larger sectional area, and are separated by more numerous fibres, the elements which give solidity to the wood.

We have seen that in the trunk of a tree with a large crown of leaves, the mass increment increases from above downwards: this means that the same number of vessels (per annual ring) are distributed over a smaller sectional area above. In a given case, on 1 square millimetre of area, there were 115 vessels at a height of 1·3 metre, but at 10·7 metres height there were 175 vessels on the same area; hence the latter was lighter and worse wood.

By thus counting the number of vessels per square millimetre, and taking the average size of the main vessels, it was possible to get an expression of the relative area occupied by the lumina, and that of the rest of the annual ring; of course this is only approximate.

It comes out that, in trees with large crowns, while the number of vessels is the same at all heights in the stem, the number of vessels *per square millimetre* is much fewer below than above.

In the crown of the tree, however, things are very different; the number of vessels in each annual ring rapidly diminishes, because at each branching a number are given off. Thus, where 200,000 vessels were found in an annual ring in the stem, the same in the crown gave only 57,750. This alone would explain the better quality of the wood, but the number of vessels per square millimetre is also found to *increase* in the crown, and this means corresponding depreciation. But the most important factor in explaining the superior hardness, &c., of the wood in the branches is that the average size of the vessels is less, and therefore the area of lumina in the cross-section is reduced.

Physiologically, the reduction in the lumina of the vessels is in relation with the decrease in the volume of water-current as we ascend, and several facts point to the constancy of this relation. It is well known that, if the soil around a tree is suddenly deprived of much of its water, the tips of the tree die off first: "stag-headed" trees are often produced by over-exposure. This is because the average size of the vessels has been adapted for a richer supply of water than comes to them under the new conditions. Hartig says that the average size of the vessels throughout is reduced if the land is deprived of cover, and the tree exposed too much.

As has been seen, the wood of trees below 60 years of age contains fewer vessels, and these with smaller lumina, than afterwards. It is also known that the ascending water-current is confined to the younger outer wood, or alburnum; and if we neglect younger trees, it seems that in the beech it is only the 20 or 30 outer annual rings which conduct the water.

Now the authors of the book referred to find an unexpected relation between the amount of wood produced annually, and the current of water passing up the stem. By an ingenious series of measurements and calculations, it results that much more room is provided for the water-flow in early years than in old age. Thus, a given amount of water, which has for its passage in a tree 30 years old an area of wood expressed by the number 4·04, has only an area equal to 1·64 at 140 years of age. Hence, in order to conduct the larger quantities of water which must pass to the larger crown, the smaller area of wood, in the older tree, has to *increase the number and size of its vessels*, and so the wood is lighter and poorer.

It is impossible here to enter into the bearing of these matters on questions of forest management; it is only a particular case of the dependence of technical forestry throughout on the teachings of science, the principles of which it applies.

An interesting experiment may be quoted. Two beeches 150 years old were felled and examined; they had been completely freed from neighbouring trees 7 years previously. The effect of the sudden exposure to free light, air, &c., was that the mass increment rose to 2·4 times greater than previously, and the weight of the wood formed during the 7 years of exposure was 700 kilogrammes per unit volume, as against 600 kilogrammes previously, *i.e.* 16·7 per cent. more wood-substance was formed. On going into details, it was found that *five times as much wood-substance* was formed each year, and *twice as many vessels* were developed in each annual ring. But since these twice as many vessels were distributed over five times the quantity of wood, the wood was still heavier than that of 7 years previously. On the square millimetre there were 63 vessels, as contrasted with 140.

The reason that letting in the light and air around the tree has such enormous effects is obvious enough to the physiological botanist, but it should also be clear that the knowledge thus obtained is the best guide to such forest practices as thinning and freeing timber: into these matters, however, we do not propose to enter further here, but must pass to other matters. In the section on the course of growth of the beech, an interesting discussion on the limits of height of trees occurs: Hartig regards the chief limiting cause to be the gradual disappearance of the difference in tension between the air-bubbles in contiguous elements: the osmotic forces remain constant throughout, but the lifting power diminishes with age and height, until it ceases to suffice for movement. The influences of etiolation, and judicious crowding, and other devices for timber-growing, are then discussed in the light of what has been already said, and with the aid of numerous tables of close-set and well-classified figures, sufficient illustrations are given to satisfy the most stiff-necked critic of the value of these results.

The chemist's results, however dry they may appear from the tables and curve-diagrams, allow of summary in a way that endows them with an interest to the general reader, no less real than that which attaches to other parts of the work. Methods may be passed over here.

The cortex of course contains most ash, and the quantity of total ash increases with age and with height: these facts have been shown for other trees also.

In the wood proper, the quantity of ash *as a whole* increases from the periphery to the centre, but as we shall see that the distribution of the various constituents is very different in different parts, this generalization will have to be cut up into a series of less general statements. In the same period of growth the total ash increases with the height.

It is somewhat striking that the inner zones of the inner alburnum yield most ash, and thus the central part of the highest transverse section of the stem will contain most ash.

As regards the changes due to age, the ash per cent. decreases till the tree is about 60 years old, and then it increases rapidly for twenty years or so, gradually diminishing again with increasing age. These periods show such close relation to certain facts in the culture of the trees, that they are evidently explained somewhat as follows. During the first 60 years in the plantation, the young beeches crowd one another more and more, and the competing roots restrict one another, and the percentage amount of salts absorbed diminishes year by year: at or about the age of 60 years the trees are thinned by systematic felling, and so more space is given to those which remain, as well as more soil and ingredients from the decomposition of the roots, &c., of the felled trees. The consequence is the increase of ash to a first maximum. At the period about 80 to 90 years the beech has attained the seed-bearing age, and the probability that the diminution of ash henceforth is due to the drain to supply the seeds is too great to be overlooked.

It is interesting to note that shaded beeches, at all periods and in all parts, show a higher percentage of total ash than fully exposed trees, and the same is true of the silver fir (another tree which bears much shading): the trees store up mineral substan es, which must be an advantage to them under the circumstances of growth.

If, instead of regarding the total ash, we now look at the constituents, it results that the enormous excess of ash in the cortex consists chiefly of calcium carbonate, from the calcium oxalate (which may form 70 to 90 per cent. of the whole). Much potash, magnesia, and phosphoric acid also occur.

In the wood, the quantity of potassium salts increases from the periphery to the centre; whereas the reverse is the case with the phosphoric acid, sulphur, and magnesia, a fact the more remarkable because the potash usually accompanies the phosphoric acid in other parts of plants —*e.g.* in leaves, &c. It is no accident, however, and the fact comes out that the beech forms large reserve stores of potash (this being the chief cause of the large increase of total ash in the interior of the stem), whereas the phosphoric acid and sulphur travel outwards with the proteids, being repeatedly used in metabolism in the cambium, &c.

We must pass over a number of other peculiarities of the distribution of the ash-constituents, to notice the effect of the age of the tree on the chief salts. The distribution of the potash, lime, and magnesia is little influenced by age, but an extraordinary effect comes out in the case of the phosphoric acid. The young tree starts with a relatively large quantity of this constituent, but the amount sinks year by year till the fiftieth or sixtieth year, and then rises again to about the ninetieth year, to fall afterwards: in fact, the behaviour is similar to what occurs with the total ash, and is doubtless to be referred to the same causes.

Another curious result comes out in studying shaded trees: whereas they take up as much potash and lime as exposed trees, their magnesia and phosphoric acid fall far below those of exposed trees. But the most astonishing discovery is that shaded trees *take up four times as much sulphur* as exposed ones. The analyst himself notes how astounding this is, but he insists that a second series of analyses gave confirmatory results.

Another queer fact is that the kind of soil exerts little influence on the analyses; though a similar conclusion has been come to with other plants.

The study of the absolute quantities of individual ash-constituents in 1000 parts of the dry substance brings out some interesting and important generalizations, which are expressed in the form of curves, and fully bear out in detail what has already been stated.

The quantity of ash and of each ash-constitutent in 1 cubic metre of beech-wood at various ages, as compared with the wood of other trees, is next investigated. The results show that the beech takes more potash than most trees except the *Robinia*—for instance, at 40 years it contains more than four times as much as the spruce fir.

As regards phosphoric acid, the beech and oak need more than other trees, beech-wood at 40 years old having seven times as much as spruce at the same age. With lime the facts are similar: beech needs much more than conifers.

From the whole of the preceding, it is possible to put together some ideas on the quantity of ash-constituents per acre needed for beech forests, and some interesting tables and curves are given in this connection; the return of minerals to the soil in the leaf-fall, &c., is also considered. Perhaps the most important conclusion come to here is that the increment in dry weight of the tree is nearly proportional to the up-take of potash, whereas the up-take of lime is the same—gradually increasing to old age—whether the wood is good or bad, and whatever the nature of the soil. The nitrogenous substance in beech-wood behaves very like the phosphoric acid, in that it diminishes from the tenth to the sixtieth year, and then ascends to a second maximum as the tree reaches 80 years old; and again, the cause is to be found in the influence of the thinning, and in the demands on the reserves when the tree begins to bear seed.

As in all trees, there is of course most nitrogen in the twigs and buds, and in the finer roots. Beech and oak need more nitrogen than other trees, and (so far as the wood goes) the conifers need much less. The total quantity of nitrogen taken up by the beech at 6 years old, in fully stocked plantations, is calculated to be 39·43 kilogrammes per hectare, and this rises to 389·63 at 60 years, and 896·50 at 130 years.

Calculations as to the quantity of nitrogen needed annually per hectare to produce the known yield of wood are then given, and again we meet with the rapid loss after about 90 years, due to seed-production. To these are added estimates of the nitrogen removed in the thinnings, and of that restored in the fallen leaves. All things considered, the quantity of nitrogen concerned annually varies with the age, but at the critical period of 50 to 100 years it amounts to something like 60 kilogrammes per hectare *per annum*.

It is unnecessary to point out further the extreme importance of such investigations as these: it is only in proportion as a nation is armed with statistics based on careful researches like these that it can form any conclusions worth having as to the future value of its forests and the technical merits of those administering them. As to their "practical" bearings, the results speak for themselves: if this is not allowed to be practical science, we may indeed ignore the cry.

H. MARSHALL WARD.

SPECTROSCOPIC RESEARCHES AT THE NORWEGIAN POLAR STATION.

PART II. of the Report on the results obtained at the Norwegian Polar Station at Bossekop in Alten (in connection with the International Polar Investigation,

1882–83) was recently issued at Christiania; and we have already said something as to the contents (NATURE, December 13, 1888, p. 155). The following is a translation of a statement, by Herr Cand. C. Krafft, in this Report:—

"For spectroscopic researches the Expedition took with them a Wrede spectroscope. Unfortunately the obligatory observations did not render it possible to devote adequate attention to spectroscopic researches. The writer may also specially note that the use of powerful magnifiers made measurements with the above-mentioned apparatus extremely fatiguing, and often quite impossible. It seemed to me all the more permissible to omit these measurements because the situation of the usual aurora-line is often very distinctly defined. Other lines besides these were only sometimes observed. Weak, indeterminable bands I observed on November 12, 4h. 18m. If I remember rightly, I saw similar indeterminable bands on another occasion, but I cannot find any notice of it in the observations. The red line was sometimes remarked, but it showed itself very conspicously, and flashed up only some moments (November 2, 9h. 15m.; November 17, 4h.). The general rule is that only the aurora-line was to be seen even in strong auroræ; as, for example, on November 2, 8h. 55m., during a crown-formation, and on November 5, 8h.–9h. on a bow with the intensity 2–3.

"In order to find the value of the scale-division of the spectroscope expressed in wave-lengths, I made, on October 30, 1882, the following determination of the most important Fraunhofer lines:—

B ... 25·04 (λ = 6867) *a* ... 23·27 (λ = 6276)
C ... 24·16 (λ = 6562) D (Mean) 21·78 (λ = 5892)
E ... 18·51 (λ = 5269)
b (Mean) 17·84 (λ = 5174)

"With the help of these determinations I constructed a curve, and obtained from it the following wave-lengths of the auroral lines:—

November 2, 8h. 55m. aurora-line (mean) 20·37 ... λ = 5595
November 11, 10h. 15m. aurora-line 20·26 ... ... λ = 5586
[D (NaCl flame) 21·71.]

"November 17, 4h. 20m.; Herr Schroeter found the following values:—

$$\text{Aurora-line} \quad \left.\begin{array}{l}20{\cdot}37\\ 31\\ 34\\ 34\end{array}\right\}\text{Mean } 20{\cdot}34 \;\ldots\; \lambda = 5587$$

Red line 23·00 ... λ = 6205.

"On account of the rapid flashing-up and disappearance of the red line only this one measurement could be obtained.

"The spectroscope was used chiefly to decide occasionally, in doubtful cases, whether and how far the aurora was present—a matter which, as is well known, it is very often impossible to decide in any other way. Fine cirrostratus clouds may so closely resemble the aurora as to be taken for it, especially if they are lighted by the moon or by twilight. In the latter case one may recognize the aurora-line apart from the continuous spectrum (January 15, 12h.; March 29, 14h.). Meanwhile I do not think I can decide whether the aurora line is to be regarded as absolute criterion for the aurora; I have had an opportunity of observing pulsating masses of light (December 18, 9h.), and also otherwise inexplicable phenomena of light, as well with the usual aurora colour (January 13, 10h.) as with red (November 17, 6h. 15m.), without being able to discover the aurora-line. On a red mass of light it might appear very weakly, even if the light-mass shone powerfully (November 17, 16h.). Beside, the aurora-line was very often to be recognized everywhere. This sometimes made me think that the whole firmament was covered with aurora material, although the explanation may be that the line everywhere visible springs from an aurora, only slightly extended, reflected from fine clouds, &c., floating in the air. This reflected light showed the aurora-line even on objects on the earth (snow on a field, a wall), and even when the sky was pretty well covered (November 11, 10h.; November 12, 5h.; November 14, 8h.; December 15, 15h. 25m.; December 16, 9h.)."

NOTES.

THE Croonian Lecture of the Royal Society, which, as we have already announced, is to be delivered this year by M. Roux, the "Chef de Service" of the Pasteur Laboratory, has now been fixed for Thursday, May 23, at 4.30 p.m., in the Royal Society's apartments at Burlington House.

A GOOD many arrangements for the Newcastle meeting of the British Association, over which Prof. Flower will preside, have now been made. Among the Vice-Presidents are the Duke of Northumberland, the Earl of Durham, the Bishop of Newcastle, Lord Armstrong, the Mayors of Newcastle and of Gateshead, and Mr. John Morley. The following are the Presidents of the various Sections:—A—Mathematical and Physical Science, Captain W. de W. Abney, F.R.S. B—Chemical Science, Sir I. Lowthian Bell, F.R.S. C—Geology, Prof. James Geikie, F.R.S. D—Biology, Prof. J. S. Burdon Sanderson, F.R.S. E—Geography, Colonel Sir Francis de Winton. F—Economic Science and Statistics, Prof. F. Y. Edgeworth. G—Mechanical Science, Mr. William Anderson. H—Anthropology, Prof. Sir W. Turner, F.R.S. The first general meeting will be held on Wednesday, September 11, at 8 p.m. On Thursday evening, September 12, there will be a *soirée;* on Friday evening, September 13, a discourse on "The Hardening and Tempering of Steel," by Prof. Roberts-Austen, F.R.S.; on Monday evening, September 16, another discourse; and on Tuesday evening, September 17, a *soirée*. Excursions to places of interest in the neighbourhood of Newcastle-on-Tyne are being arranged for Saturday, September 14, and Thursday, September 19.

AT a recent meeting of the Executive Council of the British Section of the Paris Exhibition, the cordial thanks of the Council were given to Sir Frederick Leighton, P.R.A., and the Fine Arts Committee, for their exertions to insure that the Fine Arts Department at the Exhibition should be a credit to the British Section and the country. The result of the exertions of the Committee will be that British art will be represented in Paris by works of many of our foremost artists. Why is not like energy being displayed by English men of science? There ought to be a Science as well as a Fine Arts Committee, and the necessary arrangements might easily be made, as there are several members of the French Institute in England.

THE Directors of the Ben Nevis Observatory have applied to the Association of the Glasgow International Exhibition of 1888 for a grant from the surplus fund of the Exhibition. In the memorial setting forth the claims of the Observatory on the support of the public and of public bodies, reference is made to the immediate and important advantages that will result from the work of the High and Low Level Observatories of Ben Nevis towards the further development of the meteorology of the Clyde, in which Glasgow has taken so prominent a part, and by the results of which the shipping and commercial interests will to a certainty be largely benefited; and it is urged that, in carrying out these national objects, the Directors must look to the liberality of the public and of public bodies, for the assistance required to supplement the aid offered by the Government towards the completion and maintenance of this double Observatory.

THE Botanical Society of France has issued a circular signed by its President, M. de Vilmorin, and Secretaries, inviting foreign

botanists to attend a Botanical Congress to be held in Paris during the second half of August in the present year, and to present treatises on botanical subjects, pure or applied, that may be most familiar to them, with the view of promoting discussion on them. The following subjects are especially proposed for consideration:—(1) The usefulness of establishing joint action between the different Botanical Societies and Museums for the purpose of preparing accurate maps of the distribution of species and genera of plants over the globe, a work similar to that undertaken by International Geological Congresses. An Exhibition of maps, books, *brochures*, photographs, &c., relating to botanical geography will be held, during the Congress, at its place of meeting. (2) Characters for classification furnished by anatomy. Botanists intending to be present at the Congress should send in their names, before June 1, to M. P. Maury, the Secretary of the Organizing Committee, 84 Rue de Grenelle, Paris, when they will receive special invitations, and information as to the day and place of meeting. The titles of papers proposed to be read, or of verbal communications, should be forwarded as early as possible.

We reprint from the *Times* of March 26 the following obituary notice:—"We have to record the death, at a ripe age, of a man whose name is well known and honoured wherever the science of naval architecture is studied. Joseph Woolley, M.A., LL.D., F.R.A.S., formerly Principal of the School of Mathematics and Naval Construction at Portsmouth, and subsequently, for many years, the Admiralty Director of Education, died at Sevenoaks on Sunday, after a few days' illness. Trained at Cambridge, where he was a Fellow of St. John's College, he was selected in 1848 as the head of the Technical School founded in that year by the Admiralty. He continued to hold that office until the school was discontinued in 1853. When a School of Naval Architecture was again founded, on other lines, at South Kensington, in 1864, Dr. Woolley was appointed Inspector-General by the Committee of Council on Education, and he continued to superintend the school until his retirement from active life. In 1850 he published a "Treatise on Descriptive Geometry," which is widely known as a text-book. In 1860, when the Institution of Naval Architects was founded, very largely by his own personal influence, Dr. Woolley opened its proceedings by an address on "The present state of the mathematical theory of naval architecture." He enriched the Transactions of the Institution with frequent contributions on all current questions presenting any peculiar difficulty. He was a member of the Committee on Designs in 1871, and of other important Naval Committees. He was for many years in holy orders, but he relinquished them later in life, although he continued to be to the last a devout worshipper in the Church of England. He was a man who was much loved by all who were privileged to work with him."

We regret to learn that Prof. Donders died at Utrecht on Sunday.

Two physiologists of note have recently died: Prof. Krukenberg, of Jena, well known for his researches in invertebrate physiology, and R. Gscheideln, of Breslau, the author of a "Physiologische Methodik," which unfortunately remains unfinished.

We learn from *Science* that Captain John Ericsson, whose death, at New York, we lately recorded, continued to labour at his sun-motor until within two weeks of his death. "As he saw his end approaching, he expressed regret only because he could not live to give this invention to the world in completed form. It occupied his thoughts up to his last hour. While he could hardly speak above a whisper, he drew his chief engineer's face close to his own, gave him final instructions for continuing the work on the machine, and exacted a promise that the work should go on." *Science* says that the respect shown at Captain Ericsson's funeral was such as is seldom seen at that of a private citizen. "The streets in the neighbourhood of his late residence were crowded from the early morning hours with thousands, who for four hours passed through the house to pay homage to the departed genius. New York is a place full of human beings,—so full that each pays little or no heed to his neighbour; yet the great respect for this man of science and of action was shown in the number and character of those who followed his remains to their resting-place, in the uncovered heads as they were borne along the busy streets, and in the impossibility of admitting to Trinity all that wished. Ericsson was a man who could have endeared many to him, but he had a strong sense of duty to his work, which induced him to make few friends. This final homage of the unmindful crowds of the great city was to his genius well applied."

A gift of some scientific as well as artistic interest has just been made to the Royal Hibernian Academy, Dublin, by Miss Mary Anne Nicholl. She has presented to the Academy fifty-six studies in water-colours of the palms and foilage plants and fruits of Ceylon, painted by her late father, Andrew Nicholl, R.H.A., who held the first appointment of Master of Landscape Painting, Engineering, Drawing, and Design, in the Colombo Academy. The studies are accompanied with a list of the names of the flora.

At the distribution of prizes to students of the Polytechnic Institute, Regent Street, on Monday, Mr. W. T. Paton was able to give a good account of the past year's work. The number over and above the usual attendance had been, he said considerably more than 1000, and they now had 7000 members, who were attending classes there. The Lord Mayor, who gave away the prizes, spoke of the advance which had lately been made in technical education, and of the good influence exerted by the Polytechnic Institute. The Committee wished him to say that they had now annexed the West End School of Art to the Institute. Further funds would be required to carry on the work. The Charity Commissioners would provide £31,000 for endowment if another £4000 were forthcoming.

The Geographical Society of Bremen has commissioned Dr. Kückenthal, of Jena, to undertake another journey to the Arctic regions, in order to make zoological researches. He will start for Spitzbergen at the end of April, and is expected to return in October next.

Prof. Franz Exner, of Vienna, who has spent some months in Ceylon studying atmospheric electricity there, is now on his way back to Europe. A grant was made by the Vienna Academy of Sciences in aid of his scientific work.

The new Natural History Museum at Vienna will be opened to the public in the summer, and it is expected that the rich collections will attract large numbers of visitors.

Dr. J. Hann, Director of the Austrian Meteorological Service, has laid before the Vienna Academy of Sciences an exhaustive investigation of the diurnal range of the barometer over the globe. He has calculated the harmonic coefficients for each month, and for the year, for a large number of places, and has investigated the variation both of the phases and of the amplitudes of the single and double daily oscillations. The latter show a remarkable independence of geographical and seasonal influence (as before pointed out by Lamont and others), and appear to be connected with a cosmical origin. The investigation also shows that the amplitudes of the semi-diurnal oscillation decrease with height in exact proportion to the pressure, and have a marked dependence upon latitude. The yearly range exhibits two maxima at the periods of the equinoxes, and also a third maximum which falls in January in both hemispheres, while

in July the amplitude of the double daily oscillation is smallest over the whole globe. The author also investigates the single daily oscillation, in connection with the influence exerted by the position of the station, as well as the range of the barometer at sea, and arrives at some interesting results.

SIX shocks of earthquake were noticed at Aquila on March 11. Two were very severe, but had no injurious results. Shocks were felt at Idstein, Auroff, and Görsrod, near Wiesbaden, on March 12, at 2.29 a.m. The direction of the shocks was from west to east.

TELEGRAMS received at Madrid report that a strong shock of earthquake was felt on March 25 at Alhama in the province of Granada. No damage was done, but great alarm prevailed among the inhabitants.

M. B. HASSELBERG, of Pulkowa, has been studying the absorption spectrum of iodine, which he has succeeded in resolving into widely separated lines with a Rowland grating, and in photographing. The wave-lengths of about 3000 lines have been determined by a dividing-engine.

ANOTHER interesting pair of geometrical isomers have been discovered by Dr. Auwers and Prof. Victor Meyer. They are the monoxims of benzil, both possessing the constitution $C_6H_5 . C(NOH) . CO . C_6H_5$. Benzil, $C_6H_5 . CO . CO . C_6H_5$, is the typical di-ketone of the benzene series, and reacts, like other ketones, with hydroxylamine. As there are two CO groups present, there are two possible oxims, a monoxim and a dioxim. A few months ago, Dr. Auwers and Prof. Meyer showed that there were really two dioxims, both of the constitution $C_6H_5 . C(NOH) . C(NOH)\ C_6H_5$, but differing in the arrangement of the various groups in space. One of these isomers was shown to probably possess the configuration $\begin{array}{l} C_6H_5-C=NOH \\ \qquad\quad | \\ C_6H_5-C=NOH \end{array}$, while the other, which melts 30° C. lower than the first, may be formulated $\begin{array}{l} \quad C_6H_5-C=NOH \\ \qquad\qquad\ | \\ NOH=C-C_6H_5 \end{array}$. It is now found that there are also two corresponding monoxims, one of which, termed the α-monoxim, may be represented as $\begin{array}{l} C_6H_5-C=NOH \\ \qquad\quad | \\ C_6H_5-C=O \end{array}$, while the β-monoxim has its groups probably disposed in the manner $\begin{array}{l} C_6H_5-C=NOH \\ \qquad\ | \\ \ O=C-C_6H_5 \end{array}$. Both these monoxims are obtained when benzil and hydroxylamine, NH_2OH, are allowed to react upon each other at the ordinary temperature. If the hydroxylamine be used in the form of its hydrochloride dissolved in a little water and added to an alcoholic solution of the benzil, a preponderating quantity of the β-compound is formed, and in greater quantity the higher the temperature. At −15° C., the product consists largely of the α-monoxim; at 0°, about equal quantities of the two are formed; at the ordinary temperature of a room the product is almost exclusively of the β-compound; and finally, when the operation is conducted upon a water-bath, a quantitative yield of the β-monoxim is obtained. The α compound is best prepared by dissolving 10 parts of benzil in 30 parts ordinary alcohol, and adding a mixture of 3½ parts of hydrochloride of hydroxylamine and 4 parts of soda dissolved in a little water. After standing a few hours the mixture is poured into water, and the turbid liquid thus formed filtered. On acidifying the filtrate an oil separates out which rapidly crystallizes. On recrystallizing the mixed crystals from dilute alcohol, a large yield of the pure α-compound is obtained, owing to its much more sparing solubility, in microscopic tabular four-sided crystals possessing a mother-of-pearl lustre. It may also be recrystallized from benzol, from which it is obtained in the same form. The crystals melt sharply at 137°. On the other hand, the β-monoxim crystallizes from alcohol in thick prisms, melting at 113°, 24° lower than the α-compound. Another striking point of dissimilarity is that from benzol the β-compound crystallizes with half a molecule of benzol of crystallization. Each reacts with a further equivalent of hydroxylamine to form the corresponding dioxim; and each also forms a characteristic ethereal salt with acetic acid, the α-acetic ether forming broad flat prisms melting at 61°, and the β-acetate crystallizing in needles of melting-point 78°. Hence the oxims of benzil form a most beautiful and indubitable case of true geometrical isomerism, and a valuable further justification of the modified Van t' Hoff-Wislicenus hypothesis. It is to be hoped that, by further investigations of similar cases, we may indeed eventually be enabled to form some idea of the actual orientation of the atoms in our chemical molecules.

THE American Society of Naturalists recently appointed a Committee to report on the teaching of science in schools. The Report, which has been adopted and approved of by the Society, contains, amongst others, the following suggestions as to the mode in which, in the opinion of the Committee, science can best be taught in the schools:—Instruction in natural science should begin in the lowest grades, where it should be conducted chiefly by means of object-lessons. More systematic instruction should be given in the high schools during the four years' course preparatory to College. An elementary knowledge of some one or more branches of natural science should be required of every candidate for matriculation at College. There are some differences of opinion as to the details in carrying out this plan, but the Committee recommends that scientific study should begin with the study of plants and animals, the botanical instruction beginning with drawing the outlines of the leaves of plants, and the zoological with descriptions of the more familiar animals, special prominence being given to the study of those plants and animals which are useful to man. The simple geological phenomena of the district in which the school is situated should be taught. Children should be encouraged to collect specimens of all kinds of natural objects, and these specimens could be made the subject of the object-lessons. An attempt should be made to teach the rudiments of human physiology and hygiene. The Committee recommends the introduction into the highest grades of the grammar school of very rudimentary lessons in physics and chemistry, which would pave the way for further study in the high schools and Colleges.

WE have received several interesting papers, by Prince Roland Bonaparte, on subjects relating to geography and anthropology. One of them (in French) is an account of the early voyages of Dutchmen to the East India Archipelago. In another series of French papers the Prince deals with geographical discoveries in New Guinea. He has also reprinted from the Journal of the Anthropological Institute a note (in English) on the Lapps of Finmark. In this paper he presents various anthropological data collected during a tour of three months in Scandinavia. A more elaborate paper (in French), by F. Escard, which is printed in the same form as these essays, gives a full account of the experiences of Prince Roland and his companions in the country of the Lapps.

THE "Record of the Excursions of the Geologists' Association, 1860–84," which has been prepared by Mr. T. V. Holmes, is now ready for the press, but it will not be printed until the names of a sufficient number of subscribers have been received. The work will consist of over 500 pages, and contain accounts of all the sections and districts visited by the Association down to the end of 1884, with the illustrations (sections, &c.), which have from time to time appeared in the circulars and Proceedings.

A FRENCH translation of Prof. Romanes's "Mental Evolution in Man" is in course of preparation in Paris.

THE *Oesterreichische Botanische Zeitschrift*, now in its thirty-ninth year, is edited, from the commencement of the present year, by Dr. Richard R. von Wettstein.

AT the annual meeting of the Governors of Aberdare Hall, University College, Cardiff, which took place this month, the Executive Committee were able to submit a most satisfactory report. Several students had distinguished themselves by gaining scholarships both at the College and Hall; two had taken the B.A. degree (London); others had passed the Intermediate in Arts and matriculation examinations, among whom was Miss Moss, who took the twelfth place in Honours division, matriculation examination.

THE additions to the Zoological Society's Gardens during the past week include two Chinese Mynahs (*Acridotheres cristatellus*) from China, presented by Mrs. Rigby; a Rose-crested Cockatoo (*Cacatua moluccensis*) from Moluccas, presented by Miss Liming; a Long-tailed Copsychus (*Copsychus macrurus*, ♂) from India, two Silky Bower-Birds (*Ptilonorhynchus violaceus*, ♂ ♀) from Australia, a Blue and Yellow Macaw (*Ara ararauna*) from South America, deposited; two Squirrel Monkeys (*Chrysothrix sciurea*) from Guiana, a Four-horned Antelope (*Tetraceros quadricornis*, ♂) from India, a South American Flamingo (*Phœnicopterus ignipalliatus*) from South America, purchased; a Gayal (*Bibos frontalis*, ♀), a Vulpine Phalanger (*Phalangista vulpina*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

OBSERVATIONS OF JUPITER.—An excellent series of eighty-four drawings of the planet Jupiter at different periods during the years 1881–86, made with the reflector of 3 feet aperture at Birr Castle Observatory by Dr. Boeddicker, has just been published in the form of a communication to the Royal Dublin Society (vol. iv. series 2, March 1889). Twenty-two of the drawings were made during the opposition of 1881–82, thirty-one during 1882–83, twenty-one during 1883–84, eight during 1884–85, and two during 1885–86. The drawings made at the telescope have been exactly reproduced by a photo-mechanical process in order to avoid the errors which might have arisen by the employment of the ordinary lithographic process. Throughout the descriptive notes a very convenient notation has been employed for reference to the various features. Dr. Boeddicker draws attention to the three observations of March 16, 1883, showing remarkable changes in the appearance of one of the belts during the course of an hour. The first drawing shows two detached patches, which, in the succeeding drawings, become the shadows of large cumulus-like clouds lying across the Jovian surface. It is suggested that these apparent changes may be simply due to the combination of the more obvious details with the finer ones after prolonged examination, and that the discrepancies between drawings made at the same time by different observers may thus be accounted for. Photography may be expected in the near future to overcome this difficulty.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 *MARCH* 31—*APRIL* 6.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on March 31

Sun rises, 5h. 38m.; souths, 12h. 4m. 8·2s.; sets, 18h. 30m.: right asc. on meridian, 0h. 40·3m.; decl. 4° 21′ N. Sidereal Time at Sunset, 7h. 7m.

Moon (New on March 31, 12h.) rises, 6h. 12m.; souths, 12h. 13m.; sets, 18h. 28m.: right asc. on meridian, 0h. 49·2m.; decl. 0° 7′ S.

GEOGRAPHICAL NOTES.

AT the meeting of the Geographical Society on Monday two papers were read, both dealing with the Caucasus, midway between Kazbek and Elburz. Here the chain towers up in two great parallel crests, containing within a few square miles at least half a dozen peaks over 16,000 feet in height, an elevation probably reached nowhere else by the summits of the crystalline crest. Two of these peaks are recognized as the second and third summits of the Caucasus—Koshtantau, 17,091 feet; and Dychtau, 16,924 feet. One of the papers, by Mr. A. F. Mummery, described his ascent last summer of Koshtantau, while Mr. H. W. Holder dealt with the peaks of the neighbouring Bezingi Glacier. From Mujal, on the south-west of the Zanner Glacier, Mr. Mummery and his companion made their way round by the Thuber and Gvalda passes to Bezingi in order to make the ascent from that side. The arrangement of this part of the chain, Mr. Mummery states, is, from an Alpine point of view, very curious. There is a lofty ridge with occasional *aiguilles*, from the southern slopes of which stretch the great ice-fields of the Thuber, and there is a second and rather less lofty ridge to the north and parallel to it, from the northern flank of which flow the Basil-su and its various affluents. In the narrow trough between these two ridges lies the head of the Gvalda Glacier. Though seldom so clearly marked as in this instance, the same system of short parallel ridges may be traced throughout the whole central group, with the result that the upper and middle basins of the great glaciers are nearly always parallel to the main ridges, and it is only when the drainage from these catchment basins reaches the head of the lateral valleys that the ice sweeps round and flows away at right angles from the watershed. The Gvalda Glacier is probably the most important on the south side of the Caucasus, and far exceeds in size any on the south slope of the Alps. Its basin probably exceeds in extent that of the Glacier du Géant, to which it is not without a resemblance. The Caucasian glaciers in this part of the chain are

much less crevassed than the Alpine, apparently due to the lesser inclination of the great glaciers, and possibly to the greater thickness of their ice. With reference to Caucasian forests, Mr. Mummery has some interesting observations. The upper valley of the Basil-su can still boast a fairly extensive forest; but partly by the axe, and mainly by the agency of the sheep and goats, the forests are fast shrinking. Below a certain point in the Basil-su Valley, not a tree, not a bush is to be seen; the country has been denuded by the flocks of the natives. Mr. Mummery is inclined to attribute the extraordinary contrast between the treelessness of the northern valleys and the dense forests of the southern less to climatic differences than to the form in which the wealth of their respective inhabitants exists: in the one case, oxen, horses, sheep, and goats; in the other, well-tilled and neatly fenced fields and orchards. Though at first sight it appears difficult to believe that sheep and goats can destroy the forest over great stretches of country, a careful examination of the Upper Basil-su shows that the cause is sufficient to produce a continuous contraction of the forest area, and leaves it a mere question of time as to when the last tree in that valley shall be cut down and burnt. After overcoming many difficulties, Mr. Mummery reached the summit of Koshtantau, the first time the mountain had been scaled.

Mr. Holder and his friends also succeeded in climbing Koshtantau and several other peaks. He gave in his paper an instructive account of the striking difference in the character of the mountains which form the two great chains of the Caucasus and the Alps. Mr. Holder was much impressed with the wildness, the majesty, the awfulness, of the Caucasus. Whilst the main glacier streams, *e.g.* the Bezingi, the Mishirgi, and the Dych-su, have but a slight fall, and are but little crevassed, the upper parts of the glaciers, those which come down from the mountains to form the great streams, have so steep a fall that they may be compared rather to cascades than streams of ice, and are cut into *seracs* of the most fantastic character. Comparatively little snow lies on the steep southern faces of the mountains, and the rocks which face the south are so broken and loose that the danger of falling stones in ascending and descending is extreme. No single bit of rock can be trusted, and the rope ought never for a moment to be discarded. On the northern faces much more snow lies, and the rocks were firmer and more reliable. The climate of the Caucasus is healthy and invigorating, yet distinctly more humid than in the Alps. It may perhaps be sufficiently interesting to note that none of the party experienced the slightest inconvenience on account of the rarity of the atmosphere at the highest altitude reached, over 17,000 feet; but that above about 15,000 feet the snow was always of the light and powdery character so tantalizing and fatiguing to mountaineers.

The March number of *Petermann's Mitteilungen* contains a long paper by Spiridion Gopčević on the ethnographical conditions of Macedonia and Old Servia. Herr Otto F. Ehlers contributes a lively account of his ascent of Kilimanjaro last summer. He does not add much to our knowledge of the mountain, nor did he reach the actual summit. He went round its north face, and endeavoured from the north-east side to find out the character of the summit. He found the same wall of ice which was seen by Dr. Meyer. He states that so far as he could observe he could see no trace of a crater, while the masses of ice and snow lay in quiet wave-like lines, with much fresh snow. The height he estimates at over 19,690 feet. He makes the extraordinary statement that traces of elephants, buffaloes, and antelopes were met with at a height of about 16,000 feet, where also he found the last traces of vegetation.

M. Jules Borelli has just returned from an exploration extending over nearly two years in the country of Shoa and in Galla Land, undertaken under the patronage of the French Government. M. Borelli has added much to our knowledge of Shoa and its people, and among other things has discovered the source of the Hawash. His most important work has, however, been done in the region to the south of Shoa, in the country peopled mainly by the Gallas. He traced the Omo River, to about 6° 20′ N. lat. His map throws quite a new light on the hydrography of the region. Hitherto, the Omo has been conjectured to be the upper course of the Jub, which falls into the Indian Ocean at the equator. But the data collected by M. Borelli, and which appear to be confirmed by the recent discoveries of Count Teleki, open the field to new hypotheses. It would appear that the Omo, instead of flowing towards the east, takes a westerly and then a southerly direction, when, at about 2° N. lat., with a breadth of over 1500 feet, it expands into the great lake Samburu. It remains now to discover whether this lake is an African Caspian, or whether it has an outflow towards Lake Victoria Nyanza. In that case the Omo becomes a remote feeder of the Nile.

ELECTRICAL NOTES.

Nagaoka (*Phil. Mag.*, February 1889) of the Imperial University, Japan, has investigated the effects of torsion and longitudinal stress on the magnetization of nickel. Stress increases the magnetization of iron, but diminishes that of nickel, and the effect of torsion is also reversed in the two metals. Twisting nickel wire increases magnetization, while it diminishes that of iron. Nagaoka finds that this is true for weak stresses only. Beyond a critical value of the stress in a constant field, one end of the nickel wire acquires the two opposite kinds of magnetism during torsion and detorsion. The nickel wire used was unfortunately impure, for it contained 1·7 per cent. of iron, but the fact was clear that during untwisting the polarity of a nickel wire changed sign.

Dr. John Hopkinson, F.R.S., has given the Royal Society (March 7) some interesting facts relating to the magnetization of iron at high temperatures. At 737° C. all traces of magnetism disappear, but before this point is reached, viz. 727°, its permeability increases with great rapidity to a very high figure, when it suddenly drops to unity. In a subsequent paper, read March 21, he showed that the resistance also makes an abrupt change at the same temperature, which is that of recalescence, as discovered by Barrett.

Shelford Bidwell (R.S., March 14) showed a very pretty experiment by which the effect of radiations on the magnetization of iron were made evident. An iron bar is carefully annealed, cooled, magnetized, and then demagnetized by currents without any mechanical motion. The condensed beam from an oxyhydrogen lamp is thrown upon its pole, when magnetism at once appears. There is an instantaneous magnetic change, which is purely an effect of radiation.

A. Bernstein (*Centralblatt für Electrotechnik*, i. p. 165, 1889) has proved that the formula $C = a\sqrt{d^3}$ is not true for the fusing currents of wires of a diameter smaller than 0·25 mm. It is known that such fine wires absorb more energy than thicker ones to acquire the same temperature in air, and that the formula is $C = ad$. Bernstein has experimented with carbons of different diameters in the moderate vacuum of a glow lamp, and has obtained the following results:—

Diameter in mm.	Energy per sq. mm. of surface.
0·9	0·51
0·56	0·54
0·295	0·56
0·185	0·85
0·15	0.95

His conclusion is that lamps with thick carbons absorb less energy relatively than lamps with fine filaments, and are therefore more economical.

C. S. Bowie (*Electric World*, February 23, 1889) has found that the static electricity generated by calender rolls in a paper mill acts very injuriously on the life of glow lamps. They are now effectually protected with wire guards.

Among the numerous practical purposes to which electricity can be applied *tanning* must be added. Leather is said to be produced from the raw hide in four days.

If Prof. Oliver Lodge has failed to secure general faith in his lightning conductor theories, he at least has succeeded in directing scientific fashion to experimenting with Leyden jars. Righi (*Bull. Acad. dei Lincei*, xii. 16, 1888) has constructed a battery of 108 condensers, having a capacity of 18,810 electrostatic units. With it he has produced sparks 5 metres long over strips of glass coated with zinc filings, and 1 metre long over water. Platinum, iron, brass, gold wires, very fine and of 3½ metres length, are instantly vaporized into beautiful coloured coronæ of the same shape as that impressed on the wire. The wire becomes vapour at a high temperature, and forms as it were a vacuum tube, the sides of which are cold air.

ON THE CONFLUENCES AND BIFURCATIONS OF CERTAIN THEORIES.[1]

AXIOMS, says Proclus,[2] are common to all sciences, though each employs them in its peculiar subject-matter. A little further on[3] he cites Aristotle[4] as saying that one science is more certain than another, viz. that which emanates from more simple suppositions than that which uses more various principles; and that which tells the why, than that which tells only the simple existence of a thing; and that which is conversant about intelligibles, than that which touches and is employed about sensibles.

Proclus adds that, according to these definitions of certainty, arithmetic is more certain than geometry, since its principles excel by their simplicity. For the conception of unity has no reference to position in space, while that of a point involves such reference. In short, we may say that to count a number of objects is a simpler operation than to measure the distances between them.

All this, and much more, shows how early the notion of what is sometimes called a hierarchy of the sciences arose. Proclus's order of precedence would seem to be this, viz. logic,[5] arithmetic, geometry, mechanics, optics, dioptrics,[6] and so on; the progression being from the more to the less abstract, or from the abstract to the concrete.

Francis Bacon, mindful perhaps of Proclus,[7] and duly appreciating the power of mathematics as an instrument[8] and its value as a discipline,[9] expressly takes the degree of abstractness of a science as the mark for its classification. He places mathematics, as the most abstract of sciences,[10] at one end of the scale and "policy" at the other. He does not graduate the scale minutely, but it may be that, as in the case of the categories,[11] he attached no great value to such details. Distinguishing philosophy from theology, logic, and mathematics,[12] he assigns to it the axioms which are common to several sciences and the inquiry into essences, as quantity, similitude, diversity, possibility, and the rest. Science he divides between metaphysics, the science of the abstract and permanent, and physics, that of matter and its changes.[13] Bacon, in one place, names the one universal science by the name of philosophy, while in another he treats philosophy and metaphysics as two distinct things.[14] He uses the word metaphysics in a sense different from that in which it was then[15] received. Mathematics he places as a branch of metaphysics, and as having determined or determinate quantity for its subject. To the pure mathematics, he says, belong geometry and arithmetic; the one handling continuous, and the other discrete quantity.[16] If he means continuous quantity so far as it is immovable, he agrees with the Pythagoreans.[17]

Quantity, time, and space are placed by Aristotle among his categories, or are implied in them. With regard to space, he does not seem to have reached the Kantian view in any way, nor to be very clear in his meaning, though he apparently feels that to realize space we must have motion. His conception of time as one of the elements required for measuring motion, and his starting the problem as to whether we could have time without a mind to conceive, seem a more distinct approximation, though only an approximation, to Kant's view of time as merely a subjective condition of perception.[18]

Newton, in the Scholium to his definitions, distinguishes between absolute and relative time, the latter being time conceived in its relation to phenomena. Of absolute time (otherwise called duration) which has no relation to anything external, he says that it flows equably, and that its rate of flow and the order of its parts are immutable. In his "Fluxions" he uses the word time in a somewhat different sense, viz. as meaning the independent variable, characterized by an equable increase, fluxion, or flow.[1] Sir W. Rowan Hamilton treated algebra as the science of pure time, but his doctrine is not entirely[2] assented to by De Morgan, nor by Prof. Cayley, who indeed, in his Southport Address (p. 19), intimates dissent from it. Proclus does not connect arithmetic with time, and Prof. Cayley suggests (*ib.* p. 18) that, in any case, the notion of number or plurality is not more dependent on time than on space. By the logicians, time seems to be regarded as the more abstract of the pure intuitions. In fact, time is implied in memory and in thought itself, and Prof. Francis W. Newman observes that no man could get through a syllogism if he forgot the first premiss while dwelling on the second.[3] Moreover, he has recourse to the idea of time when he comes to discuss propositions,[4] and Boole investigates the nature of the connection of his own secondary propositions with the idea of time.[5] The ancient Indians had their cyclical periods, but not therefore necessarily any notion of a uniform curvature (so to say) of time.

Absolute space, says Newton, perpetually remains similar to itself and immovable; and, further on in the Scholium, he adds that the order of its parts is immutable. In the preface to the "Principia" he had observed that the description of straight lines and circles, on which geometry is founded, belongs to mechanics, and he follows up this train of thought. But, whether he means to detach himself from Plato, I must leave others to say. It is said to be certain that he was familiar with Bacon's works; that he uses the word axiom, not in Euclid's sense, but in Bacon's, thus giving the name of axioms to the laws of motion, which, of course are ascertained by the scrutiny of nature, and to those general experimental truths which form the groundwork of optics.[6] Now Bacon says that, in his judgment, the senses are sufficient to certify and report truth, either immediately or by way of comparison.[7] Moreover, he suggests that the rule *Quæ in eodem tertio conveniunt, et inter se conveniunt*, a rule so potent in logic as that all syllogisms are built upon it, is taken from the mathematics.[8] In seeking an origin for the more abstract in the less abstract, Bacon is not solitary. Thomas Stephens Davies suggested[9] that the argument from superposition had its origin in mechanical considerations, and from the fitting together of material figures. Moreover, it is conceivable that some observant person among the ancient Egyptians, whose custom it was to stamp their bricks, noticing the resemblances of the marks and the correspondence of the impressions with the impressing tool, may have been led to a recognition of the rule quoted by Bacon. The doctrine that there enters into geometry an element derived from the senses has, indeed, appeared in books designed for ordinary readers. Thus, Prof. Newman, writing in 1836–38, although in one part

[18] For this summary of Aristotle's views I am indebted to Mr. Reginald H. Roe, who referred me to Ueberweg's "Hist. of Phil.," p. 164, for a more general statement, and to p. 165 for a list of the best books for its fuller elucidation, adding that in Ritte and Preller's extracts, pp. 288 and 289, will be found all the important passages from Aristotle bearing on the question. As to the views of Boole, see his "Laws of Thought" (London, 1854), pp. 162 *et seq.*; see also p. 419. Boole treats of space at pp. 163, 175, and 418; and at p. 175 he quotes Aristotle's statements respecting the existence of space in three dimensions.

[1] Newton, "Fluxions," pp. 26 and 38 of the small edition (London, 1737). This is a genuine work of Newton's. As to its bibliography, see *Notes and Queries*, 2nd S., vol. x. pp. 163, 232, 233; 3rd S., vol. xi. pp. 514, 515; 4th S., vol. ii. p. 316; 5th S., vol. iv. p. 401; 6th S., vol. iv. pp. 129, 130; vol. v. pp. 263, 264, 304, 305, and 426. This octavo edition is very scarce. Indeed, I only know of two copies, viz. my own copy and one in the library of the Royal Astronomical Society.

[2] De Morgan, "On the Foundation of Algebra," Cambridge Transactions, vol. vii. pp. 173–87; see pp. 175, 176. The remarks of Prof. Cayley on Whewell, at p. 18 of his Southport Address, are applicable to Rowan Hamilton.

[9] T. S. Davies, Geometrical Notes, *Mechanics' Magazine*, vol. liii. (1850), pp. 150, 169, 262, 291, 442. Davies points out "the connection between parallels and similar triangles." He thinks that Aristotle's secession from the school of Plato arose from his enforcement of his own logical doctrines. Davies rejects the notion of a geometry built upon definitions alone without the assistance of axioms.

of his "Logic" (p. 25), he says that in geometry no results are admitted by help of observation and testimony, but only by reasoning from the definition, yet he afterwards (p. 55) states that, as space and its properties appear undeniably to be learned by sense, the argument seems to him to preponderate for naming geometry a mixed science, and believing that its propositions are real and not verbal truths. And Potts[1] says that geometry seems to rest on the simplest inductions from experience and observation, and that its principles are founded on facts cognizable by the senses.

But it is to Reid[2] that the idea of a more precise mathematical treatment of the subject is due, and his name ought to head the roll on which will be inscribed the names of Lobatschewsky, Riemann, and other investigators. Kant, indeed, disposes of such questions summarily, by saying that it follows from his premisses that the propositions of geometry are not the determinations of a mere creature of our feigning fancy, but that they necessarily hold of space, and consequently of all that may be met within it, because space is nothing else than the form of all the external phenomena, in which alone objects of sense can be given ("Prolegomena,"[3] p. 51). He adds (pp. 51 and 53) that external phenomena must necessarily and precisely agree with the propositions of the geometer. Whether Kant's allusion to "superficial metaphysicians" points to the Pyrrhonists and Epicureans[4] or to others, and, possibly, even to Reid, whom he had mentioned before (Preface, p. viii.), does not appear. Whatever opinions be formed of Kant's theory, or of the nature of space, his view is impressive. Confine that view to two dimensions, and suppose the surface of a sphere to be inhabited by a being destitute of any conception of a third dimension, and whose senses are unaffected by any point not situated or any motion not taking place on that surface. He could only estimate direction and position by the tangent to the path of the visual ray at the point where that path meets his visual organ, and would think that all objects were situate in one plane. His geometry would be Euclidian; for, if he could form a notion of the actual paths of rays, he would have a conception of the third dimension in space.[5] Here Kant and Riemann would apparently be at issue; for, if a more general conception of space is to be rendered special by actual measurements on the sphere, then, after an enlarged experience, the Euclidian conception would have to be expelled and replaced by some other. And all this would have to be done without praying in aid the excluded third dimension.

Aristotle[6] notices that the nature of everything is best seen in its smallest portions, and Kant[7] remarks that there was a time when mathematicians, who were philosophers too, began to doubt, not the truth of their geometrical propositions as far as they regard space, but the objective validity and applicability of the conception itself, and of all its determinations, to nature; as they were apprehensive that a line in nature might consist of physical points, and that consequently true space in the object might consist of simple parts, though space as conceived by the geometer cannot so consist. Clifford[8] would have given due weight to the doubts of the philosophical mathematicians. He even suggests that the properties of space may change with time. Now, a number may be a function of an angle; the very angle itself determines those numbers (ratios of lines) which we call sines and cosines. But, says De Morgan,[9] in every case but this it is impossible to conceive number a function of magnitude. It seems almost equally difficult to entertain Clifford's conjecture, which, nevertheless, measurements might verify. The sentence, *Nam tempora et spatia sunt sui ipsorum et rerum omnium quasi Loca*, in Newton's Scholium, though it may suggest that omnipresence does not involve extension in space, implies no functional relation between space and time. The words "then and there," accompanying every material allegation in indictments, would suffice to show that the opinions of the world at large on certain characteristics of time and space[1] were in accord with that of the philosophers. Indeed, their isolation, as forms of intuition, may no more be a peculiarity of Kant's system than is his distinction between analytical and synthetical judgments. This distinction was present to the mind of Bacon,[2] as well as to that of Locke, whom Kant cites ("Prolegomena," p. 25), and who, elsewhere than in the place cited, adverts to the distinction. That which Locke had styled a trifling proposition, Kant called an analytical judgment; and that which Locke ("Essay concerning Human Understanding," book iv., chap. viii., Sect. 8) styled a real truth, Kant would would have called a synthetical judgment. With Hume, too, Kant is in some respects in close relation. Hume ("Treatise," vol. i., book i., part 2, pp. 53–124) treats specially of the ideas of space and time. Hume, again ("Inquiry," p. 17; Essay iv., p. 50), distinguishes between results attained by reasonings *a priori* and results arising entirely from experience ("Inquiry," p. 17; Essay, p. 49). He seems to allow conception a sufficiently wide range, for he urges ("Inquiry," p. 13; Essay ii., pp. 26, 27) that, in one exceptional instance, there may be an idea not arising from a corresponding impression; viz. in the case when from the impressions of two distinct shades of a particular colour, a conception is formed of an intermediate shade of the same colour. He asserts ("Inquiry," p. 118) that the only objects of the abstract sciences or of demonstration are quantity and number.

If, as Clifford[3] seems to think, there are no sufficient grounds for maintaining that, if our space has curvature, it must be contained in a space of more dimensions and no curvature, one difficulty is apparently removed. The one-dimensioned time is something very different to space, from which the higher-dimensioned entity might differ still more; and if a solid be treated as the shadow or projection in Euclid's space of, say, a four-dimensioned body, that part of the body which lies outside the shadow seems to have no quality analogous to impenetrability or inertia, nor indeed any quality which affects the senses or deranges the results of calculation. Prof. Cayley says (Southport Address, p. 11) that Riemann's idea seems to be that of modifying the notion of distance, not that of treating it as a locus in four-dimensional space. The suggestion (Cayley, *ib.* p. 10) of a rule changing its length by an alteration of temperature facilitates apprehension. Prof. von Helmholtz has considered the effect of the changes in sensible phenomena which a transition to a spherical or pseudo-spherical world, if such things be, would produce; and he has taken an independent view of the subject in other respects.[4]

De Morgan[5] professed to have been puzzled to know on which side the meeting of parallels took place, or whether on both. He concludes that they never meet. This, however, does not shake, nor is it to be supposed that he wished[6] it to shake, the belief in modern methods, for he apparently admits that interpretation of forms may demand conclusions which can be reached by reasoning on infinity, if increase without limit show approach. He observes that it is clearly conceived by the logicians that all division is reducible to simple dichotomy and its repetitions, and that when the logician has once shown division, difference, he does not trouble himself with the difficulty of repetitions. De

[4] A paper in *Mind*, by Prof. von Helmholtz, elicited a criticism from Prof. Land, which produced a reply; and with a brief note appended to a paper on another subject, by Prof. Land, the discussion closed. See *Mind*, vol. i. pp. 301–21; vol ii. pp. 38–46; vol. iii. pp. 212–25 and 551–55; and vol. iv. pp. 591–96.

[5] De Morgan, "On Infinity," &c. (Camb. Trans., vol. xi. Part 1, 1865, pp. 145–89; *vid.* pp. 173, 176, 180, 147). In connection with this paper, the comments of Mr. W. S. B. Woolhouse in the *Educational Times* (Reprint, vol. vi. pp. 49–52) should be considered. And in connection with a paragraph at pp. 161, 162, of De Morgan's paper, the leading paragraph of p. 424 of a previous paper of his, "On the Theory of Errors of Observation" (C. T., vol. x. Pt. 2, 1862), should be read. In the last-mentioned passage he distinguishes between the zero and the indivisible of probability. Hamilton, of Edinburgh, following earlier authorities, expressly restricts the application of logic to finite things. But it does not therefore follow that logicians in general turn a deaf ear to all reasoning upon infinities and infinitesimals, and that they reject results stamped with authority and universally accepted.

[6] This sufficiently appears from a statement at p. 15 of his paper, "On the Root," &c. (Camb. Trans., vol. xi. Pt. 2).

Morgan's remark is easily verified by turning to Potts's Note on Euc. i. 10 (p. 49). Turning again to Boole ("L. of T.," p. 91), it would seem that the logician does not completely detach himself from the notion of infinity: he has to interpret 1 : 0 as well as 0 : 0.[1]

Bacon differs from Plato, who considered forms as absolutely abstracted from matter, and not as confined and determined by it, and agrees with Aristotle in saying that words are the images of thoughts;[2] so that the agreement of the views of Bacon with those of Prof. Max Müller would seem to be tolerably close. It is easy to find cases in which a doubtful meaning of a word may give rise to disagreement on matters of substance. Boole ("L. of T.," pp. 407, 408) observes that the term "necessary" may be applied either to the observed constancy of nature or to the logical connection of propositions. He expresses no decided preference for either meaning. The meanings should be kept carefully apart. If an axiom be a necessary truth, in the strictest sense, then Newton's laws of motion are laws *a priori*, viz. giving Kant's meaning to the term ("Prol.," p. 103); they are known independently of all experience. But Laplace ("Méc. Cél.," pp. 14–18[3]) treats them as results of experience. Moreover, he treats (pp. 65–69) the laws of motion under all the relations mathematically possible between force and velocity. Newton, in fact, usually speaks of "law," and gives the term "axiom" Bacon's meaning.

Boole's chapter xx. ("L. of T.," pp. 320–75) relates to problems on causes, but his use of the word "cause" has given rise to much discussion. He proposed a question on causes in 1851, which was answered by Prof. Cayley in 1853. The solution was criticized by Boole in 1854, who arrived at a different result, and in 1854, Mr. H. Wilbraham examined both solutions. Prof. Cayley returned to the subject in 1862, and Boole thereupon admitted that it would have been better, in stating his problem, not to have employed the word "cause" at all.[4] One mode of stating the nature of the relation between "cause" and "effect" may be this, viz. when a certain (antecedent) change is immediately and invariably followed by a certain other (subsequent) change, then the relation in which the antecedent stands to the subsequent (which may now be called the consequent) change is that of cause and effect. This is, in substance, if not in form, a view common to Algazel, Glanvil,[5] Hume,[6] Brown,[7] Kant, and, as I believe, Reid; for the question seems to be one about words. It differs but slightly from the view (C. T., vol. x., part 2, p. 300) of De Morgan. Perhaps "unvarying" might be a better word than "invariable," for one instant of time is the immediate and invariable antecedent of its consecutive instant; but the idea of "cause" does not seem to arise. When "cause" is used in the above sense, the solutions of Boole and Prof. Cayley agree. Boole's question has been dealt with in our Proceedings (vol. xi. p. 118) by Mr. McColl.

The import of the word "principle" is not the same when we speak of the principle of contradiction or of excluded middle, as when we speak of the principle of the permanence of equivalent forms, or of the sufficient reason, or of continuity. That of sufficient reason has been assailed by Brown ("C. and E.," sect. iv. pp. 222, misnumbered 322, to 306), and by De Morgan (C. T., x., part 2, pp. 290–304). Clifford (*op. cit.*, p. xl.) was prepared to sacrifice the principle of continuity, even in the case of space, and the author of anonymous "Strictures" on Peacock's "Algebra" (Camb., 1837), who was (so at least I was told many years ago by Davies) Hind, concludes (p. 21) that number is perfectly abstract, that it is the only thing which is so, that it is not rightly denominated a species of quantity, being equally connected with every species. An instance of a striking failure of the principle of the permanence of equivalent forms is given by Dr. J. W. L. Glaisher in the *Messenger of Mathematics*, N. S., vol. ii. (1872) p. 95. Again, take another word —viz "disparity." Supposing it to be said that there are two persons in a room, whose united ages are twenty-one years, and between whose ages there is the greatest disparity possible. This is intelligible if one be a new-born or nascent infant, and the other a person aged twenty-one. But suppose the same statement made of three persons; the proficient in language might have to inquire of the mathematician what meaning, if any, the statement bears. Or, again, the mathematician might be asked what, or whether any, numerically definite meaning can be attached to the words, "triangle of maximum scalenity."

Prof. Newman ("Logic," 1838, p. 52) says that the truths of arithmetic are verbal. Perhaps this, and the corresponding statements of Dugald Stewart, would not now be insisted on. They are opposed to the views of Kant, Clifford, and De Morgan (C. T., xi., part 1, p. 160). The identities $3^2 + 4^2 = 5^2$, and $3^3 + 4^3 + 5^3 = 6^3$, seem to be something very different from definitions of words. Kant considers $7 + 5 = 12$ to be a synthetical judgment ("Proleg.," pp. 22, 23).

Metaphysics and mathematics are consorts in the East as well as in the West. Bhascara says that the analytical art is merely sagacity exercised, and is independent of symbols, which do not constitute the art.[1] If De Morgan[2] be right in placing Diophantus as late as the beginning of the seventh century, Aryabhatta was earlier, by two centuries, than Diophantus. The name certainly seems to have been a very common one. Josephus[3] relates that Alexander (a son of Herod the Great) said that Diophantus the scribe had imitated his hand. But Mr. Heath's work[4] renders it scarcely possible to sustain De Morgan's contention.

[1] See the last footnote but one.

EXHIBITION OF METEOROLOGICAL INSTRUMENTS.

THE Royal Meteorological Society's tenth annual Exhibition of Instruments was held in the rooms of the Institution of Civil Engineers, 25 Great George Street, Westminster, from the 19th to the 22nd instant. This Society's Exhibitions are always interesting and instructive, as each one is devoted to some special class of instruments: this year the instruments consisted principally of actinometers and solar radiation apparatus. Specimens of most of the various forms of these instruments were exhibited; but when it was not possible to obtain an instrument itself, a photograph or drawing of it was shown, so that the visitors to the Exhibition could readily see what instruments have actually been made.

Several specimens were exhibited of Sir John Herschel's actinometer, for ascertaining the absolute heating effect of the solar rays, in which time is considered one of the elements of observation. This consists of a large cylindrical thermometer bulb, with a special open scale, so that minute changes may be easily seen. The bulb is of transparent glass filled with a deep blue liquid, which is expanded when the rays of the sun fall on the bulb. When taking an observation, the actinometer is shaded for one minute and read off; it is then exposed for one minute to sunshine, and its indication recorded; it is finally shaded again, and its reading again noted. The mean of the two readings in the shade, subtracted from that in the sun, indicates the expansion of the liquid produced by the sun's rays in one minute of time.

The Kew Committee exhibited Hodgkinson's actinometer, the principle of which is the same as that of Sir J. Herschel's,

and also Pouillet's direct pyrheliometer, which consists of a cylindrical box of steel filled with mercury, into which the bulb of a thermometer is introduced, the stem being protected by a piece of brass tubing. As the surface on which the sun's rays fall and the quantity of mercury in the cylinder are both known, the effect of the sun's heat upon a given area can be expressed by stating that it is competent in five minutes to raise so much mercury so many degrees in temperature. The Rev. F. W. Stow showed an improved form of Pouillet's pyrheliometer, in which the instrument is placed in a silvered tube to shield it from wind and from all solar rays, except when the tube is turned directly towards the sun. Mr. Casella exhibited Secchi's solar intensity apparatus, in which two thermometers are kept immersed in a liquid at any convenient temperature, and a third, of which the stem passes through the same liquid and the bulb is outside it, is exposed to the rays of the sun shining down the hollow cylinder. The increase of temperature thus obtained is found to be the same, independent of the temperature of the liquid which surrounds the thermometer.

The British Association Solar Radiation Committee showed Prof. Balfour Stewart's actinometer; and Dr. Ångström, of Stockholm, sent one of his pyrheliometers and a photograph of another pattern.

Luvini's dietheroscope for observing the changes of atmospheric refraction optically, and Bellani's lucimeter, as arranged by Prof. G. Cantoni for use at the Italian meteorological stations, were exhibited by the Meteorological Council; and Mr. Hicks showed some of Crookes's radiometers.

Dr. A. Downes illustrated his method of slow actinometry by oxalic acid, in which a definite quantity of a standard solution of oxalic acid is exposed to the action of light for a definite period; subsequently it is used to bleach a standard solution of permanganate of potash. The quantity of oxidized oxalic acid solution, compared with the quantity originally required to produce the same effect, is a measure of the intensity of the light.

Engravings illustrating Violle's, Crova's, and Frölich's actinometers were also exhibited.

The solar radiation thermometer consists of an ordinary maximum thermometer, with the bulb and about one inch of the stem coated with lamp-black, inclosed in a glass shield exhausted of air. Various specimens of this instrument were exhibited, with arrangements for testing the degree of exhaustion. Hicks's black bulb maximum thermometer *in vacuo* is supplied with platinum wires and a battery for testing the vacuum, while Negretti and Zambra's has a mercurial test gauge. Mr. Hicks also showed one of these instruments which had at the end of the outer jacket a second chamber in which is mounted one of Crookes's radiometers for testing the vacuum.

The Royal Meteorological Society showed a pair of black-bulb and bright-bulb maximum thermometers *in vacuo* as recommended for use at the Society's stations; while Messrs. Negretti and Zambra exhibited a similar pair of thermometers mounted in an upright position with the bulbs uppermost, as used at the Montsouris Observatory, Paris.

Mr. Casella showed Southall's helio-pyrometer for testing the accumulated heat of the sun in a confined blackened space, under glass. A black-bulb maximum thermometer is fixed on a cushion at the bottom of a box, the sides of which are also cushioned, and a thick piece of plate-glass is laid upon the top to prevent currents of air carrying off the heat. The box is placed in such a position that the sun's rays may strike as nearly as possible perpendicularly on the glass, when water contained in a small vessel will boil violently in the box.

The practical working of sunshine recorders may be said to date from 1854, when Mr. J. F. Campbell mounted a hollow glass sphere filled with acidulated water in the centre of a bowl of mahogany so arranged that the sun's rays were focussed on the interior of the bowl and burned it. The lines of burning therefore indicated the existence of sunshine. Solid glass spheres were substituted for the hollow ones in 1857, and in 1875 cards in metal frames were substituted for the wood. The Meteorological Council exhibited a number of wooden bowls showing the effect of sunshine by burning in the years 1855–56, 1883–84, and 1887–88; and the Astronomer-Royal sent the sunshine recorder with a hemispherical metal bowl which was in use at the Royal Observatory, Greenwich, from 1876–86. Specimens of the Campbell sunshine recorder with the improved Stokes's zodiacal frame for a fixed latitude, were shown by the Meteorological Council; a recorder with adjustments for use in any latitude, by Messrs. Negretti and Zambra; and the Whipple-Casella sunshine recorder, by Mr. Casella.

Mr. Jordan exhibited an experimental instrument for recording the intensity of daylight, the results being obtained by revolving a disk of sensitized paper behind a screen with a rectangular aperture. Messrs. Negretti and Zambra showed the various patterns of Jordan's photographic sunshine recorder, which consists of a cylindrical box, on the inside of which is placed a slip of cyanotype paper. Sunlight being admitted into this chamber by three small apertures, is received on the paper, and travelling over it by reason of the earth's rotation, leaves a distinct trace of chemical action. In the second pattern of this instrument two apertures are used instead of three; while in the new pattern two semi-cylindrical boxes are employed, one to contain the morning and the other the afternoon record. Prof. McLeod's photographic sunshine recorder was exhibited by Mr. Hicks. This consists of a glass sphere silvered inside and placed before the lens of a camera, the axis of the instrument being placed parallel to the polar axis of the earth. The light from the sun is reflected from the sphere, and some of it passing through the lens forms an image on a piece of sensitized paper within the camera.

Mr. A. S. Marriott showed two patterns of his instrument for comparing the active value of light at different stations; and the Kew Committee sent the chemical photometer devised by Sir Henry Roscoe.

Among the new instruments exhibited were Fineman's and Galton's nephoscopes for observing the direction of motion of clouds; Davis's improved air meters; Negretti and Zambra's recording hygrometer; Casella's Boylean-Mariotte barometer; and de Normanville's self-compensating sympiesometer. Mr. Murday showed in action his apparatus for obtaining readings of an aneroid placed at a distance by means of electric currents. An instrument, called the stephanome, which is used at the Ben Nevis Observatory for measuring the angular size of halos, fog-bows, glories, &c., was also exhibited.

Mr. Clayden showed a very ingenious and instructive working model illustrating the generation of ocean currents, which was a great attraction to all the visitors at the Exhibition. This model shows how the prevalent winds over the Atlantic are the chief cause of the circulation of the waters. A number of tubes are so arranged that when an attached blower is worked the circulation of air produced resembles that of the atmosphere; the imitation winds thus set up react upon the surface of the water, creating a system of currents which reproduces the main features observed in the Atlantic. Special attention was drawn to the Gulf Stream issuing from the Gulf of Mexico, and to the return current flowing eastwards between the equatorial currents. Mr. Clayden also showed some lantern slides illustrating the spiral circulation of the wind in both a cyclone and an anticyclone.

One of the chief features of last year's Exhibition was the large collection of photographs of flashes of lightning which had been gathered together by the Royal Meteorological Society from all parts of the world; this year the Society exhibited a number of similar photographs which have been received since May 1888. Near to these were placed a number of photographs of the electric spark taken by Mr. Wimshurst when the sensitive plate was rotating 2500 times per minute. These flashes are quite sharp and distinct, and show no sign of the movement of the plate.

A very interesting and valuable collection of sixteen photographs taken on the summit of Ben Nevis during the last eleven months were exhibited by the Directors of the Observatory, of which the following were of special interest: (1) cirrus cloud at the northern horizon, taken at midnight at the time of the summer solstice when the clouds are seen brightly illuminated; (2) St. Elmo's fire, at 11 p.m., on the top of the stove-pipe; and (3) views of the Observatory after continued fog and strong wind, but no fall of snow, when everything is covered with long crystals of ice formed out of the fog.

Mr. Bromhead exhibited two large photographs showing the thick rime on trees at Lincoln on January 7 last; and Mr. H. P. Curtis showed a photograph taken by moonlight.

Photographs of clouds were exhibited by Captain Wilson-Barker, Mr. Shepherd, and Captain Maclear.

The Exhibition also included a number of photographs and drawings of instruments, &c., as well as some models of hailstones, 7 inches in circumference, which fell near Montereau, France, on August 15, 1888.

WILLIAM MARRIOTT.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The recent discussion on the proposed new buildings for anatomy and physiology disclosed that the Financial Board do not consider that the whole plan can be proceeded with at present. They hold that only £10,000 is available; but this is because it is proposed to diminish the annual contributions from the Colleges for some years. It appeared to be agreed that the lecture-room or middle block could be best dispensed with if absolutely necessary, the blocks of physiological and anatomical class-rooms and dissecting-rooms being most essential. Prof. Foster mentioned that the labour of conducting the practical classes in physiology was so great as to leave no time for research, and to strain the health of himself and his demonstrators almost to the point of breaking down. The present buildings not only limited but spoiled their work.

The adjudicators of the Hopkins Prize in connection with the Philosophical Society have recommended that it be awarded to Sir William Thomson for his mathematical researches upon the theory of the tides, and other important investigations in mathematical physics.

The General Board of Studies has issued a report deprecating the proposed diminution of College contributions, and showing that that proposal will destroy any chance of appointing new teachers, or increasing the small stipends now paid to University lecturers and readers, or of making any payments in aid of research. A great number of detailed needs for all the departments are specified, the scientific Boards being well represented. The Reader in Botany and the Lecturer in Animal Morphology and others are strongly recommended for immediate increase, and a capital expenditure of £30,000 is needed for museums, laboratories, lecture-rooms, &c.

The following is the subject for the Adams Prize to be adjudged in 1891:—The motion of a satellite about a spheroidal planet, and the reaction on the planet. The ordinary approximation is supposed to be inadequate, either because the ellipticity of the planet is too great, and the distance of the satellite too small, or because the obliquity of the orbit is too great. It is also desired that the influence of a distant disturbing body (such as the sun) may be taken into account in so far as is found practicable. The successful candidate will receive about £170, but is required to print the essay at his own expense.

The report on the local examinations of last December states that in chemistry the answers were on the whole satisfactory, but chemical calculations were in general inaccurately performed. In heat, the juniors answered badly, the senior boys better, but many of the senior girls were quite ignorant of the subject. In statics, dynamics, and hydrostatics, the juniors had not grasped the elementary ideas, while the seniors did better, except in the arithmetic of calculations. The answers seem to show that these physical subjects are not suitable for juniors. In electricity and magnetism, taken only by seniors, the boys did well. The botanical answers varied greatly at different centres, and questions on flowering plants were much better answered than those on cryptogams. In zoology the elements were known, but many answers were very wordy and irrelevant. Several seniors described the structure of a Vorticella rather well, but also named and described the mouth-appendages of a crayfish (the specimen being before them) likewise as a Vorticella.

SCIENTIFIC SERIALS.

American Journal of Science, March.—Some determinations of the energy of the light from incandescent lamps, by Ernest Merritt. Two series of experiments are described, which have been carried out for the purpose of determining what portion of the energy supplied to a lamp is given off as light, and what proportion is wasted practically as dark heat. In the first, based on Melloni's calorimetric method, the light is separated from the dark heat by passing the radiations to be measured through a thin layer of water, or, better still, through a solution of alum in water. The energy of the dark heat, which is almost entirely absorbed, is then measured by the rise in temperature of the water, and that of the light by a thermopile. In the second process the calorimeter was abandoned, and a cell, 1 decimetre thick, containing a strong solution of alum, was used for absorbing the dark heat. The light, after passing through this cell, was allowed to fall on a thermopile, and the deflection was observed. Then the alum cell was removed, and the deflection corresponding to total radiation was observed, the ratio of the two deflections giving the ratio of the light energy to the total energy. This being determined by electrical measurements, the energy of the light could be calculated.—On the ophiolite of Thurman, Warren County, New York, with remarks on the *Eozoon canadense*, by George P. Merrill. This ophiolite, a kind of verdantique marble, is found to be an alteration, or metasomatic product after a mineral of the pyroxene group. Its constitution promises to throw some light on the Eozoon problem.—On the origin of the deep troughs of the oceanic depression; are any of volcanic origin?, by James D. Dana. A general survey of the oceanic regions leads to the inference that volcanic action can only have had a very subordinate part in determining the origin and position of the great marine depressions. Their source must be sought still less in superficial causes, such as erosion, but rather in the interior agencies of primordial development. The paper is accompanied by a bathymetric map of the Pacific and Atlantic, based on the recent charts of the British and United States Hydrographic Departments.—Description of a problematical organism from the Devonian, at the Falls of the Ohio, by F. H. Knowlton. These puzzling organisms, here provisionally named *Calcisphæra lemoni*, from the collector, have been submitted to various American and European palæontologists, and the evidence both for and against the view that they are a fruit of Chara, is given in detail.—Papers are contributed by George H. Williams, on the geology of the Island of Fernando de Noronha (part 2, petrography); by S. L. Penfield, on some curiously developed pyrite crystals from French Creek, Delaware County, Pennsylvania, and on some crystallized bertrandites from Maine and Colorado; and by J. S. Diller and J. E. Whitfield, on dumortierite from New York and Arizona, peridotite from Kentucky, and gehlenite occurring in furnace slag in Pennsylvania.

THE *Memoirs of the Novorossian* (Odessa) *Society of Naturalists*, vol. xiii. fasc. 1, contain a series of papers on the late L. Cienkowski, by P. Boutchinsky, W. Zalensky, L. Richavi, G. Sadkowsky, and S. Karwatzky, being full reviews of the late Professor's extensive scientific work, and giving a full bibliography of his contributions to science.—The next papers of importance are: on the rainfalls in South-Western Russia, by A. Klossovsky; on the copulation of the nuclei of cells during the sexual processes of Fungi, and on the absorption of water by the overground parts of plants, by W. Chmielevsky; on the Jurassic beds of Orenburg and Samara, by I. Sintsoff, being revised lists of fossils found in various parts of these provinces; on the action of methylene-iodide upon the ether of malonic acid, by S. Tanatar; and on the influence of the medium, and especially of temperature, upon *Planorbis vertia*, by Mary Balashova.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 7.—"On the Cranial Nerves of Elasmobranch Fishes. Preliminary Communication." By J. C. Ewart, M.D., Regius Professor of Natural History, University of Edinburgh. Communicated by Prof. Burdon Sanderson, F.R.S.

This paper contains a short account of the cranial nerves of *Læmargus microcephalus* and of *Raia batis*, and it is especially shown that in connection with the roots of the trigeminal and facial nerves there are altogether five large ganglia—one of them apparently representing two ganglia—and that in connection with the vagus there are three separate ganglia in Læmargus and six in Raia. It is further pointed out that the nerve to the lateral line arises by a special root quite distinct from the rest of the vagus complex, and that it is provided with a separate ganglion, and also that the mucous canals of the head and trunk, together with the numerous ampullæ of the sensory tubes, are either supplied by nerves belonging to what is termed the facial complex or the lateralis division of the vagus complex.

Attention is especially directed in Læmargus to the following facts: (1) that the ganglion of the ophthalmicus profundus lies only very slightly in front of the ganglion (Gasserian) of the trigeminal; (2) that there is no connection between the oculo-motor nerve and the ophthalmicus profundus ganglion; (3) that the ciliary nerves spring from the trunk of the ophthalmicus profundus some distance in front of its ganglion; (4) that neither in

any part of the trunk or main branches of the oculo-motor nerve nor in connection with the branches which pass from the oculo-motor to join the ciliary branches of the ophthalmicus profundus are there any ganglionic cells; (5) that the so-called facial consists of four separate nerves, the ophthalmicus superficialis, buccal, palatine, and hyomandibular—the last receiving a special bundle of fibres while still in the cranial cavity from the ophthalmicus superficialis; (6) that there are numerous ganglionic cells at the base of the palatine nerve—the nerve which is said to correspond to the great petrosal nerve of higher Vertebrates; and (7) that the lateralis nerve supplies the aural mucous canal as well as the canal of the lateral line.

In Raia the following points are brought out, viz., (1) that the ganglion of the ophthalmicus profundus, which is some distance in front of the Gasserian ganglion, lies over the deep branch of the oculo-motor nerve, from which minute branches pass *under* the ophthalmicus profundus ganglion to join two or more of the ciliary branches of the profundus; (2) that the ciliary branches usually arise from the under surface or outer edge of the ganglion of the ophthalmicus profundus, none of them except on rare occasions springing as in Læmargus from the trunk in front of the ganglion; (3) that were the root and trunk of the ophthalmicus profundus greatly reduced in size an arrangement similar to that which exists in the higher Vertebrates would be produced, and the ganglion of the ophthalmicus profundus would appear to especially belong, as has often been taken for granted, to the oculo-motor nerve; (4) that the nerve, generally stated to correspond to the chorda tympani of higher Vertebrates, consists chiefly of fibres which spring from the large ganglion at the base of the hyomandibular nerve; (5) that the ganglion of the lateralis lies several inches (three or four) from the origin of the nerve, and that in addition to supplying the canal of the lateral line the lateralis supplies the dorsal pleural mucous canal, the aural canal, and part of the occipital; (6) that the five additional ganglia of the vagus complex are disposed as follows, one for each of the four branchial nerves, and one for the intestinal nerve.

In this preliminary communication the segmental value of the various cranial nerves is not considered, but it is pointed out that further investigations may show that the ganglia in connection with the superficial ophthalmic buccal palatine and hyomandibular nerves are related to the geniculate, otic, spheno-palatine, and sub-maxillary ganglia of the higher Vertebrata.

Physical Society, March 9.—Prof. Reinold, President, in the chair.—Prof. O. J. Lodge read a paper on magneto-optic rotation by transient currents, with reference to the time required for the production of the effect. If a piece of heavy glass, or tube of carbon bisulphide, be placed between two crossed Nicols, and surrounded by a solenoid, light passes through when a Leyden jar is discharged through the wire. That the discharge is oscillatory, may be proved by turning the analyzer slightly to one side or the other, this having no effect on the result; or the beam may be examined by a revolving mirror, in which case a beaded band is seen when the discharge takes place. When the spark itself is analyzed in the same way, a serrated band results. The frequency of the oscillations being given by the formula—

$$n = \frac{1}{2\pi\sqrt{\frac{LS}{\mu K}}},$$

it is evident that n will be decreased by increasing the capacity S and self-induction L, and this fact was demonstrated by connecting two condensers, first in series and then in parallel, and placing coils of wire in the circuit. The pitch of the sound emitted by the spark was by these means brought within the musical scale. Contrary to expectation, the insertion of a coil with an iron core produced little or no change in the pitch, the reason given being that the induced currents in the skin of the iron wire due to such rapid oscillations of current prevent the interior being magnetized. From the mathematical theory of the brightening of the dark field, it appears that the relative brightness, B, when compared with the light field obtained from the uncrossed Nicols, is given by—

$$B = \frac{1}{\tau}\int_0^\tau \sin^2 \theta dt,$$

where τ is the time during which an impression can be accumulated on the retina, and θ the angle through which the polarized beam is rotated. When θ is considered small,

$$B = 16\pi^2 k^2 n^2 \frac{\frac{1}{2}SV_0^2}{R\tau},$$

where k = Verdet's constant, n = number of convolutions on the solenoid, R = resistance of circuit, and $\frac{1}{2}SV_0^2$ = the initial energy of the static charge. The general solution is given as—

$$B = \frac{1}{2m\tau}\int_0^A \frac{1 - J_0(x)}{x} dx,$$

where $m = \frac{R}{2L}$, $A = 8\pi k n \mu V_0 \sqrt{\frac{S}{L}}$, and $J_0(x)$ Bessel function.

Taking the approximate solution, the question as to what is the best size of wire wherewith to wind the solenoid is considered, and as the insulation is very important, it is concluded that the secondary of a Ruhmkorff coil is very suitable. The main interest of the experiment is said to lie in the evidence afforded of the practical instantaneity of the development of the rotary property in the substance under examination, for Villari (from experiments made on a glass drum revolving in a magnetic field) inferred that a distinct time, between 1/800 and 1/400 of a second, was necessary, whereas Profs. Bichat and Blondlot, of Nancy, have concluded that the time required is less than 1/30000 of a second. The author finds that carbon bisulphide is able to show the effect when the rate of alternation is 70,000 per second, and has no reason to believe that glass is in any way inferior. As a possible explanation of Villari's results, he suggests that the strain due to centrifugal force would modify the components of the polarized beam, and produce elliptic polarization. Mr. Ward mentioned that experiments similar to Villari's were now being carried out at the Cavendish Laboratory, a disk of glass being rotated about two hundred times per second by means of a turbine. The results so far obtained do not confirm Villari's, but, owing to difficulties in keeping the speed constant, it is difficult to make exact measurements. It has, however, been found that the strain due to centrifugal force rotates the plane of polarization, and elliptically polarizes the beam; and that passing an alternate current round a stationary glass bar produces a distinct rotation of polarized light passing through it. Referring to the oscillatory discharge of a jar, Prof. Rücker directed attention to Dr. E. Cook's experiments, described before the Society in June 1888, when photographs showing the dust-figures produced by sparks were exhibited, and pointed out that the frequency required to produce air-waves of the length there indicated was of the same order as the rate of oscillatory discharge—viz. about one million per second. Prof. Rücker also wished to know whether glass behaved precisely like CS_2. Dr. Lodge said his experiments were not exact enough to decide the latter question, and mentioned that Mr. Chattock had, some time ago, produced dust-figures in tubes by jar-discharges, and shown that the wave-length depended on the capacity and self-induction. Prof. Ayrton suggested the use of a phonograph as a means of recording and reproducing the oscillations, in the same way as himself and Prof. Perry have analyzed the current-curves of alternating dynamos. The discharge could be passed through a small coil fixed to a diaphragm, and placed near a coil through which a steady current was passing, the attractions and repulsions serrating the surface of the rapidly revolving cylinder. By means of a mirror attached to a delicate magnifying spring, the section of the surface may be determined. He also inquired whether the experiments shown do prove that the effect is instantaneous. Dr. Thompson remarked that it was satisfactory to learn that Villari's results admit of an interpretation other than by time effect, and thought it advisable to vary the experiment by rotating a bar of glass; but Mr. Ward said he attempted that experiment four years ago, and abandoned it on account of the enormous speed required.—Dr. Lodge showed some experiments allied to those of Hertz, and pointed out that all the effects were due to resonance. The plates of an air-condenser were connected by a wire loop, and placed near a Holtz machine in action. On adjusting the distance between the plates to a particular value, sparks were observed to pass between them; but, on increasing or decreasing that distance, the sparks ceased. It was also shown that the sparking was interrupted if the connecting loop was replaced by a coil, though the coil was effective when connected to a condenser of smaller size, thus demonstrating that the time-constant of the condenser circuit was all-important. Another important condition to be observed in such experiments is, that the receiving circuit must be closed, except at the sparking place, so as to permit the surgings of the electricity to take place freely. Other experiments were shown, in which two spheres provided with rods terminating in knobs were used as a Hertz's oscillator, and sparks could be obtained from straight pieces of wire of

suitable length held at some distance from the spheres. Dr. Lodge remarked that sparks could be obtained from almost any scrap of wire or metal in close proximity to an induction-coil and oscillator; but, to produce the effects at considerable distances, careful timing of the receiving circuit was necessary. The author also mentioned the results of some experiments on the velocity with which electric waves travel along wires, and concluded (contrary to Hertz) that this was not greatly different from the velocity of light.—Owing to the late hour, the other papers announced to be read were postponed.

Entomological Society, March 6.—The Right Hon. Lord Walsingham, F.R.S., President, in the chair.—Mr. F. P. Pascoe exhibited several specimens of the Saüba Ant (*Œcodoma cephalotes*) from Parà, carrying portions of dried leaves. It seemed questionable whether the leaves were collected by the ants for the purpose of making their nests, or for the sake of some Fungus which might be growing on them.—Mr. Jenner-Weir exhibited, and read notes on, specimens of a Butterfly (*Tirumala petiverana*) from Mombaza, Eastern Africa.—Mr. J. H. Durrant exhibited a living larva of *Cossus ligniperda*, which had entirely lost its ordinary colour, and had become first pink and then white. He attributed the change, and subsequent loss, of colour to the fact that it had been deprived of its natural food, and fed for eighteen months on pink paper, with which the box in which it was kept was lined, and subsequently on white cardboard. Mr. McLachlan remarked that the most extraordinary peculiarity about this larva, in addition to the loss of colour, was the absence of the usual odour of *Cossus*. Lord Walsingham observed that it was questionable whether the colours of larvæ were dependent on the colours of their surroundings, or whether they were affected by the contents of the intestinal canal. Prof. Meldola, F.R.S., said that the caterpillar exhibited, having eaten the pink paper, had most probably become dyed by the colouring matter, and he did not think the observation had much bearing on the question of the protective colouring of caterpillars. It was well known to physiologists that certain dye-stuffs could be introduced into the tissues of animals by mixing the colouring-matters with the food, and paper was frequently stained with coal-tar dyes, such as eosin, magenta, &c., so that it was simply a case of direct dyeing of the larva.—Mr. B. A. Bower exhibited a specimen of *Parasia neuropterella*, bred from heads of *Centaurea scabiosa*, and said he believed the species had not been previously bred. He also exhibited series of *Coleophora olivaceella*, *C. solitariella*, and *Laverna subbistrigella*.—Mr. White exhibited a series of male and female specimens of *Orgyia thyalina*, obtained by the late Mr. H. J. Pryer in Japan. Some of the females had their wings fully developed, and some of them were semi-apterous, as is usual with the females of this genus. Mr. White remarked that he knew of no other species of the genus in which the females had fully-developed wings. Lord Walsingham, Prof. Meldola, and Mr. R. South took part in the discussion which ensued.—Lord Walsingham exhibited specimens of preserved larvæ of *Eupithecia extensaria*, from King's Lynn; also a preserved larva of *Smerinthus ocellatus* and one of *Sphinx ligustri*. The larva of the last-named species was a variety, and the President remarked that it was the only one of this species he had ever seen.—The Secretary read a communication from the Rev. Dr. Walker, announcing his intention of making an expedition to Iceland this year, from June 23 to July 29, and asking that any entomologists who might wish to accompany him would send him their names.—Mr. Distant suggested that the meeting should pass a resolution expressing regret at the death of the Rev. J. G. Wood.—Mr. Gervase F. Mathew, R.N., communicated a paper entitled "Descriptions and Life-histories of New Species of Rhopalocera from the Western Pacific."

Zoological Society, March 5.—Prof. Flower, F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of February 1889, and called attention to four Marbled Polecats (*Putorius sarmaticus*), presented by Colonel Sir Oliver B. C. St. John, new to the collection; and to a fine specimen of Owen's Apteryx (*Apteryx oweni*) from the South Island of New Zealand, presented by Prof. T. Jeffrey Parker.—Mr. A. Thomson exhibited a series of insects reared in the Insect House in the Society's Gardens during the past year, and read a report on the subject.—Prof. G. B. Howes exhibited and made remarks on some specimens of the embryo of *Myrmecobius fasciatus*.—Mr. O. Thomas exhibited a specimen of a new Muntjac from Tenasserim, lately discovered by M. Fea, and proposed to be called *Cervulus feæ*.—A communication was read from Mr. Joseph S. Baly, containing descriptions of some new South American Coleoptera of the genus *Diabrotica*.—A communication was read from the Rev. H. S. Gorham, containing descriptions of some new species and a new genus of the Coleopterous family Telephoridæ, from Eastern Asia. Thirty-nine new species and one new genus (for which the name *Lycocerus* was proposed) were described. Of these new forms, the greater part were from India and China.—Colonel R. H. Beddome read a paper on new land-shells from the Island of Koror (Pelew Group), based on specimens collected for Dr. Hungerford by a resident in that island. The series comprised examples of eight new species of the genus *Diplommatina*, of two new and very curious species of *Endodonta* (a section of *Helix*), and of a remarkable new genus, allied to *Diplommatina*, proposed to be called *Hungerfordia*.—Mr. W. E. Hoyle read a paper on the anatomy of a rare Cephalopod (*Gonatus fabricii*), originally discovered by Fabricius in the last century, but little known in recent times. The author gave a general description of the anatomy of the species, and recorded the existence of several tracts of cartilage hitherto unobserved in the Cephalopoda. Some details were given regarding the structure of the pen-sac and the development of the pen, as well as some new facts reregarding the structure of the funnel-organ, and a suggestion regarding its function. The genus was regarded as being somewhat more nearly related to *Onychoteuthis* than to *Enoploteuthis*, but as much further removed from them both than they are from each other. The creation of the sub-family Gonatidæ was thus held to be justified.

Mathematical Society, March 14.—Mr. J. J. Walker, F.R.S., President, in the chair.—The following papers were read:—Notes on plane curves: iv., involution-condition of a cubic and its hessian; v., figure of a certain cubic and its hessian, by the President (Mr. E. B. Elliott in the chair).—The problem of duration of play, by Major MacMahon, R.A.—Some results in the elementary theory of numbers, by Mr. C. Leudesdorf.—The characteristics of an asymmetric optical instrument, by Dr. J. Larmor.—A new angular and trigonometircal notation, with applications, by Mr. H. MacColl.

EDINBURGH.

Royal Society, March 4.—Sir W. Thomson, President, in the chair.—A paper, by Dr. J. Oliver, on deductive evidence of a uterine nerve-centre and of its location in the medulla oblongata, was communicated.—The President exhibited a gyrostatic model of a medium capable of transmitting waves of transverse vibration. The model was two-dimensional, but a three-dimensional model could readily be constructed on the same principle.—Dr. Thomas Muir read a paper on the relation between the mutual distances of five points in space. He has reduced Cayley's determinant to one of the fourth order.—Dr. Muir also communicated a note, by Prof. Tait, on the relation among four vectors. In this note Prof. Tait gave an investigation of the same problem by means of quaternions. His result can be interpreted in two ways; one interpretation leads to Dr. Muir's result, while the other gives the well-known relation among the sides and diagonals of a spherical quadrilateral.—Dr. Muir exhibited a diagram illustrating the history of determinants.—Dr. Noel Paton and Dr. Ralph Stockman communicated a paper on the metabolism of man during starvation.

March 18.—Dr. John Murray, Vice-President, in the chair.—Prof. Haycraft read a contribution, written by Dr. Harold Scofield and himself, to the chromatology of the bile.—A paper by Prof. Tait on a relation between two groups of four vectors was read. When the two groups are identical, the result reduces to that obtained by him in his paper read at last meeting. When one spherical quadrilateral is the polar of the other, the relation reduces to $\cos Ab \cos Bc \cos Cd \cos Da = \cos Ac \cos Bd \cos Ca \cos Db$. Cayley's determinant can at once be obtained from the identity $\Sigma x(\alpha - \theta)^2 = \Sigma x\alpha^2 - 2S\theta\Sigma(x\alpha) + \theta^2\Sigma(x)$, where there are five vectors $\alpha_1 \ldots \alpha_5$, and $\Sigma(x) = 0$, $\Sigma(x\alpha) = 0$, by replacing θ by the various vectors α in turn and eliminating the x's from the resulting equations by aid of the equation $\Sigma(x) = 0$.—A paper by Mr. John Aitken, describing a portable apparatus for counting the dust particles in the atmosphere, was read. This apparatus is constructed on the same principle as his former one, but various improvements have been made. The paper also included an account of some of Mr. Aitken's observations with the large apparatus. It is pointed out that when much dust is pre-

sent in the atmosphere the heat of the sun is greatly absorbed. Hence it seems probable that dust particles may aid in the formation of fogs in another way than by acting as nuclei. Their great radiating power will cause rapid cooling of the air, and so produce saturation.—Dr. Sims Woodhead communicated a paper, by Mr. R. W. Gray and himself, on the stomach of the narwhal.—Dr. Crum-Brown read the third part of a paper, by Dr. A. B. Griffiths, on micro-organisms.—A second note by Prof. Tait, on the virial equation, was read.

PARIS.

Academy of Sciences, March 18.—M. Des Cloizeaux, President, in the chair.—On the fixation of nitrogen during the process of slow oxidation, by M. Berthelot. The object of these researches is to determine the fixation of nitrogen during the slow oxidation especially of those principles that give rise to certain intermediate oxides endowed with mixed oxidizing and oxidizable properties which temporarily fix free oxygen, afterwards transforming it to an almost indefinite extent to other bodies capable of definite oxidation. Such are ordinary ether, the essence of terebenthine, various aromatic hydrocarbons, and other substances capable of producing those effects which their discoverer, Schoenbein, attributed to ozone.—On the heat of formation of antimoniuretted hydrogen, by MM. Berthelot and P. Petit. The formation of this extremely unstable compound is described, and its heat of formation determined by six experiments at – 84·5 calories.—On the essays that have been made to explain the fundamental principles of thermodynamics by mechanical laws, by M. H. Poincaré. The paper deals mainly with the views developed by Helmholtz in his memoirs on the statics of the monocyclic systems, and on the principle of least resistance (*Crelle's Journal*, vols. xcvii. and c.). M. Poincaré accepts the mechanical explanation as satisfactory for the reversible phenomena, but shows that it is not applicable to those of the irreversible order.—On certain fourfold periodical expressions depending on two variables, by M. E. Picard. In this note the author indicates certain series depending on two independent complex variables, and possessing in relation to them four couples of conjugated periods.—On the movement of a material point on a sphere, by M. Gustave Kobb. In his treatise on some applications of the elliptical functions, M. Hermite has reduced the integration of the equations in the movement of the conic pendulum to the integration of Lamé's differential equation. Here M. Kobb shows that there also exists another kind of movement of a material point on a sphere which leads to a similar application of Lamé's equation.—On the elastic equilibrium of arches forming arcs of circles, by M. Ribière. Two typical cases are worked out mathematically, which offer a complete solution of the problem of the elastic equilibrium of circular vaults.—On the solubility of salts, by M. H. Le Chatelier. The author replies to some critiques on his own researches (*Comptes rendus*, vol. c. p. 50), made by M. Bakhuis Roozeboom, in the remarkable work recently published by him on the solubility of salts.—On the chloride and bromide of copper, by M. Denigès. The author describes a simple process for preparing these substances by means of the haloid salts of the alkalies and the sulphate of copper. The same chemist indicates a new and characteristic reaction of the salts of copper, the principle of which rests on the easy transformation of these salts into cupric bromide under the influence of potassium bromide, and on the dehydratation of the resulting salt by means of sulphuric acid.—Researches on the saccharine substances contained in certain species of mushroom, by M. Em. Bourquelot. These researches have been made on eight species belonging to the genus *Lactarius* of Fries, and to Sowerby's *Boletus aurantiacus*. The proportion of mannite was found to vary from 1·90 to 15 per cent., according to the different species, and sometimes in the same species from season to season. From *Lactarius piperatus* a substance was obtained identical with M. Berthelot's trehalose, the presence of which in mushrooms had already been indicated by M. Müntz.—On the physiological and therapeutic action of orthomethylacetanilide, by MM. Dujardin-Beaumetz and G. Bardet. This substance, which has recently been prepared by M. Brigonnet under the name of exalgine, with formula $C_9H_{11}NO$, is toxic, therapeutic, and anæsthetic, according to the dose administered. In these respects it greatly resembles antipyrine, but appears to be superior as a cure for all forms of neuralgia.—Thermic classification of fresh-water lakes, by M. F. A. Forel. Lacustrine basins are here grouped as tropical, temperate, and polar, according as the surface waters are always above, about, or under 4° C. respectively. But with this grouping is combined the variation of temperature due to depth, this variation increasing with the shallowness of the lake. Further modifications are caused by special climatic conditions, such as altitude, latitude, aspect, volume, so that from the thermic stand-point every fresh-water basin has its special features. All are comprised in six broad classes, based, however, mainly on the two more important elements of surface temperature and depth.

BERLIN.

Physical Society, February 22.—Prof. von Helmholtz, President, in the chair.—Prof. Neesen demonstrated several pieces of mechanical apparatus which he is in the habit of using in his lectures to illustrate and explain the parallelogram of forces, the laws of inertia, and the action of friction with special reference to the slipping of locomotives. He further described several arrangements connected with mercurial air-pumps by which some of their defects and inconveniences may be avoided.—Dr. Wolff gave an account of the results of a long series of measurements which he had made on galvanic cells, consisting of zinc and zinc sulphate or chloride and a second metal, either copper, silver, or iron. By determining the electromotive force of each cell and the simultaneous heat-production (by means of an ether calorimeter), he endeavoured to prove that the source of the current-energy in each case is due to the combining of oxygen with the several metals, copper, silver, or iron. He hence considered himself justified in giving the name "oxygen-elements" to the above class of galvanic cells.

THURSDAY, APRIL 4, 1889.

A "PRACTICAL MAN" ON ELECTRICAL UNITS.

AT the last meeting of the British Association an energetic attempt was made to prove that the progress of the human race has been chiefly due to the "practical man," and this teaching was quickly caught up and explained to mean that the triumphs of industry have been achieved without the help of workers in the field of pure science. We have before us a periodical which is instructive reading when viewed in the light of the discussion on this subject. It is a recently issued number of the Transactions of an Institute connected with one of the most important of our national industries. Among other provincial organizations it holds high rank. Meetings are held at frequent intervals, papers are read, and not only are they printed at length, but the discussions by which they are followed are also given in full. Two papers were recently communicated to this Society on the application of electricity to the industry with which its members are chiefly connected. One of them was by a gentleman who, according to the Chairman, represented an important firm "who have done more of this class of work in this country than anyone else," and he added that on this account "anything that he may say will carry great weight and give information to us unattainable otherwise, and I am sure we shall therefore appreciate the more, the trouble he has been at in coming here." The whole of the last number of the Transactions of the Institute—forty-one pages in all—is filled with the discussion that followed the speech in which this passage occurred.

We give these details because we wish to make it clear from the outset that the thing which we are about to discuss was not done in a corner. No circumstance which could add to the formality and importance of the occasion was wanting. A full account of the whole is published, and is matter for public comment.

Let us now see how the gentleman thus introduced and who calls himself a practical man utilized this opportunity. In the course of his remarks he discussed the theory of the electric motor, and then proceeded to say that he was frequently asked

"why we measure electrical quantities in volts, amperes, and watts, rather than in foot-pounds. Well, the main reason is that the practical units, the *volt*, *ampere*, and *ohm*, are so easy to measure and so simply connected by the equation

$$C = \frac{E}{R},$$

in which C = the ampere, the unit of current;
E = the volt, „ „ pressure;
R = the ohm, „ „ resistance.

Now, the product of one *ampere* and one *volt* = one *watt*, and 746 *watts* = one horse-power.

"In the mechanical units 33,000 foot-pounds = one horse-power per minute; and if we are doing electrical work at the rate of 746 watts per minute, we are doing 33,000 foot-pounds per minute. The electrical unit of work is then related to the mechanical unit by the ratio $\frac{746}{33,000}$, or one *watt* is equal to 4·4 foot-pounds.

"We could thus measure all electrical quantities in foot-pounds if it were desirable, but it is far more convenient to measure the volts and amperes, and then estimate the horse-power. If anyone, however, wishes to express electrical quantities in foot-pounds, he will now be able to do so; but bear in mind that the electrical horse-power is equal to the mechanical brake horse-power."

It is hardly necessary to point out the blunders with which every sentence of this passage teems, but it is necessary that they should be made evident to "practical men." To talk of measuring a volt or an ampere in foot-pounds is as ridiculous as to propose to measure miles or gallons in seconds; and yet, when the inquirer asks why it is not done, he is told that "all electrical quantities could be measured in foot-pounds if it were desirable."

In the equation C = E/R, the symbols, when applied to the practical system of units, do not represent the ampere, volt, or ohm, but certain numbers of amperes, volts, and ohms.

The "horse-power per minute" is an old friend; it has as much meaning as the statement that a man has walked four miles per hour per second. Of course, the equally absurd phrase "watts per minute" follows.

Next, we find the "electrical unit of *work*" confounded with the unit of power, and the statement that their ratio is 746/33000; the truth being that the ratio between the watt and the horse-power is 1 : 746. As the first of these fractions is nearly seventeen times greater than the second, this sentence, in so far as it means anything, makes the watt seventeen times too great.

Lastly, like a cockney, who, having put in unnecessary *h*'s, proceeds to redress the balance by leaving them out where ordinary mortals insert them, the speaker, having liberally distributed "per minute" where it makes nonsense, proceeds to leave it out where it is absolutely necessary. The statement that "1 *watt* is equal to 4·4 foot-pounds" is wrong, (1) because the ratio of 33,000 to 746 is 44, and not 4·4; (2) because it is necessary to add "per minute" after "foot-pounds." The "practical man" of this type apparently thinks that it is quite unimportant whether a machine does 44 foot-pounds of work in a second, or in a minute, or in all eternity.

In drawing attention to this extraordinary series of statements, it is necessary to point out that nobody desires to interfere with such engineers provided they confine themselves to fulfilling the useful function of putting together machines they do not understand, and learning by bitter experience, but, be it well understood, at other people's expense, practical wrinkles which may no doubt often be of great service.

When, however, they pose as electricians, go down to the provinces as instructors of the ignorant, and print their opinions on "Sir William Thompson's" (*sic*) address to the Institute of Electrical Engineers, the matter becomes serious.

The speech from which we have quoted was characterized as "clear and explicit." A "junior member of the Institute enjoyed this lecture more than any we have had since I have joined," and thought that "we have had a very instructive meeting."

Thus these guileless representatives of a great British

industry sit agape while enjoying phrases which have as much meaning to them, and to the speaker, as "that blessed word Mesopotamia" to a village crone. But, surely, there must be a limit to their endurance. Even from the point of view of the most practical of "practical men" it must be a serious thing to find, in one line containing eleven words and ten figures, the ratio of the watt to the horse-power made seventeen times larger than it really is, a decimal point misplaced so that the watt is made ten times less than it really is, the vulgar fraction from which the ratio is deduced in decimals inverted, and the essential statement as to the time in which the work is done omitted in a calculation of power.

If men are to be "practical" and nothing else, they must at all events be accurate. If they are to use formulæ which they do not understand, they must at all events know how to use them correctly. If the representative of a great firm—in explaining the answer to a question, which is not sprung upon him unawares, but which he himself puts forward as one which he has been "frequently" asked, and to which, therefore, he volunteers a reply—can in addition to employing language which makes all his statements nonsense, turn a fraction upside down, misplace a decimal, and, finally, pass the report of his speech for press with these blunders uncorrected, how can outsiders avoid suspecting that similar mistakes may be not infrequent in calculations upon which specifications and contracts are based, and on which very "practical" questions of success or failure, and of pounds, shillings, and pence, depend?

And now for the application of all this. The speaker gave as his reason for using volts and ohms that they are "so easy to measure, and so simply connected." Do the supporters of the "practical man" think that this easy measurement, this simple connection, came by accident? Do they think that this system which they find so useful could have been elaborated by men who, when it has been before the world for years, cannot open their mouths or put pen to paper, without showing in every sentence that they are absolutely ignorant of the fundamental conceptions on which the whole system is based, and equally incapable of using it correctly?

In the course of the evening the same speaker claimed for himself and for practical men that "we don't want to know what [electricity] is, but what it will do." He, and such as he, have yet to learn that what electricity has done is mainly the outcome of the work of men who did want to know what it is, being certain that if they knew that they could make it do more than under any other conditions.

They elaborated a system of units which our authority finds *easy* and *simple*, by the aid of investigations which even now require a good knowledge of mathematics and physics on the part of those who would really understand them, and which at the date of their original performance were masterpieces which only intellects of a very high order and knowledge of a very wide grasp could have achieved. Among them were numbered some engineers, but these ranked among them not because they were practical men who did not "want to know what electricity is," but because they had risen above such wretched cant, and had become not only "practical" but scientific.

The mischief done by the Bath meeting is not yet ended. It may or may not be a good joke to discuss whether Sir William Thomson is or is not an engineer. But the views then expounded are, all over the country, leading so-called "electrical engineers," who are ignorant of all that concerns what is, by their own confession, the easy part of their subject, to fling their cheap sneers at men who do "want to know what electricity is," who have made it possible to use and measure electrical quantities, and who have directly or indirectly created the very trades by which their detractors earn their daily bread.

"We don't want to know" will be the ruin of British industry, unless its leaders use their influence to crush the spirit indicated by this expression. In the March number of the *Fortnightly Review*, Lord Carnarvon relates that chairs, of which the various parts are fastened by glue, as is the custom in this country, will not hold together in the warmer climate of Australia. English makers did not know, perhaps did not "want to know, this. "The Austrian manufacturers, on the other hand, had discovered the cause of the defect, and, by a very simple alteration in the fastening, had practically driven out of a large part of the country our home-made furniture." "Wherever I went," says Lord Carnarvon, "I observed that, as a matter of fact, German, and not English, furniture was in use." And so, while the columns of every newspaper are full of the unity of the Empire, and of the unemployed, another tie between mother-country and colony is broken, another outlet for British industry is closed, because our manufacturers do not know what the Austrian discovers for himself.

It is all of a piece with this that in England, in the year of grace 1889, an electrical engineer, who is, as we gather from the Chairman's statement, no tyro or underling, but who was welcomed at an important meeting as a worthy exponent of the views of a well-known firm, was not ashamed to tell his hearers that he does not "want to know what electricity is," and that he could "measure all electrical quantities in foot-pounds."

THE CEPHALOPODA.

Catalogue of the Fossil Cephalopoda in the British Museum (Natural History), Cromwell Road, S.W. Part I., containing part of the Sub-order Nautiloidea, consisting of the Families Orthoceratitidæ, Endoceratidæ, Actinoceratidæ, Gomphoceratidæ, Ascoceratidæ, Poterioceratidæ, Cyrtoceratidæ, and Supplement. By Arthur H. Foord, F.G.S. Pp. xxxii. and 344, and Fifty-one Woodcuts. (London: Printed by Order of the Trustees, 1888.)

JUST as heraldry in the Middle Ages formed a necessary part of the education of every knight and noble, without which it would have been impossible to trace the connection of the great families whose genealogy was symbolized on banner, shield, and crest, so palæontology is essential to the biologist, if he would successfully trace the connection of the living forms around him with their remoter progenitors whose records must be sought for in rocks of Palæozoic age.

Of such high lineage are the Cephalopoda, whose ancient life-history Mr. A. H. Foord has essayed to write in the carefully-prepared volume before us. There is evidently a fascination about the nautilus and cuttle-fish family, which seems specially to attract the attention

of naturalists. The living animals of the cuttles and squids are remarkably vivacious, as well as cosmopolitan, whilst the Octopus, or "devil-fish," has been invested with quite supernatural powers and intelligence. As to the gigantic calamaries of the North Atlantic, they almost realize in size De Montfort's fancy sketch of the "colossal poulpe" seizing a three-masted ship in its arms; or the fabled "Kraken," described by Dr. Paullinus and the Bishop of Bergen in the last century as a beast so huge that a regiment of soldiers could conveniently manœuvre on its back!

Striking and varied as are the animals of living Cephalopods, their shells, both recent and fossil, are of immense interest, indeed they are unsurpassed for elegance and variety of form by any of the Molluscan sub-kingdom; and as we have seldom the other parts left to us—especially in the older rocks—save the shell alone, it becomes necessary to study these structures with increased attention, and strive to elicit from them all that is possible of the past life-history of their inhabitants, and thus, by the light which they afford us, to trace the origin of the allied living forms.

The labours of naturalists during the past fifty years have tended to eliminate certain groups formerly classed with the Mollusca, and thus to define more clearly the characters of this great phylum of the Cœlomata as now recognized. The first group to be removed from the Mollusca was that of the Cirripedia by the labours of J. V. Thompson in 1830. In 1866, Kowalewsky showed that the Tunicata had affinities with the Vertebrata, and that their agreement with the Mollusca was only superficial. In 1844, H. Milne-Edwards had placed the Polyzoa with the Brachiopoda and Tunicata in a large group, the "Molluscoidea"; but the investigations of Cardwell, in 1882, showed that the Polyzoa and Brachiopoda had only a delusive agreement with the Mollusca, and must be removed from that phylum also.

There now remain, according to Prof. Lankester, only two great branches of the Molluscan phylum; namely, (1) the GLOSSOPHORA (characterized by possessing an odontophore), embracing the Gasteropoda, the Scaphopoda, and the Cephalopoda; and (2) the LIPOCEPHALA (= *Acephala*, Cuvier), including all the Lamellibranchiata (mussels, oysters, cockles, clams, &c.), without any definite head.

The question that interests us most to-day is, To which of the Mollusca belongs the honour of representing the primitive type from which all the varied forms we now recognize have arisen? Leaving out of consideration the earlier Brachiopoda, as having been already excluded from the Mollusca, we find in the older Palæozoic rocks that the Pteropoda, Heteropoda, Nautiloidea, and Lamellibranchiata (or Lipocephala) appear almost contemporaneously. But the Pteropoda (represented by *Theca* and *Conularia*), and the Cephalopoda (by *Orthoceras sericeum*, and at least three other species), begin in the Tremadoc rocks; Lamellibranchs (such as *Palæarca* and *Ctenodonta*) in the Arenig; whilst Gasteropods of several well-marked genera (*Murchisonia*, *Pleurotomaria*, *Euomphalus*, *Trochus*, &c.), with *Bellerophon* and the strange *Maclurea*, are found in the Bala series. If, as appears from the views of Prof. Lankester, we are to regard the *Lipocephala* as degenerated forms of *Glossophora*, they must have begun very much earlier indeed to have become so differentiated as we find them in the Arenig group. Nor do the Gasteropoda of the Bala series present the appearance of primitive forms (unless it be the genus *Maclurea*), for we find mollusks with turreted, turbinate, and discoidal shells, already defined as distinct generic types.

That the Pteropoda preceded the higher Cephalopoda in time seems pretty certain, and that both of these preceded the Gasteropoda seems established; but of the priority of the latter over the Lamellibranchiata there is no evidence.

As Prof. Lankester, in his recent classification of the Mollusca, places the Pteropoda with the Cephalopoda as Branch A. *Pteropoda*, Branch B. *Siphonopoda*, we must be content, for the present, to consider that the Cephalopoda represent the most ancient type of Mollusca, and that the shells of the little Pteropod, *Theca*, are the earliest representatives which we at present know.

In *Orthoceras* we become acquainted with the first and simplest form of camerated Cephalopod shell. They were straight shells, with plain suture-lines marking the septa, the siphuncle varied in position, the septa being concave towards the aperture; the initial chamber was conical, with a cicatrix, the body-chamber large, and its aperture simple (pp. 1–128). Nearly 200 species of these straight simple shells are described by Mr. Foord, ranging from the Tremadoc shales of Portmadoc to the Trias of St. Cassian. That they were external shells is proved by their surface-ornamentation, consisting of transverse and longitudinal ridges, and fine decussating striæ, with occasional colour-bands and markings rarely preserved.

In *Endoceras* (pp. 129–63) the internal structure of the shell is varied by the undulating character of the septa, which bend downwards, and overlap the neck of the preceding septum, forming a complete shelly siphuncular tube. The siphuncle, moreover, is eccentric in position, and often half the diameter of the shell. Within this wide siphuncle a series of funnel-shaped conical sheaths (endosiphons) have been observed, of the nature of which we are at present left in doubt. *Piloceras* has also an unusually large siphuncle, within which a series of invaginated sheaths, similar to *Endoceras*, occur.

The genus *Actinoceras* presents other peculiarities in the structure of the shell. Within the siphuncle, which is very large, a slender tube passes down the centre, called the endosiphon (pp. 164–99). The siphuncle expands between each septum into a broad bead-like dilatation, perforated around its periphery by a series of minute shelly radiating tubuli given off from the endosiphon. It has been suggested by Owen that these were connected with the vascular system of the animal, and were designed to convey nutrition to the lining membrane of the septal chambers. No such complex siphon and endosiphon exists in the shell of any living Cephalopod; nevertheless, it is difficult to accept for them the interpretation here suggested, unless we would invest the shells of these ancient Mollusca with a structure akin to that of the skeletons of the Vertebrata!

The huge siphuncles of *Huronia*—allied to *Actinoceras*—have been described by Stokes, Bigsby, Hall, and

Woodward (pp. 199–207). The septa and shell-wall are thin, and but rarely preserved. These weathered tubes were frequently noticed by Dr. Bigsby standing out in relief from the limestone cliffs of Drummond Island on Lake Huron, and were as large as the vertebra of a man, and not unlike them in shape, and over 6 feet in length.

In the family of the *Gomphoceratidæ* (pp. 211–45), we meet with shells ranging from nearly straight, through varying degrees of curvature, to one in which a complete whorl is attained. The aperture of the shell in this family is so contracted that it is obvious the animal could not have withdrawn its head into its body-chamber as does the living *Nautilus*. The mouth of the shell is T-shaped, and reminds one of the mouth of the shell in some land-snails, like *Helix globulosa* and *Auricula scarabæus*, which are so guarded by tooth-like projections from the margin of the aperture as seemingly to preclude the animal from ever retreating into its shell, or emerging from it if withdrawn.

The *Ascoceratidæ* (p. 246) have the test of a sac-like form, the body-chamber extending to the lower end of the dilated portion of the shell, while the septa adhere to the dorsal wall, and bend upwards with their convex side towards the mouth of the shell. The apex was unknown, the shell being always found truncated, but Barrande, first, in Bohemia, and subsequently Lindström in Sweden, have discovered the earlier apical portion of the shell of *Ascoceras*, which was nearly straight, and with the septa normal, as in *Orthoceras* (p. 335).

The *Cyrtoceratidæ* (pp. 262–318) are more regular in their growth than the preceding; the shell is more or less curved, and tapers rapidly, or more slowly, according to the species or variety examined. The siphuncle is small, and varies in position in the different species, being external, internal, or sub-central; they range from the Carboniferous to the Tremadoc series, and are well represented in the Devonian of Gerolstein, Eifel, by large and handsome forms.

In his introduction the author discusses many points of great interest relating to the class, as, for example, the classification, the structure of the shell, the range in time, and the distribution of the group.

Seventeen genera and 403 species are described, but there yet remain the *Lituitidæ*, *Trochoceratidæ*, *Nautilidæ*, and *Bactritidæ*, to complete the NAUTILOIDEA; while the AMMONOIDEA and the DIBRANCHIATA will be treated of still later on.

Mr. Foord writes:—

"The classification of the Nautiloidea adopted in this volume will be found to differ in some of its details from systems hitherto employed, the more recent writings of Noetling, Zittel, Mojsisovics, and Hyatt having furnished the basis of the changes introduced. The arrangement of the groups described in the following pages is primarily zoological, secondarily stratigraphical, each genus being dealt with separately, from its appearance to its extinction."

The author passes in review the various systems of classification of the Cephalopoda proposed by Prof. Hyatt, Dr. Paul Fischer, Barrande, and other writers on this group.

"Hyatt considers that the generic terms *Cyrtoceras*, *Gyroceras*, *Lituites*, *Nautilus* are merely 'descriptive terms for the different stages in the development of an individual, and also the different stages in the development or evolution of the adult forms in time. In other words, each of these genera, as now used, includes representatives of all the different genetic series of Tetrabranchs, which are either young shells in the corresponding stage of growth, or adult shells in the corresponding stage of evolution.' He finds 'that genetic affinities on a large scale are best exhibited by the siphuncle, particularly by the funnels of the septa, which are more invariable than any other part of the shell.'

"He next discusses the embryonic relations of the structure of the septa and of the siphuncle, and mentions the difference between the Nautiloids and the Ammonites exemplified in these structures, the one commencing with a globular initial chamber ('protoconch' of Owen), the other with a conical initial chamber and a cicatrix. He remarks that generally among the Palæozoic Cephalopod types much greater differences exist, in regard to the septa, the position of the siphuncle, and so on, than among the Mesozoic forms, thus indicating that the evolution of forms was quicker in the Palæozoic epoch than at subsequent periods, and from these circumstances he concludes that 'types are evolved more quickly, and exhibit greater structural differences between genetic groups of the same stock, while near the point of origin, than they do subsequently.' It must not be forgotten, however, that the Palæozoic epoch was of much longer duration than the Neozoic. 'In the smaller divisions (families and genera) of Hyatt's scheme of classification, an important place is assigned to the characters of the sutures for distinguishing the different groups. In some groups, however (notably the Orthoceratidæ), the less stable characters presented by the ornamentation of the shell are for a like purpose employed.'

"While there can be no question as to the value of Prof. Hyatt's work, and the thoroughness of research which he has brought to bear upon the class he has with so much boldness and originality attempted to re-classify, the extremely revolutionary nature of the changes he has proposed in the minor divisions of his system (involving the wide separation of many forms hitherto associated together) challenges the inquiry as to whether our knowledge of the developmental history of the Cephalopoda is not as yet far too imperfect to justify such a radical departure from existing systems. The suppression of the familiar names *Cyrtoceras* and *Gyroceras* seems quite unnecessary, and seeing that the names *Orthoceras* and *Nautilus* are retained, in a restricted sense, in Hyatt's scheme, there seems to be no good reason why the two former should not have been similarly used" (Introduction, p. vii.).

Mr. Foord discusses at some length the nature of the camerated structure of the Cephalopod shell, and the question as to whether the *camera* should be called "air-chambers" or "water-chambers"; he concludes to avoid the difficulty by calling them "septal chambers." Bearing in mind the fact that each sealed-up chamber of the shell is but the partitioned-off lower portion of the animal's body-chamber, it is obvious that it must, at the moment of separation, contain the same medium as that which envelopes the animal.

In the case of the living *Nautilus*, dredged by the *Challenger* off Matuku Island, in 320 fathoms,[1] it seems improbable that the "septal chambers" could have been full of gas when the animal was crawling upon the sea-bed at a depth at which the pressure would be equal to about 750 pounds on each square inch of surface, or fifty-three times greater than at the sea-level. Any such

[1] See "Notes of a Naturalist on the *Challenger*," by H. N. Moseley, M.A., F.R.S. (p. 297).

inclosed gas-filled chambers would have sufficed, by their buoyancy, to bring the shell and animal at once to the surface.

That the living Nautilus, noticed by Prof. Moseley, should have been unable to sink in the tub of sea-water in which it was placed on the deck of the *Challenger*, and that this inability was due, as he observes, "to some expansion of gas in the interior, occasioned by the diminished pressure," is equally certain; but Moseley does not state that the expanded gases were in the shell-chambers; had such been the case, the gas, in order to expand, must have ruptured the rigid shell-wall. But gases are, no doubt, evolved within the crop and alimentary canal of the animal, and these, by their expansion, on coming to the surface, would suffice to produce the effect observed by Moseley. "The living specimen," he says, "seemed crippled, and unable to dive, no doubt because it had been brought up so suddenly to the surface from the depths" (*op. cit.*, p. 298). Exactly similar effects were observed in fishes with "swim-bladders." These "come up" (says Moseley), "in the deep-sea dredge, in a horribly distorted condition, with their eyes forced out of their heads, their body tense and expanded, and often all their scales forced off" (*op. cit.*, p. 580).

Mr. Foord quotes an observation by Dr. Woodward, "that many dozens of specimens of newly-imported shells of *Nautilus*, examined by him at the Docks, were, when shaken, all found to contain fluid within their chambers, just as in the camerated shell of the Water Spondylus (*S. varians*)" (Introduction, p. xiii.). We cordially indorse Mr. Foord's remark that "it is much to be regretted that recent opportunities of setting this question (of the contents of the septal chambers) at rest should apparently have been neglected."

What we would strongly insist upon is, that, it being admitted on all hands that the Cephalopoda are, in every respect, Glossophorous Mollusks, their shells must, in a similar manner, be found to conform to the ordinary Molluscan type. The striking regularity of their septal chambers has usually hindered a comparison with those of other camerated Molluscan shells; but in *Caprinella*, the camerated interior of the "water-chambers" is quite equal in regularity and symmetry with that of the Cephalopoda, and many of the *Hippuritidæ* show not only septa, but a pseudo-siphuncle, reminding one still more of the chambered Nautilus.

Space does not permit a longer notice of Mr. Foord's excellent "Catalogue"; it is a most valuable addition to the now really fine series of descriptive Catalogues issued by the Trustees of the British Museum of Natural History. We hope soon to welcome the appearance of the second part of this useful work, when we may be tempted to reopen the question of shell-growths and shell-structures.

SANITARY SCIENCE.

Transactions of the Sanitary Institute of Great Britain. Vol. IX. (1887–88.)

THIS volume is largely composed of the papers and addresses read at the Congress of the Institute at Bolton. The authors are chiefly men well known in their different professions, whose contributions are not only of much scientific interest, but carry weight with the public. Sanitation is a science in which the "faddist" delights to dabble, but his effusions have but little representation in the volume before us. The majority of the workers appear to be content to record steady advances in knowledge, or to make practical suggestions for administrative reform, rather than to air brilliant theories, popular with the public for their novelty, but greatly wanting in substantial proof. To force premature conclusions in sanitation, as in other older sciences, is to retard true progress; and on the whole it may be said that sanitary reformers, however earnest, are content to preach the doctrine of pure air, earth, and water, which is as old as Hippocrates.

In the department of practice, improved sanitary administration is urged on all hands. Such reforms take largely the shape of what has been called "interference with the liberty of the subject"; an interference, however, which is not unnecessary or uncalled for, but is imperative in health matters where the act or default of one individual may imperil the lives of many. Those who on this plea found their objections to such measures as compulsory vaccination, compulsory notification of infectious disease, isolation of infectious disease in hospitals, better supervision of building operations, dairies, and cow-sheds, and stricter enforcement of nuisances clauses and sanitary regulations generally, appear to forget that civilized existence depends upon the observance of mutual obligations, and that society could not exist if every individual were free to exercise his liberty of action at the expense of the community. Little is thought of the restrictions that already exist, and to which all law-abiding citizens cheerfully adhere, but when, with advancing knowledge of cause and effect in disease, certain measures are pointed to as being necessary to avoid unwholesome conditions, or to prevent the dissemination of epidemics, an outcry is raised which is too often not only illogical but insincere.

In the section of chemistry, meteorology, and geology some valuable papers are contributed on the application of bacteriology as a means of obtaining evidence as to the purity of water-supplies, and of ascertaining the degree of contamination of the air of buildings and sewers. As a science, bacteriology is still in its infancy, but already its teachings are producing a most profound effect in the domains of medicine and hygiene. The recognition of the bacterial and fungoid organisms as the principal factors in the processes of fermentation and putrefaction of organic substances, and the discovery that certain specific microbes are the actual agents provocative of certain contagious diseases, have secured a basis on which can be founded rational measures for the prevention and alleviation of disease and for the control of insanitary conditions. Hygiene was a science practised with most beneficial results before the discoveries of Pasteur, Koch, and Tyndall, but many of its teachings and precepts were at that time empirical, although founded more or less on experience and observation. With the more definite knowledge of disease causation and dissemination now arrived at, it is most satisfactory to find that the measures of sanitary reform and improvement which have marked the latter half of the present century are almost entirely in accord.

At the close of the Congress addresses were given to the working classes of the town of Bolton. The Sanitary Institute appears to fully recognize the desirability of bringing home to the minds of all classes of the community the importance of healthy homes and temperate living; and the lesson it should aim at inculcating is that if the public sanitary authorities can do much for the working man, he can do for himself by his own efforts—if he only knew how—very much more to improve his own surroundings, and bring up his family in health and comfort.

The annual visits of the Institute, for the purpose of holding Congresses, to the large towns of this country, must rank as one of the most influential means of popularizing sanitary science. The proceedings of the Congress are watched with interest by persons whose attention it is not easy otherwise to engage; whilst the exhibition of sanitary appliances brings under their notice the latest improvements in domestic and municipal sanitation, and is an incentive to manufacturers to turn out none but the most approved articles.

It also appears that the Institute holds examinations and grants certificates to local surveyors and inspectors of nuisances to sanitary authorities. These examinations should prove of the greatest use to the public sanitary service, for the certificate is a guarantee that the holder possesses sound knowledge on sanitary subjects; and there can in future be no reason why Local Boards should appoint incompetent and ignorant officials, when certificated candidates for office present themselves.

GLEANINGS IN SCIENCE.

Gleanings in Science. By Gerald Molloy, D.D., D.Sc. (London: Macmillan and Co., 1888.)

THIS is a pleasantly-written book, containing ten popular lectures which have, from time to time, been delivered by the author to popular audiences. They were, with one exception, delivered under the auspices of the Royal Dublin Society. The lectures are not offered as containing anything new, but simply as an attempt to popularize some of the most important of modern developments in physical science.

The author has, in our opinion, been thoroughly successful. In a short space he has been able to put before his hearers and his readers, in a satisfactory and thoroughly intelligible manner, a great variety of most important scientific facts and principles. The subjects of the lectures are well chosen.

First, we have two lectures on "Latent Heat," in which the fundamental discoveries of Black are explained and the great results which have flowed from them are recounted. Three lectures on electrical subjects follow. Then we have two lectures on "The Sun as a Storehouse of Energy." Two lectures on the Electric Light enable the author to lay before his readers in a popular but scientific manner the principles of dynamo-machines and the modes of producing the light from the electric current. The transformations of energy which take place during production of the light are also explained. The last lecture is on the Glaciers of the Alps.

The illustrations, which take the place of the experiments of the original lectures, are for the most part suggestive and satisfactory. The lecture on glaciers contains three or four striking, if somewhat sensational, woodcuts by Mr. Whymper, whose Alpine sketches are well known.

A book of the kind we have described is scarcely likely to be absolutely free from blemishes, particularly of style; and there are two or three to which we would call the attention of the author. One of them, at any rate, can be easily amended in another edition. It is the habit of saying "indefinitely small" when he means either infinitely small or extremely small. This use of the word indefinite he shares with some, sometimes indefinite, writers on certain branches of mathematics and dynamics. But indefinite does not in pure nor in common language mean infinite; much less can "indefinitely small" be put for "extremely small," as in speaking of the length of the path of a molecule. There is nothing indefinite about the path of a molecule any more than about the path of a billiard ball. Again, there is nothing "inconceivable" about the velocity of the radiant energy of the sun (p. 191). It is measurable and well known. The pruning down of some exaggerated language would make the wonders of science all the more wonderful.

A lover of Nature is apt to get into difficulties if he invokes her aid too frequently in descriptions of the physics of our universe. When we read of Nature dealing out the sun's energy *to man* with the prodigality of a spendthrift, we are apt to think of the much more prodigal way in which the sun's energy is poured out all round. The energy which comes in our direction is a very small proportion of the whole. There are too many references to personified Nature in these lectures.

The parts which seem to us least satisfactory are the early part of the lecture on storing of electrical energy, and the classification of the forms of energy contained in the next lecture. The enumeration of various forms of energy available to man is very imperfect. For example, energy of chemical separation is omitted from the list, and yet dynamite, gunpowder, and the gas-engine, are surely worthy of mention. Dynamite is manufactured as electrical energy is; but an engine worked, say, by native petroleum, would be far more efficient than the *earth currents* which Nature provides, but which, as our author properly remarks, are more of a trouble than a pleasure. In another place "bags of oxygen and hydrogen" are referred to as examples of stored-up heat. This seems a little far-fetched, to say the least of it. Just about the same place a rod of "chalk" is used to produce the lime-light.

Perhaps, however, it may seem somewhat ungracious to prolong the list of minor corrections. The book is most readable, and is deserving of praise throughout.

OUR BOOK SHELF.

The Gamekeeper's Manual; being an Epitome of the Game Laws of England and Scotland, and of the Gun Licences and Wild Birds Acts. By Alexander Porter, Chief Constable of Roxburghshire. Second Edition. Pp. 120. (Edinburgh: Douglas, 1889.)

ASSUMING, and we are not in a position to affirm or deny the assumption, that the legal points laid down in this little book are sound, it will certainly fulfil its author's

intention, which, he tells us, is "to place within the reach of all connected with the protection of game a knowledge of the law which it is their duty to administer," and we may hope, also in his words, that it may contribute "to a more effective suppression of a form of lawlessness which leads to so many crimes of a more serious nature." Seeing that it is a second edition, that the author is the head of the constabulary of an important Border county, and that in compiling it he has had the assistance of other chief constables, Mr. Porter is probably right on all points that have been decided. Within his prescribed limits he traces his subject, as it seems to us, very well, though tersely enough, beginning with the earliest records of both Kingdoms, and ending with the silly (but well-meant) Sand Grouse Act which closed the labours of the last session of Parliament—an admirable instance of locking the stable-door after the steed was stolen. However, his treatment is so purely from an executive aspect that comments upon the book are hardly suited to these pages. Yet we may remark that the game law question, which, not so many years ago, was a party cry, has through certain modifications of opinion ceased to occupy that position. There are now few reasonable men who do not perceive that if our ever-increasing population is to continue the enjoyment of the delicacies which "game" (using the word in a wide and not a legal sense) affords, some sort of preservation of such "game" is a necessity. The practical extermination, in many large districts, of *Lepus timidus* since the passing of the Act of 1880 (43 and 44 Vict. cap. 47), leading to the almost prohibitive price of hares in our markets, has fully shown this. The way in which the principle of preservation should be applied is, of course, quite another thing. All men nowadays agree in condemning the savagery of the early laws, though many are apt to forget that it was only of a piece with the savagery of other contemporary laws; but until within the last twenty years few enactments, whether in Great Britain or Ireland, grasped the scientific truth which has been at the bottom of the most recent legislation (the Ground Game Act excepted), and should be at the bottom of all—namely, take care of the parents, and you may leave the offspring to take care of themselves.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Meteoric Theory of Nebulæ, &c.

MY last letter in NATURE of March 7 (p. 436) substantially contended that there must be a certain limit to the rate of translatory motion possible to meteoric masses, beyond which they would be rapidly resolved into vapour and consequently be unable to maintain the weight of the heaped-up material constituting the nebula (supposed to be formed of meteorites). It appears tolerably evident that there must be such a limit as to size to which the system can apply, if a period anything like "a few thousand years" mentioned[1] by Prof. G. H. Darwin is to be accorded to this stage of evolution. The doubt was expressed whether the size (or mass) of the original solar nebula was not past that limit, in view of the rate of translatory motion required, viz. $5\frac{1}{2}$ kilometres per second in the mean.

That the theory is in principle true, appears but little open to doubt. For when masses fall in a confused manner to a centre, the kinetic movement is naturally and inevitably produced, and corrected so as to be maintained symmetrically in all directions by the masses themselves. The main question seems to be, What is the limiting mass of the future sun to which such a system can apply in its completeness, so as to allow anything like permanence enough for the forcible tendency of the energy to equalize itself to extend to a notable radial distance (to settle down into a sort of temporary kinetic equilibrium, that is)? It is conceivable that in the case of an eventual very large sun, the system of meteorites may be heaped up to a certain height, and then collapse at or near the nucleus, where the density is greatest, and consequently the impacts most numerous. Such a partial collapse would give rise to violent oscillation in the nebula, and perhaps assist the throwing off of rings (query). The fact that meteorites are exceptionally the only celestial masses that we can handle and analyze in our laboratories, gives a basis of certainty to inquiries about them, which lends a special interest to theories as to the part played by them in Nature.

In my last letter I avoided the use of the term "elasticity," considering purely the physical conditions which constitute its basis. Prof. G. H. Darwin remarks on this point:—"It may, however, I think, be shown that the very greatness of the velocities will impart what virtually amounts to an elasticity of a high order of perfection" (NATURE, p. 82). "Ordinary elasticity must be nearly inoperative" (p. 107). To produce this exceptional degree of elasticity, the expansive action of the gas generated by the high velocity of impact is relied on, which is regarded to act as "a violent[1] explosive introduced between the two stones." No doubt the volatilized gases due to the collision expand and assist rebound; but in estimating its value we must consider if the chilling of the gas, in doing the work, is at all the equivalent of the heating. If the gas is left in an incandescent state (as is probable, from spectroscopic evidence also), that represents so much spent work, so much[2] imperfect elasticity. The gas is not confined as in a gun, and so cannot exert its expansive effect to full advantage.

Meteorites constituting a nebula having a mean velocity of $5\frac{1}{2}$ kilometres per second represent an energy about eighty times that of a cannonade. Taking the velocity of an ordinary projectile at 2000 feet per second, that of the meteorites ($5\frac{1}{2}$ kilometres) is 18,000 feet per second, about. Meteorites normally composed of materials imperfectly welded together, cannot stand the same knocking about as steel projectiles. If it were imagined that the latter could have a velocity of 18,000 feet per second imparted to them, they would doubtless leave a luminous track in the atmosphere from friction, and the energy of their mutual collision at this speed may be imagined. It must be remembered, however, that the collisions are generally oblique or glancing.

No doubt in a nebula a metallic rain flying in all directions like the meteorites would accompany the motion. This rain of metal we may suppose under favourable accidents to collide together to form nuclei in various parts of the nebula; and an incipient nucleus constituting a sort of shelter would collect more rain (or hot metal), and so constitute a new meteorite—much as the occasionally dissociated lumps or molecular clusters of a compound gas reunite in another part of the gas, so that the mean state of aggregation remains the same.

The mean interval between encounters depends, of course, on the mean size of the meteorites. It appears from the data afforded that thirty days or a month would be the average interval between collisions (at about one-third radius of the supposed original solar nebula), for meteorites of mean mass equal to $3\frac{1}{3}$ kilogrammes, which would possess a volume of about half a cubic decimetre.[3] So that a nucleus, which we may suppose at rest or only slowly moving—as it is, on the average, struck equally on all sides by the metallic rain—would have, as a mean, a month to collect or grow before the chance of being disturbed by a collision in a nebula under the conditions named. In this way, doubtless, nuclei could be formed, and the meteorites renewed.

The question of the applicability of the theory would seem to

[1] Abstract of Mr. G. H. Darwin's paper "On the Mechanical Conditions of a Swarm of Meteorites," appeared in NATURE, November 22 and 29, 1888 (pp. 81 and 105). The complete paper is in the Philosophical Transactions, vol. clxxx., 1889.

[1] The entire passage is: "It must necessarily be obscure as to how a small mass of solid matter *can* take up a very large amount of energy in a small fraction of a second, but spectroscopic evidence seems to show that it does so; and if so, we have virtually what is a violent explosive introduced between the two stones" (NATURE, November 22, 1888, p. 82).

[2] It will be seen afterwards that this radiation must not be considered as absolutely lost, but in great part radiated to another region of the nebula of meteorites.

[3] For meteorites of $3\frac{1}{3}$ tonnes (about half a cubic metre in volume), the interval between collisions would be 300 days, nearly a year; and the mean length of path 130,000,000 kilometres, nearly the sun's distance. Multiplying the mass by a thousand (or the diameter by 10) increases the interval between collisions and the length of path ten times. At this rate we should get to the stellar distances and stellar movements, regarding the visible universe as a nebula, if a merely speculative remark may be allowed.

be one of degree rather than of principle. For, even if its application for the full time required for that stage of evolution, in the case of so large a nebula as the original solar one, were considered doubtful, there is no objection apparently on that head to be adduced in the case of smaller nebulæ, or comets (the smallest class of nebulæ); in which latter case there is some support to the theory afforded by experiment and observation.

In regard to the question of "elasticity," the only resource, in my view, is to abandon this idea, in the ordinary sense of that term (which conveys the idea of retention of form), and suppose that there may be complete disintegration by the collisions at times,[1] welding or fusion together at others; so that the mean degree of aggregation remains constant so long as the translatory motion remains constant. This idea of the existence of a number of possible mean states of aggregation of matter between the extremes of complete integration into one mass, and complete disintegration into molecules (the states being dependent on the rate of translatory motion), was thrown out by me in NATURE (vol. xix. p. 461);[2] also, further, in the *Philosophical Magazine*, August 1879, p. 153.

According to this view, it is implied that "cohesion," as a central force, can play the same part as "chemical action" under translatory motion, and produce fluctuations about a mean state of aggregation—just as in a compound gas, for example, even at normal temperature, the small lumps of matter which move as wholes in the motion of translation are disintegrated now and then, and integrated elsewhere, the *mean* state (only) of the gas remaining unchanged.

The above, with the exception of the last two paragraphs, was written before the appearance of Prof. G. H. Darwin's reply (March 14, p. 460), to some criticism I ventured to offer (March 7, p. 436) on certain points of his theory in my first letter. I would make a few remarks in addition here.

I am not quite able to agree with the view of M. E. Minary, expressed in a paper brought before the French Academy on February 18, of which an abstract appeared in NATURE of February 28, p. 432, and is referred to in Prof. Darwin's letter. The chief passage, as given in the abstract, is as follows:—

"The gases being perfectly elastic bodies, and in the upper atmospheric regions in an extremely rarefied state, heat cannot be produced by the shock of bodies endowed with great velocity and impinging on perfectly elastic molecules capable of receiving the motion and acquiring the velocity of these bodies: in this case the movement is communicated, not dissipated or transformed into heat."

This view is opposed, I venture to think, to the deduction we may draw from such an experiment as that with the "fire syringe," where the air in a cylinder is inflamed by suddenly compressing a piston. What is the flame here observed through the tube of glass due to? It is due, of course, to the *vibrations* of the molecules of air, which break the ether up into waves, and so affect the eye. From the fact that the air molecules are "perfectly elastic," it becomes impossible for a moving body to impinge against them violently without throwing the molecules into energetic vibration, which is the physical basis of "radiant heat." The same must occur on a greater scale, as it appears, when the air is compressed by a flying meteorite, although I accept M. Cornu's suggestion (quoted in the abstract, p. 432) that the *luminosity* observed may partly be of electric origin.

In Joule's "Scientific Papers," vol. ii., experiments in association with Sir William Thomson are described, of whirling thermometers through the air (attached to a lathe). The experiments, which were numerous, gave 163·7 as the velocity in feet per second; on the average, equivalent to a rise of temperature of 1° C. (vol. ii. p. 316). Whirling a thermo-electric junction attached to a reflecting galvanometer was tried with consistently the same result as the thermometer (p. 310). These experiments were made partly[3] with the view to test the theory of the heating of meteorites. The temperature was found to be as the square of the velocity. The law of Clausius, that the translatory motion and the vibratory motion (which latter motion alone affects the eye and senses as radiant heat) of the molecules of an ordinary gas are proportional to each other, has—as Prof. Darwin allows—been experimentally verified through[1] a considerable range of temperature. To my mind it appears obvious that these two forms of motion (translatory and vibratory) must be interconvertible and mutually sustain each other. When the gas, for example, is exposed to the pulsations of ether waves (radiant heat), this vibratory motion is first taken up by the molecules, but part of it is converted into translatory motion, as proved by the rise of pressure. If, on the other hand, the translatory motion of the molecules of gas be augmented, part of this is instantly, as we know, converted into vibratory motion, the source of radiant heat. S. TOLVER PRESTON.

Paris, March.

[1] A special property of iron, which may have importance here.

[2] It would seem even curious to my mind, if there were no intermediate state between these two extremes of complete integration and complete disintegration, by a varying rate of translatory motion (or energy). It may be observed that the radiant energy set free so abundantly at a collision is not lost, but radiated in great part to another region in the nebula (and there absorbed).

[3] Also see vol. i. pp. 399, 536. The temperature was found to be independent of the form and size of the thermo-electric function, and was assumed as evidently independent of the density of the air. No doubt the more air there is the more there is to heat. But it nevertheless seems plain, I think, that the temperature of a meteorite must rise higher in dense air than in excessively rarefied air. How is this to be explained? Each individual molecule of air in striking the moving meteorite, is thrown into violent vibration, and this (temperature) is independent of the number of air molecules evidently. But in dense air, no doubt, the heat accumulates much faster than it can be radiated away, and so the temperature of the meteorite attains a final *maximum*, which is greater the denser the air is. The temperature may probably be appreciably constant within certain limits of variation of density; but it appears obvious that in excessively rare air the temperature developed must be less, owing to rapid dissipation in space by radiation.

[1] The ratio of Maxwell referred to in my last letter, and which Prof. Darwin remarks in a footnote (p. 460) was stated inaccurately by me—was not, I may explain, the one quoted by him from Maxwell's "Theory of Heat." It is contained in Maxwell's paper "On the Dynamical Evidence of the Molecular Constitution of Bodies" (NATURE, vol. xi. pp. 357 and 374). After alluding to the law of Clausius, Maxwell remarks:—"In 1860 I investigated the ratio of the two parts of the energy on the hypothesis that the molecules are elastic bodies of invariable form. I found, to my great surprise, that, whatever the shape of the molecules, provided they are not perfectly smooth and spherical, the ratio of the two parts of the energy must be always the same, the two parts being in fact equal" (p. 375).

The Molecular Formulæ of Aluminium Compounds.

IN a letter to NATURE, December 27, 1888 (p. 198), I gave a tabulated statement of the numerous vapour-density determinations of halogen, and a few other compounds of aluminium and the allied metals, and pointed out what appear to me to be the legitimate conclusions to be derived from the experiments, regarding the molecular formulæ of these compounds.

Since then two interesting articles have appeared in NATURE (pp. 447 and 495), in which accounts are given of determinations of the vapour-densities of aluminium acetyl acetonate, $Al(C_5H_7O_2)_3$, and aluminium methide, $[Al(CH_3)_3]_n$. The simple formula given for the first compound has been proved to be correct, at any rate for the conditions under which the experiments were made. The results given for aluminium methide are: calculated for $Al_2(CH_3)_6$, 4·98; calculated for $Al(CH_3)_3$, 2·49; observed (10° above the boiling-point under atmospheric pressure), 3·92.

What I ask permission to call attention to and to criticize is the conclusion drawn by the author of these articles from the experimental results. Speaking generally, the conclusion may be stated in this way: Molecules of the formula MR_3 do exist, *therefore* molecules with the double formula M_2R_6 do not. I confess that I am wholly unable to appreciate the force of the argument. Must we take the existence of the molecule NO_2 as a proof of the non-existence of N_2O_4?

That I have not stated the argument unfairly may be shown by quotations from the article (p. 495). Speaking of aluminium acetyl acetonate the author says: "It is supremely satisfactory that in this case the density, at a temperature only 45° above the boiling-point, was found to actually correspond precisely with that required by the triad formula, *precluding again the possibility of the existence of molecules of the type* Al_2R_6." And previously, after giving the results for aluminium methide, notwithstanding the fact that the observed density 3·92, obtained by Quincke, corresponds rather more closely to the higher than the lower formula, the author remarks: "*Hence it can no longer be doubted that molecules of the double formula are incapable of existence.*" The italics in both cases are mine. The conclusion I should draw from all the experiments with aluminium compounds is this: The experiments of Deville and Troost, Friedel and Crafts, and Louïse and Roux, prove conclusively that molecules of the higher formula Al_2R_6 are capable of existence; the results obtained by Nilson and Pettersson, and by Buckton and Odling, point also to the existence of molecules of the lower formula, but further proof was certainly needed, and this has now been afforded by the valuable experiments of M. Alphonse Combes with aluminium acetyl acetonate.

In conclusion, it appears to me that the close relationship of the metals aluminium, gallium, indium, iron, and chromium, makes it probable that molecules of both formulæ M_2R_6 and MR_3 may be capable of existence in the case of all these metals, even though the conditions necessary for the stability of the higher molecules have not yet been attained for indium and chromium chlorides. That the conditions have been attained in the case of the chlorides of aluminium, gallium, and iron, appears to me to admit of no doubt. SYDNEY YOUNG.

University College, Bristol, March 23.

Luminous Night-Clouds.

IN accordance with my anticipations (see *Astr. Nachr.*, 2885), luminous night-clouds have now been seen at the southern point of South America. Herr Stubenrauch, meteorological observer at Punta-Arenas, writes to me that he twice saw the phenomenon in December 1888. According to the same observer, it was noticed several years ago by a naval officer in the Beagle Channel, rather to the south of Punta-Arenas. The description given by Herr Stubenrauch leaves no room for doubt that the phenomenon is identical with that observed in Europe.

Sternwarte, Berlin, March 28. O. JESSE.

Zodiacal Light Observations.

COULD any of your readers furnish me with a list of observations of zodiacal light, or refer me to any record where such a list can be found? I applied to the Meteorological Office some years ago, and found that no such list was to be obtained. All I require is the precise time of the display, the place of observation, and any other mathematical observations concerning the angle of inclination, &c., which may be relied on.

W. DONISTHORPE.

32 Pembridge Villas, W., March 30.

Vapour, or Meteoritic Particle.

ABOUT 6.30 p.m. on Friday last, while out in the country, I observed a large meteor falling slowly and almost vertically in the north-north-east. After it had disappeared, half-way between the zenith and the horizon, I noticed, in the strong twilight, a faint phosphorescent trail, which did not disappear, but changed to a straw-colour, like a streak of vapour illuminated by the setting sun. Gradually the shaft expanded in the centre and contracted at the ends, until it assumed the shape of a balloon. Continuing to change, it flattened out horizontally like a football, and apparently about half the size; and it looked a little brighter as it became more condensed. This process occupied quite half an hour, and the object remained like a nebulous patch lit up by the sun's rays, until that orb was well below the horizon, finally disappearing about 7.15 p.m. That part of the sky was perfectly clear—there were no clouds except the usual dense bank on the horizon. F. B.

Rugby, March 27.

The Satellite of Procyon.

WITH reference to Mr. Barr's letter on p. 510, I would mention that Mr. Burnham has lately observed Procyon with the 36-inch refractor at the Lick Observatory, and finds no trace of any close companion with powers up to 3300. H. SADLER.

March 29.

RECENT RESEARCHES ON THE RARE EARTHS AS INTERPRETED BY THE SPECTROSCOPE.[1]

IF I name the spectroscope as the most important scientific invention of the latter half of this century, I shall not fear to be accused of exaggeration. Photography has rendered vast services in recording astronomical and biological phenomena, and it even supplies us with indirect means of studying ray vibrations to which the human retina does not respond. The electro-acoustic devices of Edison and his co-workers permit almost magical communication between human beings. Ruhmkorff's coil and the Geissler tube have rendered notable service in physical investigations; and the electric lamp promises to aid in exploring the internal parts of living animals as well as in studying the organic forms of the deep sea. But in the spectroscope we possess a power that enables us to peer into the very heart of Nature. In the extent of its grasp and the varied character of its applicability it surpasses the telescope, and at least rivals the microscope. It enables the astronomer to defy immeasurable distance, and to study the physical condition and the chemical composition of the sun and the stars as if they were within touch, and even to ascertain the direction of their movements.

Without attempting to discuss the import of the results thus gained—which would lead us too far—I may point out that they overthrow a dogma concerning the classification of the sciences. It has been said that the simpler and more general sciences lend both doctrines and methods to the more complex and less general sciences, and that the latter give nothing in return. But we now see chemistry endowing astronomy with an original and fruitful method of research.

Turning to the very opposite extremity of the scientific hierarchy, we find that to the biologist the spectroscope is of value in studying the relations of animal and vegetable fluids, and even of certain tissues. But this wonderful instrument is clearly destined to play its chief part in what is called terrestrial chemistry—the field where it has won the most signal triumphs.

It must be remarked, despite this vast range of applicability—a range sweeping through the whole universe and embracing all the four elements of antiquity—and despite the astonishing results already achieved and the prospect of greater revelations to come, that the spectroscope is still inadequately appreciated by professed men of science, and in consequence is to a great extent ignored by the "educated and intelligent public." In urging its more thorough recognition, I do not advocate the formation of Spectroscopic Societies for the fragmentary study of everything that can be observed with a spectroscope. But I recommend researching chemists to appeal to this instrument wherever requisite and possible.

An elaborate spectroscopic study of the basic constituents of rare minerals from different localities would be of great value, and I would suggest that on all possible occasions meteorites should be submitted to careful spectroscopic analysis.

I do not propose to discuss all the splendid achievements of the spectroscope in chemistry; nor its applications in ordinary analysis, qualitative and quantitative; nor the conduct of technical operations, such as the Bessemer process. I confine myself to the light thrown by the spectroscope upon the nature and the relations of our *elements*, real or supposed.

Though systematically employed by few experimentalists, the spectroscope has already led to the discovery of several hitherto unknown elements. In the early days of spectrum analysis, attention was mainly concentrated on the flame spectra: that is, the bodies in question were vaporized and rendered luminous by the action of a flame, such as that of the Bunsen burner or of the oxyhydrogen jet. This procedure in the hands of Bunsen and Kirchhoff gave us cæsium and rubidium; afterwards, in my own hands, thallium; and in those of Reich and Richter, indium.

Then followed the production and examination of spark spectra. The spark produced by means of the induction coil, especially when its energy is reinforced by the intercalation of a Leydén jar, volatilizes and renders luminous minute portions of matter, solid, liquid, or gaseous, which may then be examined by the spectroscope. In this

[1] Abstract of Address delivered on Thursday, March 28, at the annual general meeting of the Chemical Society, by the President, Mr. W. Crookes, F.R.S.

manner gallium was discovered, in 1875, by Lecoq de Boisbaudran. In consequence of the sharpness and the well-marked character of these spark spectra, they are relied on by chemists as certain proof of the identity of any two elements which yield identical spectra.

Next was introduced the systematic study of the absorption spectra seen when a beam of light is passed through certain transparent solids or through solutions of various substances. One of the earliest observers in this branch of spectroscopy was Dr. Gladstone, who, in 1858, read before this Society a paper on the absorption of light by various metallic salts, and gave the first description of the absorption spectrum of didymium. This branch of spectroscopy has proved not less fruitful in the recognition of new metallic elements.

In the investigation of the rare earths my principal object has been to separate the true from the undemonstrated and spurious, verifying the true, rejecting the spurious, and reducing as far as possible the number of the doubtful. In the following table I have given a list of the so-called "rare elements," with which for the last seven or eight years I have been specially occupied.

TABLE.

	Atomic Weight of Metal and Formula of Oxide.	Gives Spectrum by	Component Meta-Elements according to Crookes (1886).	Component Meta-Elements according to Nilson and Krüss (1887).
Didymium	Neodymium—140·3, Nd_2O_3 Praseodymium—143·6, Pr_2O_3 Unnamed.	Absorption.	Dα λ = 475	Diα Diβ Diγ Diδ Diε Diη Diθ Diι Diχ
Decipium				
Samarium	150·12, Sm_2O_3.	Absorption and Phosphorescence.	Sδ Gε Gγ Gθ	Smα Smβ
Lanthanum	138, La_2O_3.	Phosphorescence.		
Erbium	166, Er_2O_3.	Absorption and Phosphorescence.	λ 550 λ 493	Erα Erβ
Philippium	45—48, PpO.	Phosphorescence.		
Holmium		Absorption.		Xα Xβ Xγ Xδ
Thulium	170·7, Tm_2O_3.	Absorption.		Tmα Tmβ
Dysprosium		Absorption.	λ 457 (1888)—448	Xζ Xε Xη
Yttrium	88·9, Yt_2O_3.	Phosphorescence.	Gα Gβ Gδ Gζ Gη	Zα Tb Yt Lecoq de Boisbaudran.
Terbium	124·7, Tb_2O_3.			
Gadolinium (Yα)		Phosphorescence.	Gβ Gζ	
Ytterbium	173·01, Yb_2O_3.	Phosphorescence.		
Scandium	44·03, Sc_2O_3.			

Column 1 gives the names by which they are commonly known. Column 2 gives their atomic weights, &c. Column 3 shows in what manner they come under the domain of spectroscopy; and columns 4 and 5 notify the components or meta-elements into which some of these bodies have been decomposed in 1886 by myself, and in 1887 by Krüss and Nilson. In the first column I have exercised a judicial leniency in retaining candidates, for the sake possibly of old associations, when strict justice would have disestablished them. Thus, it may be doubted whether decipium, philippium, or gadolinium should have been retained. But since doubts have been cast on the integrity of nearly all the occupants of this column, the line should not be drawn too strictly.

At first spectroscopic examination was applied directly to substances, natural or artificial, which had not undergone any special preparation. The idea next occurred of attempting to split up substances supposed to be simple into heterogeneous constituents before appealing to the spectroscope. The refined chemical processes

used for this operation may be summarized under the name of fractionation, whether they be fractional precipitations, crystallizations, or decompositions. The essential principles of this process were so fully discussed on the last occasion when I had the honour of addressing you that I need not further allude to them.

The Didymium Group.

A combination of such delicate and prolonged chemical processes with spectroscopic examination applied to bodies showing absorption spectra soon led to important discoveries. When in that year the didymium from samarskite was examined by M. Delafontaine (*Comptes rendus*, vol. lxxxvii. p. 632; *Chemical News*, vol. xxxviii. p. 223), he found it to differ somewhat from ordinary didymium as extracted from cerite and gadolinite, and by a series of chemical fractionations he succeeded in separating from it an earth which he called decipium, giving at least three absorption bands, one having a wave-length of 416 ($1/\lambda^2$ 578); another narrower and stronger, at wave-length 478 ($1/\lambda^2$ 438), and a very faint "minimum of transmission" near the limit of the blue and green. Nine months later, M. Lecoq de Boisbaudran (*Comptes rendus*, vol. lxxxix. p. 212; *Chemical News*, vol. xl. p. 99) announced the discovery of samarium as a constituent of the didymium from samarskite.

Still didymium was not reduced to its ultimate simplicity. In 1885, Dr. Auer von Welsbach (*Monatsh. Chem.*, vi. 477), by fractionally crystallizing the mixed nitrates of ammonium, didymium, and lanthanum, showed it was thus possible to cleave didymium in a certain direction and separate it into two other bodies, one giving green salts and the other pink salts. Each of these has a characteristic absorption spectrum, the sum of the two sets of bands approximating to the old didymium spectrum. These bodies the discoverer has named respectively praseodymium and neodymium. The neodymium spectrum, according to Dr. Auer, consists of the whole of the bands in the red, with part of the large one in the yellow; it then misses all the green and blue, and takes in the second line in the violet. The spectrum of praseodymium takes the other part of the yellow band and all the green and blue, except the second blue, which belongs to neodymium. Subtracting these two spectra from the old didymium spectrum, there are still two bands left at λ 462 and 475 ($1/\lambda^2$ 465 and 443). Assuming that the argument from absorption spectra is a legitimate one—and all recent research tends to show that if not quite trustworthy it is at all events a weighty one—the inference I draw from these results is that the old didymium still contains a third body distinct from neo- and praseo-dymium, to which one or both of these extra bands is due.

I must venture to lay especial emphasis on the words *in a certain direction*. Didymium in my own laboratory has undergone other cleavages, and I have not yet decided whether we shall have to recognize further decompositions of neodymium and praseodymium, or whether the original didymium is capable of being resolved differently according to the manner in which it is treated. Keeping the band in the orange always of the same strength, in many of the fractions of didymium from different sources the other bands of neo- and praseodymium are seen to vary from very strong almost to obliteration (*Chemical News*, vol. liv. p. 27). In this way I have worked on the spectra of didymium from allanite, cerite, euxenite, fluocerite, gadolinite, hielmite, samarskite, yttrotitanite, &c., and the further I carry the examination the more the conclusion is forced upon me that didymium must not be regarded as compounded of two elements only, but rather as an aggregation of many closely allied bodies. Later researches of Messrs. Krüss and Nilson have led them to the same conclusion.

By examining the absorption spectra of solutions of rare earths obtained from widely different sources, MM. Krüss and Nilson (*Berichte der deutsch. chem. Gesellschaft*, vol. xx. Part 12, p. 2134; and *Chem. News*, vol. lvi. pp. 74, 85, 135, 145, 154, 165, 172) came to the conclusion that the elements giving absorption spectra, and known as didymium, samarium, holmium, thulium, erbium, and dysprosium, were not homogeneous, but that each one contained almost as many separate components as it produced bands of absorption.

They have discovered that in didymium obtained from some minerals one of the fainter lines of the normal didymium spectrum is strong, while others usually stronger are almost or quite absent; results to which I shall presently refer will show that this cannot be explained by dilution or concentration. In this way, by examining a great number of minerals, they found anomalies occurred in the case of almost each of the old didymium lines, and therefore decided, as above mentioned, that it is a compound body, capable of resolution into at least nine separate components.

Identical arguments are brought forward to prove that each of the other so-called elements, samarium, erbium, holmium, thulium, dysprosium, &c., are compounds of many closely allied bodies.

Messrs. Krüss and Nilson, I believe, are pushing their investigation with the object of isolating the separate components of these different earths. They, however, question the possibility of resolving the erbia and didymia earths into their several ultimate constituents by a fractionated decomposition of the nitrates. In fact, they assert that by means of the methods of separation at present known it would be almost impossible to completely isolate any single constituent of the mixed earths. They therefore propose, as I had previously done,[1] a method by which we may certainly arrive nearer to the mark and dispense with much tedious fractionation. If we examine the minerals which contain these rare earths, we find they occur in very different states of mixture or combination. Sometimes many of the constituents which we wish to separate are conjointly present, and sometimes but few. The desired differentiation, in fact, has already been commenced by Nature. Krüss and Nilson, therefore, whichever ingredient they wish to separate, propose to operate upon a mineral which contains that ingredient as far as possible in a state of isolation. In other words, they will take advantage of the work that Nature has already begun, and endeavour by refined chemical means to put the last finishing touches to her work. Thus they will be able to work with smaller quantities of primary material,—no small consideration in the case of some minerals,—and to obtain results in a shorter time. How widely the composition of one and the same mineral, as judged by our searching physical tests, may vary, will be seen from the following instances. Fergusonite from Arendal shows six of the bands of holmium, fergusonite from Ytterby four, and that from Hitterö only three. Moreover, the ingredient provisionally called X*a* is to be found in the fergusonite from Ytterby, but not in that of Arendal and Hitterö.

The foundation for thus firmly declaring what I had previously ventured to infer, is the striking differences in the spectra given by several specimens of one earth, say didymium, when obtained from different sources.

We are anxiously waiting the results of this investigation, but although the paper quoted was published in July 1887, no further communication has come from these illustrious workers.

Chemists recently have stated, as proof of the existence of new elements, the fact that certain bands of absorption as seen in various fractions "follow the same variations

[1] Address to the Chemical Section of the British Association, Birmingham Meeting, *Chem. News*, vol. liv. p. 123. "On the Fractionation of Yttria," *Chem. News*, vol. liv. p. 157. *Proc. Roy. Soc.*, vol. xl. (1886), p. 505.

of intensity." Before deciding the question whether didymium is a homogeneous whole, or whether an argument in favour of its heterogeneity can be based on the fact that the absorption spectra of didymium from different minerals differ *inter se*, it was necessary to ascertain if the absorption bands seen in its solutions, whatever the thickness of the layer, whether dilute or concentrated, followed the same variations, and also to ascertain the nature of these variations. To contribute to this inquiry I examined the absorption spectrum of a solution of neutral didymium nitrate containing 1 part by weight of metal in 10 of water, as seen through a series of cells from 1 mm. to 25 mm. in thickness. For this work I used a new form of binocular spectroscope, fitted with a mechanical tracing arrangement, so that each spectrum can be automatically mapped on paper strips. At the bottom, at 25 mm. thickness, all the known bands are visible, and they become fainter and die out in order, some of them remaining visible almost to the end. For instance, almost as long as the deep line in the blue part of the spectrum at $1/\lambda^2$ 507 can be distinguished, it is possible to see the group of three very narrow ones next to it. Two or three other less characteristic bands can be seen only when there is a very considerable depth of liquid; thus, the group in the red at about $1/\lambda^2$ 255 cannot be seen distinctly through less than 20 mm. of this strength of solution.

Having ascertained in this series how the spectra varied in appearance with different thicknesses of the same solution (strength 1 of Di in 10 of water), I repeated the experiments, keeping the thickness of layer of solution constant, and diluting the standard solution of didymium so that the rays of light passed through the same quantity of metal as in the former series. The results in each case were practically identical; the differences being too slight to be detected in my apparatus. The spectrum exhibited, for instance, by 1 mm. of the standard solution of didymium is found to be identical with the spectrum shown by the same solution diluted twenty times and viewed through a 20 mm. cell.

There are at least two points in these researches that I must touch, since they illustrate the necessity of great caution in drawing conclusions from an examination of absorption spectra. Messrs. Paul Kiesewetter and Krüss (*Berichte der deutsch. chem. Gesellschaft*, vol. xxi., 2310; *Chem. News*, vol. lviii. pp. 75, 91) have recently published a paper on this subject. They have examined gadolinite, and find that some of the constituents of didymium and samarium are absent, notably the group of lines in the green to which I have already referred. In my own laboratory I have worked for the last two years almost exclusively upon the earths from gadolinite—of which I obtained a large quantity from Fahlun—and there is not the shadow of a doubt that in my gadolinite earths the lines reported absent by Kiesewetter and Krüss are present in abundance.

Some hitherto unexplained condition doubtless rendered these lines invisible to Messrs. Kiesewetter and Krüss—perhaps the presence of some other earths, or some condition of concentration or acidity. In the light of this knowledge I do not see how we can take the results of Messrs. Krüss and Nilson or my own as final.

Owing to its complicated nature, Kiesewetter and Krüss consider gadolinite an unfavourable source of didymium for these investigations, and recommend that a large quantity of earth from keilhauite should be systematically worked up, for the reason that keilhauite didymium is more simple in constitution.

The Erbium Group.

It is known that a certain oxide, ten years ago called erbia, and regarded as belonging to a simple elementary body, has been resolved by the investigations of Delafontaine, Marignac, Soret, Nilson, Clève, Brauner, and others into at least six distinct earths—three of them, scandia, ytterbia, and terbia, giving no absorption spectra, whilst others, erbia (new), holmia, and thulia, give absorption spectra.

The first to announce that erbium was not a simple body was Delafontaine, who in 1878 (*Comptes rendus*, vol. lxxxvii. p. 556; *Chemical News*, vol. xxxviii. p. 202), published an account of philippium, a yellow oxide characterized by a strong band in the violet, λ 400 to 405, a broad black absorption band in the indigo-blue, about λ 450, two rather fine bands in the green, and one in the red.

The history of philippium is curious, and I may perhaps be allowed to give it in some detail. A year after Delafontaine's discovery, Soret (*Comptes rendus*, vol. lxxxix. p. 521; *Chemical News*, vol. xl. p. 147) published a paper in which he declared that philippia was identical with his earth X. The next month, in a note on erbia, Clève (*Comptes rendus*, vol. lxxxix. p. 708; *Chemical News*, vol. xl. p. 224) said he could not identify Soret's X with Delafontaine's philippia, as the latter was characterized by an absorption band in the blue which occupied the same place as one of the erbia bands. In February 1880 (*Comptes rendus*, vol. xc. p. 221; *Chemical News*, vol. xli. p. 72), Delafontaine returned to the subject, enumerating ten new earths in gadolinite and samarskite, viz., mosandra, philippia, ytterbia, decipia, scandia, holmia, thulia, samaria, and two others unnamed. He said that the properties of philippia were those of Soret's X and of Clève's holmia, and proposed that the name "holmia," being a duplicate name for an already known earth, should be discarded in favour of philippia. In July 1880 (*Comptes rendus*, vol. xci. p. 328; *Chemical News*, vol. xlii. p. 185), Clève repeated his former statement that philippia was not the same body as Soret's X or holmia. Delafontaine next withdrew all he had said about the absorption spectrum of philippium, and decided that it had no absorption spectrum (*Archives de Genève*, [3], 999, p. 15). Finally, Roscoe (Journ. Chem. Soc., vol. xii. p. 277), in an elaborate chemical examination of the earth-metals in samarskite, proved that philippia was a mixture of yttria and terbia. From a prolonged chemical study of these earths I have since come to a similar conclusion; but a spectroscopic examination of the earth left on igniting some specially purified crystals of "philippium formate" tested in the radiant-matter tube, has shown me that in the separation of Delafontaine's philippium the yttria undergoes a partial fractionation, and three of its components or meta-elements, $G\zeta$, $G\delta$, and $G\beta$, are present in great abundance, while others, $G\alpha$ and $G\eta$, are almost if not quite absent.

Shortly after the announcement of philippium, Soret (*Comptes rendus*, vol. lxxxvi. p. 1062) described an earth which he provisionally called X. This was soon found to be identical with an earth subsequently discovered by Clève (*Comptes rendus*, vol. lxxxix. p. 479; *Chemical News*, vol. xl. p. 125), and called by him holmia. Soret admitted the identity, and agreed to adopt Clève's name of holmia. The absorption spectrum of X consists of a very strong band in the extreme red, λ 804, two characteristic bands in the orange and green, λ 640 and 536, besides fainter lines in the more refrangible part of the spectrum.

Simultaneously with the discovery of holmia, Clève announced the existence of a second earth from erbia, which he called thulia. Its absorption spectrum consists of a very strong band in the red, λ 684, and one in the blue, λ 464·5.

In 1886 (*Comptes rendus*, cii. 1003, 1005), Lecoq de Boisbaudran showed by fractional precipitation of Soret's X, and by spectroscopic examination of the simple fractions, that this X, or holmium, consisted of at least two elements, one of which he named dysprosium, retaining the name of holmium for the residue left after deducting

dysprosium. The absorption spectrum of dysprosium contains the two bands λ 753 and λ 451·5, the residual holmium having a spectrum consisting of the remaining two bands, λ 640 and 536.

Phosphorescence Spectra.

I will now deal with phosphorescence spectra. Not a few chemists and physicists, conspicuous among whom is Ed. Becquerel, have carefully studied the phenomena of phosphorescence. Phosphorescence may be excited by elevation of temperature, by mechanical action, by electricity, and by exposure to the rays of the sun, and the light thus given off, for example in the case of fluor-spar, has been examined by means of the spectroscope. In my own spectroscopic research I have dealt with the phosphorescence occasioned by the impact of the molecules of radiant matter upon certain phosphorescent bodies, or what I have ventured to call molecular bombardment.

It is not necessary for me to describe the mode of procedure further than to say that the substance under examination is placed in a very high vacuum—a vacuum which varies in degree in the case of certain earths. In such a vacuum, when submitted to the action of the induction current, substances phosphoresce very differently from what they do when treated similarly at the ordinary pressure of the atmosphere. Under such circumstances the spectroscopic examination of matter affords what I have called the radiant matter test. The number of substances which are thus phosphorescent is very considerable. Glass of different kinds, according to its composition, phosphoresces with various colours. Phenakite (glucinium silicate) phosphoresces blue; spodumene (aluminium and lithium silicate) gives off a rich golden-yellow light; whilst the emerald phosphoresces crimson, and the diamond, being exceptionally sensitive and brilliant, throws off a bright greenish white light.

The ruby, one of the minerals I examined earliest in this manner, glows with a rich brilliant red tone, quite independent, as regards its depth and intensity, of the colour of the stone as seen by daylight; the pale, álmost colourless specimens, and the highly-prized variety of the true "pigeon's blood," all phosphoresce with substantially the same colour.

This method of observing the constitution of the rare earths, duly aided by delicate and prolonged chemical processes, has permitted us to push our investigations further than had previously seemed practicable. It enables us to determine whether we have reached the end of our investigations—a consummation which had hitherto been vainly sought. It has enabled us to prove that yttrium, samarium, &c., are not simple, homogeneous bodies. But what of the constituents into which they have been thus resolved? Suppose we refine them down until each displays merely one spectral band—what then? Is each one of such bodies, barely differentiated from its neighbours chemically or physically, entitled to rank as an element? If so, as I pointed out in the address which I had the honour to deliver before you in March last, we shall have to deal with further perplexing questions, arising in part from the relation of such elements to the periodic system. In a discussion of the elements, not as yet published, Dr. Wundt maintains that their possible number cannot exceed seventy-nine. But I myself see no definite and sufficient reason for limitation to this number. If these bodies are not elementary, possessing as they do the properties commonly regarded as characteristic of an element, we must be prepared to show why not?

Whatever rank may ultimately be assigned to these substances, they must, for convenience sake, have names as soon as our knowledge of their properties is in a sufficiently advanced state to allow of their removal from the suspense account.

The Yttrium Group.

Yttrium—the old yttrium—proves now to be not a simple element, but a highly complex substance. I have come to the conclusion that it may be split up certainly into five and probably into six constituents. If we take these constituents in the order of their approximate basicity—the chemical analogue of refrangibility—the lowest of these constituents gives a deep blue band, $G\alpha$; then follows a strong citron band, $G\delta$, which increases in sharpness until it may be called a line; then a red band, $G\zeta$: then a deeper red band, $G\eta$; and lastly a close pair of greenish blue lines, $G\beta$. Following these are frequently seen $G\epsilon$, $G\gamma$, and $G\theta$, the yellow, green, and red components of samarium.

A possible explanation of the existence and nature of the new bodies into which "old yttrium" has been split up, and of parallel cases which will doubtless be found on closer examination, is this. Our notions of a chemical element must be enlarged; hitherto the elemental molecule has been regarded as an aggregate of two or more atoms, and no account has been taken of the manner in which these atoms have been agglomerated. The structure of a chemical element is certainly more complicated than has hitherto been supposed. We may reasonably suspect that between the molecules we are accustomed to deal with in chemical reactions, and the conponent or ultimate atoms, there intervene sub-molecules, sub-aggregates of atoms, or meta-elements, differing from each other according to the position they occupy in the very complex structure known as "old yttrium."

The arguments in favour of the different theories are as yet not unequally balanced. But the assumption of compound molecules will perhaps account for the facts, and thus legitimate itself as a good working hypothesis, whilst it does not seem so bold an alternative as the assumption of eight or nine new elements.

I have just mentioned that the earth heretofore called yttria, and supposed to be simple, has been split up into a number of simpler bodies. Now these constituents of the old yttria are not *impurities* in yttria, any more than praseodymium and neodymium are impurities in didymium. They proceed from a real splitting up of the yttrium molecule into its components, and when this process is completed the "old yttria" has disappeared. If these newly-discovered components on further examination should be found worthy to take the rank of elements, I think, as first discoverer, I am entitled, by the custom prevailing among men of science, to name them. For the present, and until their investigation is more advanced, I designate them by provisional symbols. One of the most distinct characteristics of "old yttria" is its very definite spark spectrum. To which of its components this spark spectrum belongs I am not yet able to say. It is possible the particular component to which the spark spectrum is due yields no phosphorescent spectrum. It is also possible that the spark spectrum, like "old yttria," may prove to be compound, and then the well-known lines it contains will have to be shared between two or more of the newly-discovered bodies.

I wish emphatically to re-state that at present no single component of old yttria can lawfully lay claim to what may be called the paternal name; and it seems to me that in the present state of the question no one is entitled to call one of the new bodies "yttria," and to characterize the remainder as impurities.

Interference of Phosphorescence Spectra.

A recent discovery of some beautiful spectra given by the rare earths when their pure oxides are highly calcined, shows the remarkable changes produced in the spectra of these earths when two or more are observed in combination. It has likewise opened to me a wide field of in-

vestigation in the nature of the elements themselves. Alumina is especially active in inducing new spectra when mixed with rare earths. I have given more than a twelvemonth to the exclusive study of alumina phosphorescence, and still the research is incomplete. But I have obtained some remarkable results. A moderate amount of fractionation has enabled me to penetrate below the surface of the red glow common to crude alumina, and to see traces of a most complicated sharp line spectrum. By pushing one particular process of fractionation to a considerable extent I have obtained evidence of a body which is the cause of some of these lines. The spectrum, described by me in 1887 (*Chem. News*, vol. lvi. pp. 62, 72), is one of great beauty. The new body is probably one of the rare elements or meta-elements closely connected with decipia, for I have reproduced the spectrum very fairly by adding decipia to alumina. Before arriving at definite conclusions much time must be devoted to the subject. Certain it is that this new earth is not yttria, erbia, samaria, didymia, lanthana, holmia, thulia, gadolinia, or ytterbia, the spectrum of each of these when mixed with alumina being very beautiful, but differing entirely from the decipia-alumina spectrum.

M. de Boisbaudran's Reversion Spectra.

Another modification of the phosphorescence process is afforded by the "reversion spectra" of M. Lecoq de Boisbaudran.

The following is the description of this process by M. Lecoq de Boisbaudran read before the Academy of Sciences on June 8, 1885:—"When the electric spectrum of a solution *with a metallic base* is produced, it is customary to make the outside platinum wire (whence the induction spark strikes) positive, the liquid consequently forming the negative pole. If the direction of the current is reversed, the metallic rays (due to the free metal or to one of its compounds) are scarcely or not at all visible; at all events, so long as the exterior platinum wire now forming the negative pole is not coated with a deposit."

M. de Boisbaudran continues:—"Having again taken up last year my researches on the rare earths belonging to the didymium and yttrium family, I had occasion to observe with many of my preparations the formation of spectrum bands, nebulous, but sometimes tolerably brilliant, having their origin in a thin layer of a beautiful green colour, which appeared at the surface of the liquid (a solution of a chloride) when it was rendered positive."

M. de Boisbaudran further adds:—"The production of my reversion spectrum appears to be analogous physically with the formation of the phosphorescence spectra obtained by Mr. Crookes at the negative pole in his high vacuum tubes containing certain compounds of yttria. The conditions of the two experiments are, however, practically speaking, very different."

By this method M. de Boisbaudran has discovered phosphorescent spectra, which he considers due to the presence of two earths, one of which, supposed to be new, he has provisionally named $Z\alpha$, and another, also thought at first to be new, and therefore called $Z\beta$, but since admitted by him to be terbia (*Comptes rendus*, vol. cviii. p. 167, January 28, 1889). In the hands of so skilful an experimentalist as my accomplished friend, this method may give trustworthy indications, but the test is really beyond the range of practical analysis, owing to the difficulty of eliciting the phenomena. Unless the strength of the spark, the concentration and acidity of the solution, and the dispersive and magnifying power of the spectroscope bear a certain proportion to each other, the observer is likely to fail in seeing a spectrum even in solutions of earths which contain considerable quantities of $Z\alpha$ and terbia.

The Phosphorescence of Alumina.

I now wish to draw attention to some recent researches on the phosphorescence spectrum given by alumina. So far back as 1859, Becquerel examined in his phosphoroscope pure alumina carefully prepared, and described it as glowing with a splendid red colour. He rendered his specimens phosphorescent by exposure to the sun, and made no use of the induction spark. As described by Becquerel (*Annales de Chemie et de Physique*, vol. lvii., 1859, p. 50), the spectrum of the red light emitted from alumina agrees with that of the ruby when submitted to the radiant matter test. It displays one intensely red line a little below the fixed line B in the spectrum, having a wave-length of about 689·5. There is a continuous spectrum beginning at about B and a few fainter lines beyond it, but in comparison with this red line the faint ones are so dim that they may be neglected. My latest observations in the vacuum tube prove this line to be double, the distance apart of the components being about half the distance separating the D lines (Roy. Soc. Proc., vol. xlii. p. 26, December 30, 1886), their respective wave-lengths being 694·2 and 693·7 ($1/\lambda^2$ 207·5 and 207·8).

The red phosphorescence of this alumina is exceedingly characteristic. M. de Boisbaudran (*Comptes rendus*, vol. ciii. p. 1107; vol. civ. pp. 330, 478, 554, 824) contends, however, that this red phosphorescence is due, not to the alumina itself, but to an accompanying trace of chromium, 1/1100 part of chromium being sufficient to give a splendid red phosphorescence, whilst even 1 part of chromic oxide in 10,000 will produce a very distinct rose colour. In testing this view I have purified alumina most carefully, so as to secure the absence of chromium, and on examining it in the radiant-matter tube I have still obtained the characteristic phosphorescence and spectrum. I have then added to my purified alumina chromium in known varying proportions, but without finding any increase in the intensity of the phosphorescence. I fractionated my purified alumina by different methods, and found that the substance which forms the crimson line becomes concentrated towards one end of the fractionations, whilst chromium concentrates at the other end. I have suggested four possible explanations of the phenomena—

(1) The crimson line belongs to alumina, but it is liable to be masked or extinguished by some other earth, which accumulates towards one end of the fractionations.

(2) The crimson line is not due to alumina, but to the presence of an accompanying earth which accumulates towards the other end of the fractionations.

(3) The crimson line belongs to alumina, but its development requires certain precautions to be taken in the duration and intensity of the ignition, and absolute freedom from alkaline and other bodies carried down by precipitated alumina, and difficult of removal by washing.

(4) The earth alumina is a compound molecule, one only of its component sub-molecules giving the crimson one. If this hypothesis is correct, alumina must admit of being split up in a manner analogous to yttria.

Conclusions.

During the course of the investigations—whose results are briefly summarized in the foregoing pages,—I have repeatedly had recourse to the balance, to ascertain how the atomic weights of the earths under treatment were varying. An atomic weight determination is valuable in telling when a stable molecular grouping is arrived at. During a fractionation, the atomic weight of the earth slowly rises or falls until it becomes stationary, after which no further fractionation of that lot *by the same process* makes it vary. Usually a result of this kind has been relied on as proof that the elementary stage has been

reached. This constancy of atomic weight, however, only proves that the original body has been split up by the fractionating process into two molecular groupings capable of resisting further decomposition by that identical process; but these groupings are not unlikely to break up when a different fractionating process is brought to bear on them, as I found in the separation of didymium and samarium when using dilute ammonia as the fractionating precipitant. In my paper on "Radiant Matter Spectroscopy" I said ("Part II., Samarium," Phil. Trans. Roy. Soc., Part 2, p. 129, June 18, 1885):—"After a time a balance seems to be established between the affinities at work, when the earth would appear in the same proportion in the precipitate and the solution. At this stage they were thrown down by ammonia, and the precipitated earths set aside to be worked up by the fusion of their anhydrous nitrates so as to alter the ratio between them, when fractionation by ammonia could be again employed."

It is obvious that when the balance of affinities here spoken of was reached, the atomic weight of the mixture under treatment would have become constant, and no further fractionation would have caused the atomic weight to alter.

Atomic weight determinations are valuable in telling when the fractionating operation in use has effected all the separation it can: at this point it becomes constant. The true inference is, not that a new earth has been obtained, but simply that the fractionating operation requires changing for another, which will cleave the group of meta-elements in a different direction.

Meantime, I have kept strictly in view the question, What is an element, and how shall it be recognized when met?

On this subject I beg to submit the following considerations, which, primarily referring to didymium, may at any moment apply to other cases:—

Neodymium and praseodymium are simply the products into which didymium is split up by one particular method of attack.

It must be remembered that a single operation, be it crystallization, precipitation, fusion, partial solution, &c., can only separate a mixture of several bodies into two parts, just as the addition of a reagent only divides a mixture into two portions, a precipitate and a solution, and these divisions will be effected on different lines according to the reagent employed. We add, *e.g.*, ammonia to a mixture, and at once get a separation into two parts. Or we add, say, oxalic acid to the same original solution, and we then split up the mixture into two other parts differently arranged.

Thus by crystallizing didymium nitrate (in Auer's way) we divide the components into two parts. By fusing didymium nitrate we divide its components in a different way; but so long as different methods of attack split up a body differently, it is evident that we have not yet got down to "bed rock."

Further, a compound molecule may easily act as an element. Take the case of didymium, which is certainly a compound, whether the products of Auer's operation be final or not. Didymium has a definite atomic weight; it has well-defined salts, and has been subjected to the closest scrutiny by some of the ablest chemists in the world. I refer particularly to Clève's classical memoir. Still the compound molecule known as didymium was too firmly held together to act otherwise than as an element, and as a seeming element it emerged from every trial. The simple operations to which it had been submitted in the preparation of its salts, and in its purification from other compound molecules, such as samarium and lanthanum, were not sufficient to split it up further. But subjected to a new method of attack it decomposes at once.

We have, in fact, a certain number of reagents, operations, processes, &c., in use. If a body resists all these, and behaves otherwise as a simple substance, we are apt to take it at its own valuation and to call it an element. But for all that it may, as we see, be compound, and as soon as a new and appropriate method of attack is devised, we find it can be split up with comparative ease. Still, we must never forget that, however complex, it can hardly be resolved into more than two parts at one operation.

From considerations above laid down I do not feel in a position to recognize neodymium and praseodymium as elements. We need some criterion for an element which shall appeal to our reason more clearly than the old untrustworthy characteristic of having not as yet been decomposed; and to this point I must beg to call the special attention of my colleagues. It may be that whatever body gives only one absorption band is an element, but we cannot conversely say that an element may be known by its giving only one absorption band, since most of our elements give no bands at all!

Until these important and difficult questions can be decided, I have preferred to open what may be figuratively called a suspense account, wherein, as I have previously suggested, we may provisionally enter all these doubtful bodies as "meta-elements."

But these meta-elements may have more than a mere provisional value. Besides compounds, we have hitherto recognized merely ultimate atoms or the aggregations of such atoms into simple molecules. But it becomes more and more probable that between the atom and the compound we have a gradation of molecules of different ranks, which, as we have seen, may pass for simple elementary bodies. It might be the easier plan, so soon as a constituent of these earths can be found to be chemically and spectroscopically distinguishable from its next of kin, to give it a name and to claim for it elemental rank; but it seems to me the duty of a man of science to treat every subject, not in the manner which may earn for him the greatest temporary κῦδος, but in that which will be of most service to science.

If the study of the rare earths leads us to clearer views on the nature of the elements, neither my colleagues nor myself will, I am sure, regret the months spend in tedious and apparently wearisome fractionations. No one can be more conscious than myself how much ground is yet uncovered, and how many radical questions have received but very inadequate answers. But we can only work on, "unresting, unhasting," trusting that in the end our work will throw some white light upon this deeply interesting department of chemical physics.

NOTES.

A MOST important and profoundly interesting letter from Mr. Stanley to the Chairman of the Emin Pasha Relief Committee has been published this week. It is dated Bungangeta Island, Ituri River, or Aruwimi River, August 28, 1888, and records the adventures of the Expedition from June 28, 1887, until the time when the letter was written. There is no more stirring tale even in the long and romantic history of African exploration. On April 29, 1888, Mr. Stanley met Emin Pasha on the shores of the Albert Nyanza Lake, and it would be impossible to over-rate the courage, energy, and resource manifested by the great traveller in grappling with the terrible difficulties which had stood in his way. Having spent some time with Emin, Mr. Stanley returned to the Aruwimi River, and reorganized what remained of Major Barttelot's force. When the letter was despatched he was on the point of starting again for the Albert Nyanza, and we may have to wait some time for further intelligence. Next week we hope to give an account of the geographical results of the Expedition, so far as they are now known.

THE Executive Committee of the International Exhibition of Geographical, Commercial, and Industrial Botany, to be held at Antwerp in 1890, has decided to celebrate on this occasion the three hundredth anniversary of the invention of the microscope. It proposes to organize what it calls a retrospective exhibition of the microscope, and an exhibition of instruments produced by living makers. Conferences relating to all important questions connected with the microscope will also be held. The Exhibition ought to be remarkably interesting, and will no doubt be a great success.

WE are glad to hear that the Congress of the United States has recently provided for the establishment of a Zoological Park in the City of Washington, and has appropriated money for the purchase of a tract of land of not less than one hundred acres in extent, immediately adjacent to that city. The proposed site for the park is the valley of Rock Creek, a small river emptying into the Potomac at Washington. This is said to be one of the most picturesque sites ever devoted to such a purpose, having several rocky cliffs of considerable extent, groves of pine, oak, beech, and other trees, and several little streams running down the steep sides of the valley into the river. Part of the land is under cultivation, but much of it is virgin forest, so that its natural advantages have been preserved by singular good fortune in spite of the neighbourhood of the growing city. Amongst the animals to be kept here will, no doubt, be a herd of the buffalo (*Bison americanus*), now nearly extinct in the Western prairies.

THE half-yearly general meeting of the Scottish Meteorological Society was held in the hall of the Royal Scottish Society of Arts, Edinburgh, on Monday, April 1. Next week we shall give some account of the proceedings. We are glad to learn from the Report of the Council that the application of the Society for a grant from the surplus fund of the Association of the Edinburgh International Exhibition of 1886 has been acceded to, the Association having granted the handsome donation of £1000 towards the completion of the Ben Nevis Observatory by the establishment of the Low Level Observatory at Fort William.

A FRIGHTFUL hurricane, which raged for nearly two days, broke over the Samoan Islands on the night of March 16. Of seven foreign war-vessels caught by the hurricane at Apia, only H.M.S. *Calliope* contrived to make the open sea. The German and American squadrons were destroyed, and many lives lost.

THE meeting of the French Meteorological Society on the 5th of March was chiefly occupied by an analysis of the report of the Krakatão Committee, by M. L. Teisserenc de Bort. The Abbé Maze presented an apparatus for rotating a thermometer fixed in a framework, and intended to take the place of the sling-thermometer in cases in which the latter was inconvenient. The Society has received a circular from the Minister of Public Instruction, asking for a list of old manuscript observations, with a view to the preparation of a catalogue for publication.

VAPOUR-DENSITY determinations of bismuth, arsenic, and thallium have been successfully carried out at extraordinarily high temperatures in the laboratory of the University of Göttingen by Dr. Biltz and Prof. Victor Meyer. The highest temperature hitherto attained in former experiments by Dr. Mensching and Prof. Meyer lay somewhere between 1400° and 1500° C. Now, thanks to a suggestion of Prof. Nilson, of Stockholm, means have been found of raising the temperature of the Perrot gas furnace, in which the well-known Victor Meyer porcelain density apparatus was heated, to a white heat of 1650°–1750°. Hence there are now from 200 to 300 more degrees of temperature at which density determinations are possible, and it may naturally be expected that substances which were only partially vaporized at 1450° may yield definite results at 1750°. The temperatures were determined by means of a glazed porcelain air-thermometer, which was decisively proved to be impermeable to the furnace gases. In order to further strengthen that portion of the porcelain apparatus placed in the furnace, it was surrounded by an outer casing of platinum. The volatilizations were effected in atmospheres of nitrogen, all traces of oxygen being rigorously excluded. Bismuth was found in the former experiment to be only partially vaporized at 1450°. At the higher temperatures now available it has been found to be rapidly and completely volatilized, and density determinations have been readily carried out. The values obtained in two experiments at 1600°–1700° are 11·98 and 10·12 (air = 1). If the bismuth molecule in the gaseous state consists of the normal two atoms, Bi_2, its vapour-density should be 14·4; if it contains only one atom, Bi_1, the density becomes 7·2. The values obtained, which are considerably less than that required for the normal molecular condition, show that this condition is impossible, and bismuth therefore resembles mercury, cadmium, and zinc, in containing only one atom to the molecule. In the case of arsenic the results agree very well with the assumption of a two-atom molecule, As_2. At 1714° the density found was 5·45; and at 1736°, 5·37. As_2 requires 5·20. Hence the four-atom molecule of arsenic at lower temperatures becomes dissociated about 1750° into the normal molecule consisting of two atoms. Thallium appears to be at once normal. At 1636° the value obtained was 16·11; and at 1728°, 14·25. The ordinary molecule Tl_2 corresponds to 14·17. The metal, however, is still difficultly vaporizable even at this tremendous temperature. Another very interesting result was obtained in case of cuprous chloride, which even at 1700° gave densities almost exactly corresponding to the formula Cu_2Cl_2. Sulphur, iodine, and mercury also gave results confirming the stability of molecules consisting of two atoms of sulphur and single-atom molecules of iodine and mercury.

MR. C. G. HALL, of Dover, sends to the new number of the *Entomologist's Monthly Magazine* the following note, written by the late moth-collector, Mr. H. J. Harding:—"On a beautiful evening at the end of June 1852, in the locality of Darenth Wood, I had just pinned my first insects taken at sugar, when I heard a strange sound behind me, and, on looking round, observed what I thought was a beetle flying round a sallow bush; when in my net, it again repeated the sound, but what was my surprise upon finding it a Lepidopterous insect. I had now got it between my thumb and finger to give it an entomological pinch, when it again produced the sound; the deadly pin was now presented, and, with the aid of my lantern, I found it was a common *Halias prasinana*. But it was a fact new to me: I I had never, during thirty years entomologizing, heard of such a thing before. The sound was as if you passed a pin sharply along three or four teeth of a comb. I suppose it was a love song to charm his lady."

RECENTLY there have been some valuable "finds" of antiquities belonging to the Iron Age in Norway. At Nötterö, on the Christiania Fjord, there were found in a mound some bones, an iron pot with handles, a sword 2 feet 6 inches long, the handle having knobs of a yellow metal, an anvil, and a pair of smith's tongs. The mound was no doubt at one time situated close to the sea; it is now some 300 yards inland. At Laurvig a large number of similar articles were discovered in two mounds.

IN a Report, just received, Mr. R. L. Jack, Government Geologist, Queensland, gives a valuable account of the geology of the Russell River, which he lately visited with Mr. Christie Palmerston. They were accompanied by eight "aboriginal boys," and Mr. Jack incidentally presents a vivid description

of these attendants, who (with one exception) had been, eighteen months before, "absolute savages." "I observed with some interest," says Mr. Jack, "Mr. Palmerston's method of 'working' his boys. Its essential elements seemed to be giving them time, feeding them well, and keeping them in good humour by allowing for their propensities to hunt or play, and by making fun with them. It is fortunately unnecessary to be a Joe Miller to keep the boys amused, as anything which would amuse children will serve the purpose as well as the most delicate jokes. Mr. Palmerston's method is evidently successful, as I never saw more contented, willing, useful, and well-bred young men of any nationality."

DR. FRANZ BOAS contributes to the Proceedings of the U.S. National Museum an interesting paper on the houses of the Kwakiutl Indians, British Columbia. In these houses, the uprights are always carved according to the crest of the gens of the house-owner. The Indians of the present time make various combinations of the emblems of the gentes of both parents of the house-owner, and this is the reason for the great variety of forms. Besides this, legends referring to certain ancestors are illustrated in the emblems, and thus it happens that seemingly the ancient styles are not strictly adhered to.

AT a recent meeting of the Swedish Anthropological Society, Prof. G. Storm read a paper on his researches relating to the Lapps. The speaker held that this race had settled in Northern Scandinavia as far back as the Stone Age, and had not begun to move southwards until the Middle Ages. These southward movements had occurred periodically. At the end of the fifteenth century the Lapps had reached the sixty-fourth degree of latitude, but were now found much further south. The subject was of interest, because of the general belief that the Scandinavians had driven the Lapps northwards. In common with others, Prof. Storm was of opinion that the Lapps belonged to the Finnish-Ugrian race.

THE Dundee and District Association for the Promotion of Technical and Commercial Education have issued an elaborate Report on education in Dundee and the neighbourhood. They bring together a mass of facts which afford "abundant and gratifying evidence of a growing appreciation of science studies." The Committee, however, point out that the increase of attendance at science classes is chiefly in the elementary stages of the different subjects. More advanced classes are small, or do not exist at all. Classes in the higher branches of mathematics, physics, chemistry, and engineering have been most abundantly provided for at the Dundee University College, and the Committee hope that a very large increase in the numbers attending these may in the immediate future be the result of the elementary teaching which is now so widely appreciated.

THE Royal University of Ireland has issued its Calendar for the year 1889. The papers set at the examinations in 1888 have already been published in a separate volume, and form a supplement to the Calendar.

PROF. ANGELO HEILPRIN has contributed to the Proceedings of the Academy of Natural Sciences of Philadelphia some valuable notes on the zoology of the Bermuda Islands. These notes are based on personal observations, and on collections made during a recent brief sojourn on the islands in company with a class of students from the Academy of Natural Sciences. Prof. Heilprin devoted much time to the study of the geological features of the Bermudas. The results of his work in this department he will embody in a future paper.

AT the annual meeting of the Asiatic Society of Bengal, on February 6, an address was delivered by the President, Colonel J. Waterhouse. This address has now been printed. It contains an interesting review of the progress of science and Oriental literature in India and its nearer border-lands during the year 1888.

WE have received Parts IV. and V. of "A Catalogue of the Moths of India," compiled by Mr. E. C. Cotes and Colonel C. Swinhoe. The subjects dealt with are Geometrites and Pyrales.

TWO works on palæontology are now being issued, in parts, in Germany: "Handbuch der Palæontologie," by Dr. A. Schenk and Prof. K. A. Zittel; and "Elemente der Palæontologie," by Dr. G. Steinmann and Dr. L. Döderlein. The former work is published by R. Oldenbourg, Munich and Leipzig; the latter by W. Engelmann, Leipzig.

ONE of the Johns Hopkins University Circulars, for March, contains the following morphological notes from the biological laboratory of the University: a preliminary abstract of researches by W. K. Brooks and F. H. Herrick on the life history of Stenopus, by W. K. Brooks; list of Actiniaria found at New Providence, Bahama Islands, by J. Playfair McMurrich; on the occurrence of an Edwardsia stage in the free-swimming embryos of a Hexactinian, by J. Playfair McMurrich; notes on the fate of the amphibian blastopore, by T. H. Morgan; on the anatomy and histology of *Cymbuliopsis calcœla*, by J. I. Peck; on a new phenomenon of cleavage in the ovum of the Cephalopod, by S. Watase; on the structure and development of the eyes of the Limulus, by S. Watase; notes on the embryology of *Mülleria agassizii*, Tel., a Holothurian common at Green Turtle Cay, Bahamas, by Charles L. Edwards; on the occasional presence of a mouth and anus in the Actinozoa, by Henry V. Wilson; on the breeding-seasons of marine animals in the Bahamas, by Henry V. Wilson; the multiplication of Bryophyllum, by B. W. Barton; notice of Dr. H. V. Wilson's paper on the development of *Manicina areolata*, by T. H. Morgan; report of Dr. Henry V. Wilson as Bruce Fellow of the Johns Hopkins University.

THE Royal Society of Victoria prints an alphabetical list of the genera and species of Sponges described by Mr. H. J. Carter, F.R.S., together with a number of his more important references to those of other authors, with an introductory notice, by Mr. Arthur Dendy, Demonstrator and Assistant Lecturer in Biology in the University of Melbourne.

ON Tuesday evening Prof. Raphael Meldola delivered an interesting lecture at the Royal Victoria Hall on "Insects in Disguise, and on Mimicry," to an audience of about 500 persons, chiefly working men. Many illustrations, lent by Mr. Poulton, were thrown upon the screen, and were much appreciated. The following lectures will also be delivered at the Royal Victoria Hall:—Tuesday, April 9, "Polarized Light," by Prof. Silvanus Thompson; Tuesday, April 16, "Electric Tram-cars," by Dr. Heming.

THE additions to the Zoological Society's Gardens during the past week include a Spanish Terrapin (*Clemmys leprosa*), South European, presented by Mr. F. T. Mason; two Tuatera Lizards (*Sphenodon punctatus*) from New Zealand, a Long-billed Butcher Bird (*Barita destructor*) from New Holland, deposited; a Common Otter (*Lutra vulgari* ♂), British, two Black-necked Storks (*Xenorhynchus australis* ♂ ♀), from Malacca, a Teguexin Lizard (*Teius teguexin*) from South America, purchased; an Alleghany Snake (*Coluber alleghaniensis*) from North America, received in exchange.

OUR ASTRONOMICAL COLUMN.

THE ASTRONOMICAL SOCIETY OF THE PACIFIC.—The increased interest in astronomy which has been felt in California in consequence of the erection of the Lick Observatory, and perhaps even more widely from the recent solar eclipse, which was so well and widely observed in the State, has led to the formation of an Astronomical Society under the above title. The Society was organized at a meeting held on February 7, 1889, and Prof. Holden was appointed interim President,

Messrs. Schæberle and Burckhalter Secretaries, and Mr. Molira Treasurer, until March 30, when a general meeting was to be held for the election of officers and Council, and other necessary business. The seat of the Society is to be in San Francisco, but only half the meetings are to be held there, the other half being proposed to be held at the Lick Observatory during the fine weather of the summer months. A circular setting forth the objects and regulations of the new Society has been widely circulated amongst those most likely to be desirous of joining it.

THE LATE W. E. TEMPEL.—We greatly regret to have to record the death, on March 16, of the Arcetri observer, William Ernest Tempel, so well known as one of the most keen-sighted and careful observers of comets and nebulæ. Herr Tempel, though his astronomical reputation was entirely associated with Marseilles or Italy, was of German extraction, having been born on December 4, 1821, at Nieder-Cunersdorf. His parents were poor, and when he grew up he followed the profession of lithographic artist. He settled down at Venice in 1859, after several wanderings, and here first began his astronomical observations with a 4-inch Steinheil, which he had purchased for himself. Here he discovered his first comet, and the famous Merope nebula. The following year he went to Marseilles, where he acted for some time as assistant at the Observatory, then under the direction of M. Valz. Here he discovered six minor planets, and ten comets, two of which proved to be of short period, and a third was rendered not less important from its being the comet connected with the Leonid meteors. The outbreak of the Franco-German war obliged him to leave France, and he returned to Italy. Giving up his lithography, and devoting himself wholly to astronomy, he acted for four years as Assistant at the Brera Observatory, Milan, and in 1875 he became Astronomer, and practically Director, of the new Observatory at Arcetri, Florence. Five more comets were discovered by him either at Brera or Arcetri, and at this latter place he took up the study of nebulæ, of which he made a great number of exceedingly fine drawings. In latter years his health obliged him to give up the work of observing, but he had already won for himself a distinct and honourable position in the history of the science. He was elected Foreign Associate of the Royal Astronomical Society in 1881, and received the Astronomical Prize of the Lyncean Academy in 1879, besides several from the Imperial Academy of Sciences of Vienna.

THE COMPANION OF SIRIUS.—Mr. Burnham, observing Sirius with the 36-inch telescope of the Lick Observatory during the past winter, finds the place of the companion as under:—

Date of Observation.	Distance.	Position Angle.
1888·97	5″·27	13°·9.

He was not able to see any other near companion.

COMET 1888 *e* (BARNARD, 1888 SEPTEMBER 2).—Herr A. Berberich gives in the *Astr. Nachr.*, No. 2883, the results of a more detailed computation of the orbit of this comet. He has formed nine normal places from observations extending from 1888 September 5 to 1889 February 17, and made at different Observatories, and deduces the following elements :—

$$T = 1889 \text{ January } 31{\cdot}256389.$$

$$\left.\begin{aligned} \omega &= 340^\circ\ 29'\ 22''{\cdot}71 \\ \Omega &= 357\ 25\ 35{\cdot}00 \\ \iota &= 166\ 22\ 12{\cdot}20 \end{aligned}\right\} \text{Mean Eq. } 1889{\cdot}0.$$

$$\log q = 0{\cdot}2587773.$$

The ephemeris shows that the theoretical brightness of the comet will undergo very little change for several months to come, and it will be almost of the same brightness as it was on the night of discovery by the time the anniversary of that date is reached.

Ephemeris for Berlin Midnight.

1889.	R.A. h. m. s.	Decl. ° ′	Log *r*.	Log Δ.	Brightness.
April 6	23 33 55	0 6·7 S.	0·2997	0·4582	1·7
10	23 33 4	0 10·3 N.	0·3043	0·4548	1·7
14	23 32 4	0 27·0 N.	0·3090	0·4508	1·7
18	23 30 53	0 43·2 N.	0·3139	0·4459	1·7
22	23 29 28	0 58·8 N.	0·3189	0·4402	1·7
26	23 27 48	1 13·8 N.	0·3240	0·4337	1·8
30	23 25 51	1 28·1 N.	0·3292	0·4264	1·8

The brightness at discovery is taken as unity.

COMET 1888 *f* (BARNARD, 1888 OCTOBER 30).—The following ephemeris for Berlin midnight for this comet is by Dr. R. Spitaler, *Astr. Nachr.*, No. 2875 :—

1889.	R.A. h. m. s.	Decl. ° ′	Log *r*.	Log Δ.	Brightness.
April 6	9 21 22	37 14·3 N.	0·4830	0·4015	0·15

22	9 26 42	37 41·0 N.	0·5049	0·4616	0·10

The brightness at discovery is taken as unity.

SATURN'S RING.—Mr. Keeler, writing to *Gould's Astronomical Journal* under date March 4, states that the very fine division on the outer ring of Saturn, detected with the 36-inch refractor early in 1888, has been recently seen again under specially favourable circumstances. The new division was about one-sixth of the breadth of ring A from its outer edge, and appeared as a distinct dark line of exceeding fineness. A dark shading extended inwards from the new division almost to the inner edge of the ring. The brightest part of the ring was the narrow strip lying outside the new division, and between it and the outer edge. The Lick observers consider this marking a permanent feature of the planet, but one which can only be observed with exceptional instrumental and atmospheric advantages. The shadow of the planet on the ring was carefully watched, but no deformation was detected.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 APRIL 7–13.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on April 7

Sun rises, 5h. 23m. ; souths, 12h. 2m. 4·7s. ; sets, 18h. 41m. : right asc. on meridian, 1h. 5·9m. ; decl. 7° 1′ N. Sidereal Time at Sunset, 7h. 46m.

Moon (at First Quarter on April 8, 14h.) rises, 9h. 17m. ; souths, 17h. 34m. ; sets, 1h. 53m.*: right asc. on meridian, 6h. 38·5m. ; decl. 22° 30′ N.

Planet.	Rises. h. m.	Souths. h. m.	Sets. h. m.	Right asc. on meridian. h. m.	Declination on meridian. ° ′
Mercury..	5 8	11 2	16 56	0 5·5	1 57 S.
Venus ...	5 35	13 54	22 13	2 58·6	23 43 N.
Mars ...	5 58	13 14	20 30	2 18·0	13 49 N.

THE FORCES OF ELECTRIC OSCILLATIONS TREATED ACCORDING TO MAXWELL'S THEORY. BY DR. H. HERTZ.[1]

III.

The Interference Experiments.

IN order to ascertain the velocity of propagation of electric force in the equatorial plane, we brought it into interference with another wave advancing with corresponding constant velocity in a wire. The result was, that the successive interferences did not occur at equal distances, but followed more rapidly in the neighbourhood of the oscillator than at greater distances.

This behaviour was explained by the supposition that the total force could be decomposed into two parts, of which the one, the electrodynamic, travelled with the velocity of light, while the other, the electrostatic, travelled with a greater, perhaps an infinite, velocity.

According to our theory now, however, the force in question in the equatorial plane is—

$$Z = Elm^3 \left\{ -\frac{\sin(mr-nt)}{mr} - \frac{\cos(mr-nt)}{m^2r^2} + \frac{\sin(mr-nt)}{m^3r^3} \right\},$$

and this expression in no way splits up into two simple waves travelling with different velocities. If, then, the present theory is correct, the earlier explanation can only be an approximation to the truth.

We will investigate whether the present theory leads to a general explanation of the phenomenon.

First, we can write $Z = B \sin(nt - \delta_1)$, where the amplitude

$$B = \frac{El}{r^3}\sqrt{(1 - m^2r^2 + m^4r^4)},$$

and the phase δ_1 is determined by the equation—

$$\tan\delta_1 = \frac{\frac{\sin mr}{mr} + \frac{\cos mr}{m^2r^2} - \frac{\sin mr}{m^3r^3}}{\frac{\cos mr}{mr} - \frac{\sin mr}{m^2r^2} - \frac{\cos mr}{m^3r^3}};$$

which, after transformation, gives—

$$\delta_1 = mr - \tan^{-1}\frac{mr}{1 - m^2r^2}.$$

In Fig. 5, the quantity δ_1 is represented as a function of mr by the curve labelled δ_1. The length ab corresponds in the

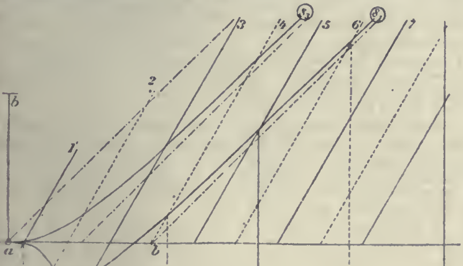

figure to the value of π, both for ordinates and abscissæ. If one considers, not mr, but r, as the variable abscissa, the length ab corresponds to the half wave-length.

In order to immediately attach the experiments which we wish to discuss, the abscissa axis is further divided into metres beneath the diagram. From the result of direct measurement (*Wied. Ann.*, xxxiv. p. 609, 1888), λ was equal to 4·8 metres, and thus the scale-length of a metre is determined. The zero of the scale is, however, not at the oscillator, but at a distance of 0·45 metre from it; for in this way the scale corresponds to the actual division of the base-line on which the position of the interferences was determined. One sees from the figure that the phase does not in general spread from the source, but its course is such that the waves arise at a distance of about $\frac{1}{4}\lambda$ from it, and give off thence a part to the conductor and a part out into space. At great distances, the phase is smaller by the value π than it would be if the waves had spread out with constant velocity from the source: the waves therefore behave, at great distances, as if they had traversed the first half wave-length with infinite speed.

The action, w, of the wire-waves at a definite position of the secondary conductor can now in any case be represented by the form $w = C\sin(nt - \delta_2)$; wherein the abbreviation—

$$\delta_2 = m_1 r + \delta = \frac{\pi r}{\lambda_1} + \delta$$

is used. λ_1 denotes the half wave-length of the waves in the wire, which in our experiment was 2·8 metres; δ, the phase of its action at the point $r = 0$, which we can arbitrarily change by adjustment of the length of the wire.

By this means we could change the amplitude, C, and give it such a magnitude that the action of the wave in the wire was approximately equal to that of the direct action. The phase of the interference depends, then, only on the difference of the phases δ_1 and δ_2. With the particular adjustment of the secondary circle to which our expression for w refers, both actions correspond (the interference has the sign +) if $\delta_1 - \delta_2$ is equal to zero, or a whole multiple of 2π; the actions disagree (the interference has the sign −) if $\delta_1 - \delta_2$ is equal to π, or any whole multiple of it. No interference occurs (the interference has the sign 0) if $\delta_1 - \delta_2$ is a whole multiple of $\frac{1}{2}\pi$.

We will now so determine δ that at the zero of the metre-divisions the phase of the interference has a definite value, δ_0, so that $\delta_1 = \delta_2 + \delta_0$.

The straight line 1 of our figure shall then represent the value of $\delta_2 + \delta_0$ as a function of the distance. The line is specially drawn with such a slant that for an increase of abscissa by $\lambda_1 = 2·8$ metres the ordinate increases by the value π, and is so arranged that it cuts the curve δ_1 in a point whose abscissa is the zero of the metre-divisions.

The lines 2, 3, 4, &c., represent further the course of the values $\delta_2 + \delta_0 - \frac{1}{2}\pi$, $\delta_2 + \delta_0 - \pi$, $\delta_2 + \delta_0 - \frac{3}{2}\pi$, &c. These lines are parallel to the line 1, and so drawn that they cut one and the same ordinate at distances of $\frac{1}{2}\pi$, and one and the same abscissa at distances of 1·4 metre.

Project now the section of these straight lines with the curve δ_1 on the axis of abscissæ below, and one gets immediately those distances for which $\delta_1 = \delta_2 + \delta_0 + \frac{1}{2}\pi$, $\delta_2 + \delta_0 + \pi$, $\delta_2 + \delta_0 + \frac{3}{2}\pi$, &c., for which, therefore, the phase of the interference increases from the origin by $\frac{1}{2}\pi$, π, $\frac{3}{2}\pi$.

One obtains immediately from the figures the following:—

If the interference at the zero of the base-line possesses the sign + (−), it vanishes for the first time at a distance of about 1 metre; it attains the sign − (+) at about 2·3 metres, vanishes again at 4·8 metres, and reverts back to the sign + (−) at about 7·6 metres; it is again 0 at 14 metres, and from thence onward the signs recur at fairly regular intervals. If at the zero of the base-line the interference was zero, it will be zero again at about 2·3, 7·6, and 14 metres, while it has a prominently positive or negative character at about 1 metre, 4·8 metres, 11 metres distance from the zero. For mean phases mean values serve.

If one compares with this result of theory the result of experiment, especially those interferences which occurred with arrangements of 100, 250, 400, 550 centimetres of wire (*Wied. Ann.*, xxxiv. p. 563), one will find a correspondence as complete as can be at all expected.

I do not succeed quite so well in calculating back to the interferences of the second kind (*l.c.*, p. 565). To get these we used an arrangement of secondary circle by which the integral force of induction through the closed circuit came prominently into account. If we regard the dimensions of the latter as vanishingly small, the integral is proportional to the rate of change of the magnetic field normal to the plane of the circle, and hence to the expression—

$$\frac{dP}{dt} = AElm^2n^2\left\{ -\frac{\cos(mr - nt)}{mr} + \frac{\sin(mr - nt)}{m^2r^2} \right\}.$$

[1] Translated and communicated by Dr. Oliver Lodge. Continued from p. 452.

Hence we get for the phase δ_3 this expression—

$$\tan \delta_3 = -\frac{\frac{\cos mr}{mr} - \frac{\sin mr}{m^2r^2}}{\frac{\sin mr}{mr} + \frac{\cos mr}{m^2r^2}}$$

or, after transformation—

$$\delta_3 = mr - \tan^{-1} mr.$$

The line δ_3 of our Fig. 5 represents this function. One sees that for this action the phase steadily increases direct from the origin. Those phenomena, therefore, which indicate a finite pace of propagation must make themselves apparent by interferences even close to the vibrator. So it shows itself in these experiments, and just herein consists the advantage which we derived from this kind of interference experiment. But the apparent velocity comes out greater in the neighbourhood of the vibrator than at a distance, and it is not to be denied that the phase of the interference must theoretically change less, but notably more quickly than was experimentally the case.

It appears to me probable that a more complete theory, one which does not consider both conductors as vanishingly small —perhaps, also, another estimate of the value of λ—would here afford a better correspondence.

It is of importance that even on Maxwell's theory the experiments cannot be explained without assuming a marked difference between the velocity of waves along wire and their velocity in free space.

(*To be continued.*)

NOTE ON THE USE OF GEISSLER'S TUBES FOR DETECTING ELECTRICAL OSCILLATIONS.

AT the suggestion of Prof. Lodge, I undertook to repeat in the Physical Laboratory of the University College, Liverpool, Hertz's celebrated experiments on electrical oscillations.

In performing these experiments, I was searching for means to make the effect of the electrical oscillations more easily observable, and I was induced to use for this purpose (1) Geissler's tubes, in order to strengthen the visible effect; and (2) the chemical action of the oscillating currents (paper soaked in solution of iodide of potash), in order to obtain a permanent trace of them.

For the present I will describe briefly the results of the use of Geissler's tubes.

In order to produce the electrical oscillations, I used a conductor consisting of two zinc plates, about 41·5 centimetres square, suspended in the same plane 55 centimetres apart; to each plate was fastened a No. 6 copper wire, which was finished off with a small brass knob. The two brass knobs were about 5 millimetres apart, and formed the *sparking gap*, as we shall call it. As receiver of the oscillations, I used, like Hertz, circles of No. 14 wire, 35 centimetres in radius.

After the example of Mr. F. T. Trouton (NATURE, February 21, p. 391), I will call the first conductor a *vibrator*, and the wire circles, or other receivers, resonators.

The vibrator was connected with a small coil, 20 centimetres long, supplied with an ordinary spring interrupter, and excited by four secondary cells.

If we connect one electrode of a convenient Geissler's tube with either side of the sparking gap of the resonator, currents pass through or into the tube, which lights up and so makes the effect of the electrical oscillations on the resonator visible even at a great distance.

Of the few tubes which were at my disposal, I found that the most convenient for this purpose was a small one with electrodes 8·5 centimetres apart, and filled with highly rarefied air. But spectral tubes 20 centimetres long and filled with hydrogen, oxygen, or nitrogen also gave good results.

With the first mentioned tube I perceived *a visible effect*, when the resonator was held horizontally in the plane containing the wires of the vibrator, and with the sparking gap turned towards it, at a distance of 4 metres from the vibrator. By this arrangement all the phenomena described by Hertz (*Wiedemann's Ann.*, xxxiv. p. 160, 1888) about the direction of the electrical lines of force can easily be shown.

A very instructive experiment is to show the directions of these lines by several resonators disposed round the vibrator. For this purpose I suggest the following apparatus:—

On a wooden frame mounted so as to be able to revolve on a vertical axis standing under the sparking gap of the vibrator are fastened several resonators, with their planes vertical and parallel respectively to the directions of the lines of force and the sparking gaps at the highest point. These resonators are supplied with Geissler's tubes. In this position of the resonators all the tubes will lighten up when the vibrator is working. But if the frame with the resonators moves round the vertical axis, the light of the tubes will become weaker, and, when the frame is turned 90°, the tubes will become quite dark; the planes of all the vibrators in this position being perpendicular to the directions of the lines of force. This change will occur inversely by turning the frame from 90° to 180°.

If, instead of one resonator, two are fastened to each point of the frame, one perpendicularly to the other, both being vertical, the changes in either of these will be contrary—that is to say, when the light in one set of the tubes becomes brighter it becomes weaker in the set perpendicular to it and *vice versâ*. Thus the strength of the light is, so to say, proportional to the magnitude of the components of the lines of force in the direction of the tubes.

If a disconnected Geissler's tube is held near the vibrator, it begins in a short time to light up, owing to oscillatory currents passing through it. The same effect is obtained if instead of holding the tube by the hand it reposes on an insulating body. This lighting occurs at all points near the vibrator, except about the sparking gap. The tube becomes quite dark if the hand or a conductor is interposed between it and the vibrator; on the contrary, the interposing of an insulating body causes no change in the tube. The tube becomes more sensitive if a portion of it is surrounded with tinfoil.

In this way the existence of electrical oscillations in space can be ascertained, and also the transparency of insulating bodies and the opacity of conductors for electrical oscillations can be demonstrated.

When the two electrodes of a Geissler's tube are connected with two different points of a resonator, the effect in the tube is produced by the difference of potential of the two points. If now we connect one point of the vibrator or the resonator with one electrode of the tube, the other electrode hanging free in the air or being earthed, we have an alternative current through the tube whenever the potential of the point connected with the electrode becomes different from zero, and thus the tube lights up. The effect is strengthened if one portion of the tube is surrounded by tinfoil. This is a very convenient arrangement for observing the form of the electrical oscillation in conductors.

If we investigate in this manner our circular resonator held vertically before the vibrator, with its plane parallel to it and the sparking gap upwards, we find that a tube hanging at the lower end of the vertical diameter of the circle, opposite to the sparking gap, remains quite dark, and lights up when moved to the right or to the left of this point. The light becomes brighter till the horizontal diameter is reached; further on the light begins to grow weaker till the sparking gap is attained, where the tube, however, continues to lighten. The light becomes weaker when the sparking gap is narrowed, and ceases when it is quite closed. Thus we see that the circular resonator possesses one node at its lowest point, two ventral segments at equal distances from the node and the sparking gap, and two minima of oscillation one on each side of the sparking gap.

That a node is situated at the point opposite to the sparking gap is also ascertained by observing that by touching this point with the finger or by hanging from it a piece of wire or by connecting it to earth, no change is to be remarked in the spark of the resonator. These manipulations, if applied to another point of the resonator, diminish the spark.

If the resonator is formed by a closed circle of wire, we find a node at each end of the vertical, and a segment at each end of the horizontal, diameter of the circle. The distance between the two nodes being here 110 centimetres, the wave-length is 220 centimetres, while the length of the primary wave is about 880 centimetres. Thus the wave-length in the resonator corresponds to the second higher octave of the fundamental oscillation.

If, instead of circular, we use linear resonators placed parallel to the vibrator, we must be very careful to distinguish between the effect produced directly from the vibrator in the Geissler tube and the effect caused by the oscillations of the resonator. In the case of the circular resonators, placed in the position above described, one need not trouble much about the direct effect of the vibrator, this being very small in the neighbourhood of the vibrator's sparking gap.

To prevent the direct action a small uninsulated metal screen can be placed between the vibrator and the tube, or the tube can be hung by a long and fine wire, in order to be removed from the sphere of the direct action of the vibrator. The best plan is, however, to surround the tube by wire gauze, which stops the direct action of the vibrator on the tube, and yet permits the tube to be observed. The absence of direct action can be ascertained in the different positions which the tube takes by insulating it from the resonator without changing its position, and noticing if it becomes quite dark.

If we place before the vibrator a resonator, consisting of a straight wire 220 centimetres long (I used copper wire No. 6), we find, by the tubes, that nodes exist in the middle and the two ends of the wire, consequently two segments at 55 centimetres from each end of the wire.

(The above-described circular resonator can be likened to a linear one which is curved to a circle and its two ends soldered together, thus the two nodes of the ends becoming one single node.)

If this straight wire is cut in the middle, a torrent of sparks passes between the separated ends, even if they are removed several millimetres apart. If then we examine each half of the wire, we find that it possesses a node in the middle and two segments, each at one end, but the node is not so well defined as in the case of the uncut wire; there is no single point the potential of which remains continually equal to zero, but a line in which the difference of potential from zero is a minimum. This complicated form of oscillation is produced by the fact that the forces acting in this resonator are not equal at all points or symmetrically distributed with respect to it, as in the case of the long resonator. The oscillations of the short resonator may be compared to those of a rod which is not firmly fixed by its middle. The state of these oscillations is not stable. If one or both ends of this resonator are touched by the finger, they become nodes, and a well-defined segment appears at the middle of the resonator. If the Geissler tube be connected with this middle point, it begins to light up when the ends of the resonator are touched, and ceases to light the moment the fingers are removed; the contrary takes place if the tube be connected with one end of the resonator. This phenomenon is analogous to the change of the form of the vibration of a rod when fixed by its middle or by its ends.

Quite similar is the mode of oscillation of a resonator 220 centimetres long disposed on one side of the vibrator; it possesses also a node at the middle not well defined, and a segment at each end.

To conclude, I will describe the mode of oscillation of a resonator, 110 centimetres long, disposed parallel and symmetrically to the vibrator. This resonator possesses one node in the middle, very clearly defined, and a segment at either end. This form of oscillation is the same as would occur in the long resonator if one-fourth of its length from each end were cut off.

In the case of the latter resonator and of the long one, which is also symmetrically disposed to the vibrator, the oscillations are very stable, and much stronger than in the case of the resonators placed on one side of the vibrator. The mode of the oscillations of these symmetrical resonators is not disturbed by touching them by the fingers at any point, although the mode of oscillation is disturbed if we touch the unsymmetrical resonators at any point whatever.

The experiments described must be performed in a dark room, and much care be used in the choice of the proper Geissler tubes. Tubes containing mercury are very sensitive, and they become more so if the mercury be allowed to flow several times from one end of the tube to the other.

Liverpool, March. E. J. DRAGOUMIS.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 21.—"An Experimental Investigation of the Circumstances under which a Change of the Velocity in the Propagation of the Ignition of an Explosive Gaseous Mixture takes place in Closed and Open Vessels. Part I. Chronographic Measurements." By Frederick J. Smith, M.A., Millard Lecturer on Mechanics, Trinity College, Oxford. Communicated by A. G. Vernon Harcourt, F.R.S.

It bas been noticed by several investigators, viz. MM. Berthelot and Vielle, MM. Mallard and Le Chatelier, and Prof. H. B. Dixon, F.R.S., that explosive gaseous mixtures after ignition do not reach their maximum velocity of propagation at once, but that a certain maximum velocity is attained soon after initial ignition.

In order to investigate this period, which may be called the acceleration period of an explosion, chronographic measurements of a peculiar nature were found necessary.

It was at once evident that but little advance in this branch of the subject of explosions could be made unless exceedingly minute periods of time could be measured with certainty.

A new form of chronograph has been devised to meet as far as possible all the requirements of the case, by means of the instrument. The following results have been obtained:—

(1) The $\frac{1}{20000}$ of a second can be measured with ease, and periods of time differing from $\frac{1}{10}$ of a second to $\frac{1}{20000}$ of a second can be recorded on the same moving surface.

(2) The surface which receives the record moves at a velocity which is practically constant during the traverse of 5 cm.; also its velocity can be varied between wide limits.

(3) A large number of time records can be made side by side, all records being made in straight lines.

(4) Fractions of recorded vibrations of a fork can be subdivided by means of a micrometer microscope. This is not the case with vibrations recorded on a surface attached to a pendulum, where the velocity varies from zero up to a maximum at the middle of the swing.

The electro-magnetic styli, by means of which events are marked, are so constructed that their period of "latency" is almost absolutely constant, and their electro-magnets are so wound that no sparking takes place on breaking the circuit.

A moving surface is carried on a carriage, which is propelled by means of a falling weight, which after a certain velocity has been attained is removed: the surface then moves with a velocity which is found to be practically constant for the limits between which a time record is made.

The chronograph is used in conjunction with a steel tube in which the explosions take place. At even distances along the axis of the tube, conducting bridges, eight to ten in number, of Dutch metal insulated from the tube, are placed; each bridge is connected electrically with a recording stylus, so that as each bridge is broken by the explosion, a mark is made on the surface of the chronograph; these markings when duly interpreted provide data for constructing a curve, which indicates the rate at which the velocity of the explosion is changing during its propagation.

The rest of the paper treats of the methods by means of which the errors due to the use of electro-magnets in chronographic work have been dealt with and reduced as far as possible.

Chemical Society, March 7.—Mr. W. Crookes, F.R.S., in the chair.—The following papers were read:—The decomposition of carbon disulphide by shock; a lecture experiment, by Prof. T. E. Thorpe, F.R.S. The author, in studying the action of the fluid alloy of potassium and sodium on carbon disulphide, obtained a yellowish-brown solid substance which exploded with great violence when subjected to pressure or friction. If the explosion occurred in contact with carbon disulphide, that substance was resolved into its elements. A similar decomposition of carbon disulphide into carbon and sulphur can readily be effected by exploding a charge of 0·05 gramme of fulminate within a stout glass tube containing carbon disulphide vapour, and the experiment affords a good illustration for class purposes of the resolution of an endothermic compound into its elements by sudden shock.—The determination of the constitution of the heteronucleal $\alpha\beta$- and $\beta\beta$-di-derivatives of naphthalene, by Prof. H. E. Armstrong and Mr. W. P. Wynne. A preliminary note on the constitution of the three chloramidonaphthalenesulphonic acids obtained by sulphonating α-chloro-β-amidonaphthalene hydrochloride with weakly fuming sulphuric acid.—The action of chloroform and alcoholic potash on phenylhydrazine, by Dr. S. Ruhemann.

March 28.—Annual General Meeting.—The following is an abstract of the Annual Report, read by the President, Mr. W. Crookes, F.R.S.:—The pleasant duty again devolves on me to present to you the annual report on the state of the Chemical Society during the twelve months just past. The following statement shows the numerical position of the Society—

Number of Fellows (March 28, 1888) ...	... 1534
Present number of Fellows	... 1614
Increase	80

103 papers have been communicated to the Society this session. Our library continues to increase, and every year becomes richer in rare volumes and books of reference. The duplicate library for lending is also becoming increasingly useful. The expenditure under this head for the current year is £308 5*s.* 6*d.*

I must now ask your attention to an event of which none of you can be ignorant, which, though not exclusively relating to chemistry, bears closely upon it and upon the future of British science. I refer to the protest against the examination system in education which appeared in November last. That protest had long been in the air. For years past, men who take the trouble to observe and to reflect have come to the conclusion that competitive examination is injurious to the individual, injurious to the race, and that it starves original research at the root. They have convinced themselves that if we flag in scientific investigation, that if a large and increasing proportion of professorships and of leading positions in industrial establishments, both in the home kingdom and in the colonies, are filled by aliens, the fault lies mainly with our educational system. Men trained chiefly to pass examinations either in theoretical or practical departments cannot equal those who have been schooled in actual research, trained to accurately observe and draw correct inferences from facts. All the earlier protests were desultory, and calculated to produce no lasting impression ; but the recent manifesto is the expression of the collective opinion of many earnest representative men and women. Hence it cannot be slighted as the mere outcry of a faction, a sect, a school, or an interest. A most satisfactory feature is the adhesion to the protest of men who formerly were in favour of competitive examination as the test for entrance into the civil or military service of the State. Prof. Max Müller, of Oxford, frankly admits he now considers competition to be a mistake, and avers that the failure springs not only from the manner in which the system has been worked, but is involved in its very nature. But if this protest is to avail it must be energetically followed up, for I must repeat what I have before declared, that the position of science in Britain is far from satisfactory. Though the number of articles devoted to research in German Transactions and journals exceeds those in our own publications, we must remember that the population of the German Empire is greater than that of the United Kingdom by at least one-fourth ; further, that the *savants* of Russia, of the Austrian Empire, of Switzerland, of Holland, and Scandinavia, largely select German journals as their medium of publication. Not a few English and American scientific men follow the same course. Hence, as regards quantity, our share in the world's scientific work is more considerable than appears at the first glance. Further, I think that if deficient in quantity English research excels in quality. If we do less detail work we furnish a larger proportion of generalizations and laws than most of our rivals. As the discoverers of laws and generalizations, Black, Boyle, Dalton, Faraday, Graham, Joule, Newton, Wollaston, and Young are household words in the laboratory—yet none of these men were the products of the examination system. There is another evil against which I must strongly protest. I refer to the system of "sealed papers." Everyone knows that on the Continent, more especially in France, it is common for anyone who has, as he thinks, approached the solution of some important question, to deposit a sealed sketch of his incomplete results with the President or Secretary of some learned Society. The sketch may lie *perdu* for years, until the author requests it may be opened and read before the Society. The practice arose from a desire that the author's priority should be guaranteed against others who might lay claim to his ideas. But priority can be quite as effectually secured by a brief preliminary notice read before some Society or sent to some journal, the author thus reserving to himself the further investigation of the subject. Among men of honour such reservations are invariably respected. But the "sealed paper" system lends itself to something which borders unpleasantly upon fraud. Suppose an investigator takes up some question, sees that it admits of two or more solutions, or that various hypotheses present themselves to him as possible. To work out the matter conclusively might require much time and trouble. He therefore writes out each hypothesis, and incloses them separately in "sealed papers," duly numbered, carefully retaining copies. In process of time some other investigator, ignorant of what the first author has done, takes up the subject, and works out one of these hypotheses to demonstration. So soon as his supplementary memoir is before the world the first investigator requests that the "sealed paper" No. 2 or No. 3 be opened and read. The new theory, laboriously considered and worked out, is found to have been anticipated, and the man who has really done the work is robbed of much of his credit. The seeming anticipator says nothing about the contents of other "sealed papers," in which he has proposed totally different hypotheses: these he now leaves to oblivion. I think the Fellows of our Society will agree with me that a system which thus enables a man to reap the fruit of another man's experiments does not deserve to be naturalized in England. There is a further abuse to which attention may usefully be drawn. It sometimes happens a man of science will send an account of researches he has completed to two journals simultaneously, English or foreign, leaving each editor under the impression that he is the sole recipient of the communication. Or, still worse, a man reads a paper before our Society, and sends it to some foreign journal, so that it may figure in print before it appears in the Society's Transactions. To this subject I felt compelled to refer when I had the honour of addressing you last year. And you are now aware, your Council declines to publish any memoir which has previously appeared in a foreign journal, unless specially recommended by the Publication Committee and approved by the Council. The reasons for this resolution are not hard to seek. Not merely is the reputation of the Society, as the original channel of the researches in question, imperilled, or at least obscured, but a serious waste of time and labour is inflicted upon anyone who needs to read up the literature of the subject. We in England are by no means the only sinners in this respect. It often happens that memoirs which have been read before the Paris Academy of Sciences reappear as "original matter" in certain French journals. I cannot pass over a discovery made this season by Prof. Krüss concerning nickel and cobalt. As at first reported it seemed that these two metals might be eliminated from our text-books, and that two or three new substances would take their place. Had this been the case, it would undoubtedly have been one of the greatest steps in pure chemistry taken this century. It now appears that each of the two metals contains a common impurity, which Prof. Krüss has been the first to detect and isolate. Nickel and cobalt thus purified will still retain their individuality, though their accepted properties, physical and chemical, will need careful revision. In any case the discovery is most instructive, warning us how careful we should be to have firm ground under our feet. It is almost humiliating that two metals which have been subjected to infinite research and scrutiny should now be found to contain such a proportion of unsuspected impurity. You are aware that at the ballots for the election of Fellows half an hour or more of valuable time is spent in a manner which, to say the least, is not very interesting. An attempt has been made to save time by taking the ballot in the library, after the meeting, but so many Fellows leave before the end of the meeting that the number remaining has not been found sufficient to meet the requirement of the by-laws. Your Council have from time to time had this matter under discussion, and at their last meeting, on March 21, it was resolved "that in future the balloting for Fellows be conducted by means of papers." The best manner of carrying out this resolution will be a subject for future arrangement. A posthumous memoir on the compressibility of hydrogen, by the late Prof. Wroblewski, reminds us of the sad and untimely death of this meritorious and distinguished worker in physical chemistry. His death, as most of us doubtless are aware, was due to the frightful burns which he received from the overturning or explosion of a paraffin lamp. In the memoir in question Prof. Wroblewski treats of the compressibility of hydrogen at 99°, at 0°, at $-103°\cdot5$ (boiling-point of ethylene), and at $-182°\cdot4$ (boiling-point of oxygen), for pressures ranging from 1 to 70 atmospheres. From the results the following data were calculated : critical temperature $-240°$; critical pressure, 13·3 atmospheres ; critical volume, 0·00335. Hence it appears very doubtful whether M. Pictet or M. Cailletet really succeeded in liquefying hydrogen. Last year I had the pleasure to announce that one of our Fellows, Mr. Newlands, had received the "Davy Medal" of the Royal Society for his splendid discovery of the Periodic Law of the Chemical Elements. I may also be allowed to state that to me, your President, the Royal Society has likewise awarded the same distinction for my researches on the behaviour of substances under the influence of the electric discharge in a high vacuum, with especial reference to their spectroscopic reactions. Hence it has been suggested that I might not unprofitably claim your attention this evening for a history of the so-called rare earths, as they have been brought to light and discriminated by the aid of the spectroscope. [We print elsewhere Mr. Crookes's address on this subject.]

Linnean Society, March 21.—Mr. Carruthers, F.R.S., President, in the chair.—Mr. T. Christy exhibited the pod (36 inches in length) of an Apocynaceous plant received from Gaboon as *Strophanthus*, but believed to be allied to the *Holarrhena*.—Prof. Stewart, referring to the specimens of *Noctilio leporinus* exhibited at the last meeting of the Society, stated that he had examined the contents of the stomachs submitted to him by Mr. Harting, and had found without doubt fragments of fish, scales, and fin-rays, and a portion of the lower jaw of a small fish, proving the correctness of the assertions which had been made regarding the piscivorous habits of this bat.—Mr. W. B. Hemsley furnished a report on the botanical collections made on Christmas Island during the voyage of the *Egeria*. This included a complete list of the plants collected, with remarks on their general distribution, the author being of opinion that the flora of this island, which lies about 200 miles south of the western end of Java, was more nearly related to that of the Malayan Archipelago than to that of Australia. Mr. C. B. Clarke, commenting on the author's observations on the buttresses of trees, described some remarkable instances which he had seen of this singular mode of growth. Mr. J. G. Baker, referring to the Ferns which had been collected, noticed their affinities and distribution. Mr. R. A. Rolfe commented on three species of Orchids which had been brought home by this Expedition, all of which were new. Mr. Thiselton Dyer, referring to Mr. Lister's Report to the British Association on the zoological collections from this island, in which it was stated that the character of the avifauna was Australian, considered that this was not borne out by an examination of the flora, which was decidedly Malayan.—A paper was then read by Mr. R. A. Rolfe on the sexual forms of *Catasetum*, with special reference to the researches of Darwin and others. The purport of Darwin's paper (Journ. Linnean Soc., 1862) was to show that *Catasetum tridentatum* had been seen by Schomburgk to produce three different kinds of flowers, belonging to the same number of supposed genera, all on the same plant, and that the three represented respectively the male, female, and hermaphrodite states of the species. Mr. Rolfe showed that Schomburgk's remarks applied to two distinct species, *C. tridentatum* and *C. barbatum*, the females of which resembled each other so closely that they were thought to be one and the same—namely, *Monacanthus viridis*. Neither of these, however, belonged to the true plant of that name, which was really the female of another species—namely, *C. cernuum*, a fact hitherto unsuspected. The key of the situation was that the females of several species resemble each other very closely, and to three of them the name *Monacanthus viridis* had been applied.—After some critical remarks by the President and Mr. Bull, a paper by Mr. MacOwan was read, on some new Cape plants.

Geological Society, March 6.—W. T. Blanford, F.R.S., President, in the chair.—The following communications were read:—On the subdivisions of the Speeton Clay, by G. W. Lamplugh. Communicated by Mr. Clement Reid. The reading of this paper was followed by a discussion, in which Prof. Judd, Mr. Strahan, Prof. Blake, Mr. Hudleston, and Mr. Herries took part.—Notes on the geology of Madagascar, by the Rev. R. Baron. Communicated by the Director-General of the Geological Survey. With an appendix on some fossils from Madagascar, by Mr. R. Bullen Newton. The central highlands of Madagascar consist of gneiss and other crystalline rocks, the general strike of which is parallel with the main axis of the island, and also, roughly, with that of the crystalline rocks of the mainland. The gneiss is frequently hornblendic; its orthoclase is often pink; triclinic felspar often occurs in places; biotite is the most common mica, but muscovite is not uncommon; magnetite is generally present, often in considerable quantities. The gneiss is often decayed to great depths, forming a red soil, and the loosened rock is deeply eaten into by streams. The harder masses of gneiss, having resisted decay, stand out in blocks, and have been mistaken for travelled boulders of glacial origin. Other more or less crystalline rocks are mica-schists, chlorite-schists, crystalline limestone, quartzite (with which graphite is often associated), and clay-slate. Bosses of intrusive granite rise through the gneiss. That east of the capital contains porphyritic crystals of felspar which near the northern edge of the granite are arranged roughly in a linear direction; here also the granite contains angular fragments of gneiss. For the most part the granite of Madagascar is clearly intrusive, but this may not always be the case. The volcanic rocks are of much interest. The highest mountains, those lying to the south-west of the capital, consist, in their higher parts, of a mass of lava, for the most part basaltic, but with some sanidine-trachyte. The lava-streams are sometimes twenty-five miles long, and successive flows, up to 500 feet in thickness, are exposed by the valleys. From the great denudation which this area has undergone, and from the fact that no cones now remain, we may assume that this volcanic series is of some antiquity. Of the newer volcanic series there are numerous very perfect cones, dotting the surface of the gneiss in many places. No active volcano now exists in the island, but the occasional emission of carbonic acid gas, the occurrence of numerous hot springs and deposits of siliceous sinter, and the frequency of small earthquake-shocks, seem to show that volcanic forces are only dormant and not entirely extinct. The ashes generally lie most thickly on the side of the cone between north and west; this is accounted for by the prevalence of the south-east trade-winds. The volcanic areas are ranged roughly in a linear direction, corresponding with the longer axis of the island. Sedimentary rocks occur mainly on the western and southern sides of the island. The relations of these to each other have not yet been determined; but from the fossils (referred to the European standard) it seems that the following formations are represented: Eocene, Upper Cretaceous, Neocomian, Oxfordian, Lower Oolites, Lias. Possibly some of the slaty beds may turn out to be Silurian or Cambrian. The crystalline schists, &c., are probably, for the most part at least, Archæan. Recent deposits fringe the coasts, and are largely developed on the southern part of the island. East of the central line of watershed there is a long depression containing a wide alluvial deposit, probably an old lake-bed. Terraces fringe its sides in many places. The lagoons of the eastern coast are due to alluvial deposits. The paper concluded with some remarks on the geological antiquity of the island, its separation dating from early Pliocene times, if not earlier. This is the conclusion arrived at by Wallace from its fauna; the author's detailed researches into its flora, recently described before the Linnean Society, show that while about five-sixths of its *genera* of plants are also found elsewhere, chiefly in tropical countries, at least four-fifths of its *species* are peculiar to Madagascar. The appendix, drawn up by Mr. R. Bullen Newton, consisted of notes upon the fossils collected by the author, with tables, and descriptions of two new species—namely, *Astarte* (?) *Baroni* and *Sphæra madagascariensis*, both from deposits of Lower Oolitic age.—Notes on the petrographical characters of some rocks collected in Madagascar by the Rev. R. Baron, by Dr. F. H. Hatch. Some remarks on Mr. Baron's paper were made by the President, Dr. Geikie, Mr. H. B. Woodward, and Mr. Topley.

PARIS.

Academy of Sciences, March 25.—M. Des Cloizeaux, President, in the chair.—On the achromatism of interferences, by M. Mascart. The conclusions arrived at by Cornu and Stokes are here applied to the particular cases of interference fringes and of Newton's rings. In the phenomenon of W. Herschel's fringes the condition of achromatism is shown to be—

$$\frac{\cos^2 i}{\sin i} = L \frac{\sin A}{\cos r}.$$

—Remarks accompanying presentation of Prof. Karl Pearson's work, "The Electrical Researches of Barré de Saint-Venant" (Cambridge, 1889), by M. Boussinesq. The period from 1850 to 1886, covered by this important treatise, comprises the most remarkable researches, by the late M. de Saint-Venant, on torsion, flexion, live resistance, the distribution of elasticities in heterotrope bodies, plasticodynamics, &c. The work, which will be found of great service to English physicists, geometricians, and engineers, unfamiliar with the French language, forms the first part of the second volume of the series begun by Todhunter on the "History of the Theory of Elasticity."—On elliptical polarization by vitreous reflection, by M. A. Potier. Rejecting Cauchy's assumption of evanescent longitudinal waves, the author here develops a theory in which he takes as his starting-point the differential equations of the vibratory movement. The principle and results of this theory were already announced at the meeting of the French Association for the Advancement of the Sciences in 1872.—Researches on the cultivation of the potato, by M. Aimé Girard. The author here deals with the progressive development of the plant, and arrives at the general conclusion that the origin of the starch is to be sought in the leaves, where it is probably represented in its initial form by saccharose, or

some analogous sugar. By its twofold decomposition this sugar becomes on the one hand the generator of the cellular tissue, on the other of the starch which is stored up in that tissue.—On the peroxides of cobalt and nickel, and on the volumetric analysis of these metals, by M. Adolphe Carnot. The action of potash combined with that of chlorine, bromine, iodine, or of an alkaline hypochlorite, yields in cobalt and nickel solutions certain black granular precipitates almost identical in appearance. Herrenschmidt, however, has pointed out that the peroxide of cobalt thus obtained has a brown colour, while the peroxide of nickel remains black under the microscope. M. Carnot here describes a series of experiments carried out for the purpose of determining the state of oxidation of the metals in these various precipitates. The general result is that the brown oxide obtained by precipitating cobalt with hydrogen dioxide and caustic potash at the boiling-point has the exact composition of the sesquioxide, Co_2O_3, and that the black oxide of nickel, precipitated by hypochlorite or by bromine and potash, is the sesquioxide, Ni_2O_3.—On the limits of the errors that may be committed in assaying fine gold, by M. Paul Charpentier. The figures here given are the result of about 300 assays executed by the author at the laboratory of the French Mint.—On the initial phase of electrolysis, by M. Piltschikoff. A protracted study of the phenomenon of retardation in the electrolytic process leads to the following results. The minimum electromotive force required to at once set up a visible electrolysis does not depend within certain limits on the nature of the salt, nor on the concentration of the solution (gold, zinc, sulphate of zinc; platinum, copper, sulphate of copper, nitrate of copper, gold, platinum or silver, &c.). The minimum does not depend perceptibly either on the heat of combination of the two metals, or on their contact electromotive force; but it depends essentially on the physical state of the cathode (negative pole), which may modify the resulting figures as much as 20 or even 25 per cent.—On the electric transport of salts in solution, by M. A. Chassy. The special case is here considered of a non-electrolyzed metallic salt, a salt of zinc, for instance, in a mixture of salts of copper and zinc.—On the glycol-ether of chloral, by M. de Forcrand. The author has prepared this compound,

$$CCl_3.CH(OH).OC_2H_4OH,$$

in the crystallized state, by combining molecular proportions of chloral and glycol at the ordinary temperature. It is soluble in water, and melts at 42° C., which is also the melting-point of chloral ethylate, according to M. Berthelot.—Determination of the heats of combustion of metaldehyde, erythrite, aud tricarballylic acid, by M. Louguinine. These experiments have been carried out by means of the calorimetric apparatus under precisely the same conditions as those already published.—Papers were contributed by MM. J. Héricourt and Ch. Richet, on the varying toxic effects of the blood of the dog transfused into the rabbit; by M. V. Galtier, on the liability of sheep and other animals to contract infectious pneumo-enteritis, hitherto regarded as a disease peculiar to the pig; by M. Joannes Chatin, on the homologies of the inferior lobes in the brain of fishes; and by MM. Jules de Guerne and Jules Richard, on the fresh-water fauna of Greenland.

BERLIN.

Physical Society, March 8.—Prof. von Helmholtz, President, in the chair.—Dr. Rubens described the experiments which he had made on the selective reflection of light by metals. The method employed was as follows: the light emitted by an incandescent plate of zirconium was concentrated by a lens on to a mirror-surface of the metal under investigation, and the reflected rays were then allowed to fall into a spectroscope with flint-glass prism, whose ocular had been replaced by a bolometer. In this way the intensity of each part of the spectrum could be determined. The next step consisted in removing the mirror and putting the glowing zirconium in the place of the virtual image of the first source of light, in such a way that the rays of light, coming from the point previously occupied by the mirror, pursued the same course as in the first experiment. These rays were then allowed to fall into the spectroscope, and the intensity of each part of the spectrum thus formed by light which had undergone no change by reflection was measured by the bolometer. The intensity was determined at fifteen different points in the spectra, extending from near F in the blue into the ultra-red down to the wavelength 2μ. The changes produced in the light by reflection from the metals were represented by curves whose abscissæ corresponded to wave-lengths while their ordinates corresponded to the intensities of the several rays after reflection. The results thus obtained showed that silver possesses even for blue rays a very considerable reflexive power, which gradually increases and reaches its maximum in the red, at which maximum the intensity of the reflected light then remains constant even for rays of the greatest wave-length. Gold possesses a much smaller reflexive power for blue and green rays; the curve then rises very rapidly to a maximum in the yellow and falls again towards the red. Copper reflects the blue and green rays even less than gold does: its reflexive power then increases rapidly into the red, and then somewhat more slowly, until in the ultra-red it reaches a value equal to that for silver. Iron and nickel gave very similar curves, rising at first somewhat rapidly, but subsequently more slowly and continuously into the ultra-red, without however reaching the maximal values observed for copper or silver. On the basis of these experimental values for the reflexive power of the above five metals, the speaker had calculated their coefficients of extinction and refraction for red and blue light, making use of Cauchy's and Beer's formulæ. From this it was possible to deduce the dispersive powers of the metals, and to compare their indices of refraction with those which had been experimentally determined by Prof. Kundt: the agreement was in most cases very close.—Prof. Preyer gave an account of some letters of Robert Meyer which are shortly to be published. They were written in the years 1842 and 1844 to his friend Dr. William Griesinger. Prof. Preyer read out several characteristic passages from these letters, in which Meyer states how he arrived at his discovery of the conservation of energy, and from which his firm belief in the correctness of his theory is quite apparent. No less characteristic is the way in which Meyer takes pains to explain his theory to his medical friend, who was but little experienced in physical matters, and to put it before him in a way which he could easily understand.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

A Class-book of Geography (revised edition): C. B. Clarke (Macmillan).—A Treatise on Chemistry, vol. iii., Part 5: Roscoe and Schorlemmer (Macmillan).—The Principles of Empirical or Inductive Logic: J. Venn (Macmillan).—Borneo; Entdeckungsreisen und Untersuchungen; Gegenwärtiger Stand der Geologischen Kenntnisse; Verbreitung der Nutzbaren Mineralien: Dr. T. Posewitz (Berlin, Friedländer).—Tägliche Oscillation des Barometers: J. Hann (Wien).—Journal of Physiology, February (Cambridge).—Records of the Geological Survey of India, vol. xxii., Part 1 (Calcutta).

BRITISH UREDINEÆ AND USTILAGINEÆ.

A Monograph of the British Uredineæ and Ustilagineæ. With an Account of their Biology, including the Methods of observing the Germination of their Spores and of their Experimental Culture. By Charles B. Plowright, F.L.S., M.R.C.S. Illustrated with Woodcuts and Eight Plates. (London: Kegan Paul, Trench, and Co., 1889.)

MR. PLOWRIGHT'S monograph will at once take its rank as the chief English authority on the interesting groups of parasitic Fungi to which it relates. The results of the author's important original investigations are here incorporated with those of other observers to form a work which brings our knowledge of these plants thoroughly up to date. The greater part of the book is systematic, the detailed description of species being preceded by a general account of the structure and life-history of the two orders. These introductory chapters will probably appeal most to the reader who is not a specialist in mycology, though the biological notes attached to the specific descriptions are also of great interest, and effectually relieve the dryness which is usually inseparable from purely taxonomic work.

In the first chapter a short summary of the biology of the Uredineæ is given. This is, perhaps, if anything, rather too short, but of course some previous knowledge in the reader is assumed. The Uredineæ, which are now probably the best known family of pleomorphic Fungi, are arranged by the author, in agreement with Schröter and Winter, in biological groups, according to the varying combinations in which their different forms of reproductive organs are present. These groups are made use of for the division of the larger genera into sub-genera. The system adopted may be illustrated by the classification of the species in the largest genus, Puccinia, in which all the modifications are represented. The sub-genera are six in number. First we have Eupuccinia, characterized by the presence of all the four reproductive structures: spermogonia, æcidiospores, uredospores, and teleutospores. This sub-genus is again divided into Anteupuccinia, which is autœcious, all the forms occurring on the same host-plant, and Heteropuccinia, in which heterœcism prevails, the spermogonia and æcidiospores being developed on one host, and the uredospores and teleutospores on another plant belonging to a distinct genus. The other sub-genera of Puccinia are all autœcious. In Brachypuccinia the æcidiospores are absent, while in Hemipuccinia the spermogonia also disappear, only uredospores and teleutospores being developed. In Pucciniopsis only æcidiospores and teleutospores are usually present, while in both the remaining sub-genera, Micropuccinia and Leptopuccinia, the teleutospores alone occur, the two groups differing from one another in the fact that the teleutospores of Micropuccinia are of the usual type, requiring a period of rest before germination, while those of Leptopuccinia germinate on the host-plant as soon as they are ripe. The essential character of the teleutospores is the production of a small promycelium which immediately bears promycelial spores (sporidia), the latter being the bodies which directly infect the host. Thus the spores of Endophyllum are classed as teleutospores, on account of their method of germination, though in all other respects they agree with the æcidiospores of other genera. The author regards the teleutospores as the constant characteristic of the Uredineæ, believing that their apparent absence in many forms is due to our imperfect knowledge of their life-history.

The second chapter is devoted to the mycelium of the Uredineæ. Here the description of the cell-contents strikes us as rather inadequate, but the subject is a difficult one to investigate. The often remarkable influence of the localized mycelium on the tissue of the host is well described.

In the next chapter those puzzling organs, the spermogonia, are described, and their functions discussed. The author and others have observed that in sugar-solution the spermatia pullulate, like yeast-cells. It was not, however, found possible to infect the host-plant with them. Still the author inclines to the view that the so-called spermatia are conidia rather than fertilizing bodies, a view which the observations of Möller on the spermatia of Lichens certainly render probable. If Mr. Massee's isolated observation of an antheridium in the Æcidium form of *Uromyces Poæ* should be confirmed, we shall have to seek the male organs of the Uredineæ elsewhere than in their spermogonia.

In the chapter on the æcidiospores there is a want of clearness in describing their development. The account given recalls the now exploded Schleidenian theory of "free cell-formation," whereas the æcidiospores are in fact formed by ordinary cell-division.

The uredospores and teleutospores are described in the two following chapters, which call for no special remark. Most of the facts brought forward will be familiar to those who know de Bary's work on the Fungi.

Chapter VII. deals with the interesting phenomenon of heterœcism, and the curious history of its discovery in the case of the mildew of wheat is well told. The old observations, dating back to the middle of the last century, on the influence of the barberry in producing this disease in corn, are described, and in an appendix the text of the "Barberry Law of Massachusetts" (published in 1755) is given. This law enacted that, "Whereas it has been found by experience that the Blasting of Wheat and other English Grain is often occasioned by Barberry Bushes," these bushes should be extirpated throughout the province. The true explanation of this mysterious power for evil of the barberry was first given by Sir Joseph Banks in 1805, and shortly afterwards a Danish schoolmaster, Schoeler, made the first successful experiments in infecting wheat with the barberry fungus. Naturally the purely systematic botanists held out for a long time against the popular belief; and it was not until 1865 that the connection between the Æcidium of the barberry and the Uredo and Puccinia of the wheat was finally established by de Bary, who thus at last brought the views of scientific men into harmony with those which had long been held by practical farmers. Forty-seven heterœcious species of Uredineæ are now known, and the life-history of eleven of these was first worked out by the author.

The remaining chapters of the introduction deal with

the Ustilagineæ. The two groups have little in common, and it must not be supposed that their association in this work implies any near relationship between them. The bond of union is rather to be found in their common biological character as more or less injurious parasites.

In Chapter VIII., the mycelium of the Ustilagineæ is described, and attention is specially called to the fact that it usually spreads throughout the tissues of the host-plant, thus differing from the localized mycelium of most Uredineæ.

The next chapter treats of the development of the "teleutospores" (resting-spores) of the Ustilagineæ. The singular processes by which the "spore-balls" arise in such genera as Soroporium, Tubercinia, and Urocystis are clearly described in accordance with the researches of von Waldheim, Woronin, de Bary, and others. The facts are not, as a rule, new, but they are well put together. The germination of the teleutospores is described in the following chapter. The extraordinary processes of conjugation, in which both the promycelium itself and the sporidia so often take part, are described; and due weight is given to Brefeld's important discovery that these cell-unions do not take place when the spore is allowed to germinate in a food-solution, instead of in pure water. There are many points here which invite more detailed notice, but this may be the better dispensed with, as most of the facts have already been brought before English readers, in the translation of de Bary's work and in some of Prof. Marshall Ward's papers.

The subject of Chapter XI., the infection of the host-plants by the Ustilagineæ, is of great practical interest. In the case of the bunt (*Tilletia tritici*), it is well known that the sporidia borne on the promycelium of the teleutospores infect the embryo of the germinating grain, the germ-tubes penetrating the cells of the leaf-sheath. But how smut (*Ustilago segetum*) infects wheat has long been a mystery. The spores ripen in the young flowers, and have disappeared long before the grain is mature. Attempts at infection of the grain or seedling are almost always unsuccessful; and, on the other hand, the protective dressings of the grain, which are so effectual against bunt, are of no avail as against the attacks of smut. The experiments of Jensen render it most probable that the plant is infected by the spores while flowering, and that either the ovum itself is entered by the mycelium, or that the spores remain dormant in the grain until its germination, and that then the parasite "grows with the growth, and strengthens with the strength" of the young plant. It would appear, then, that the only remedy against the attacks of the Fungus would lie in the destruction of all affected ears at the earliest stage when the disease is visible, and before the spores have ripened.

The last two chapters of the introduction are among the most interesting to specialists, but do not require any analysis here. They deal with the culture of spores, and with the artificial infection of plants. Under the latter head it may be noted that only the Uredineæ are taken into account. The directions given are those of a master of the subject, and cannot fail to be a most useful guide to those who intend to undertake such investigations for themselves.

The longest, and no doubt the most valuable, part of the work consists in the description of all British species of the two families; pp. 119–271 being devoted to the Uredineæ, and pp. 272–301 to the Ustilagineæ. Attention has already been called to the admirable biological notes by which the descriptions of all the more important species are accompanied. In the specific diagnoses, the æcidiospores (when present) are first described; then the uredospores, and, lastly the teleutospores. Next follows a complete list of synonyms, and then the host-plant or plants are enumerated, after which the biology of the species is discussed. The account of the Ustilagineæ is completed by the description of a few genera, such as Graphiola and Protomyces, of doubtful systematic position.

A glossary is appended to the work, and in some of the explanations of terms there is room for criticism. Thus, in defining *conidium* as "an asexual spore," it seems to be too easily assumed that the other spores are sexual. The word *endochrome* is no longer required, and might perhaps be allowed to become obsolete. A *germ-pore* is not an "opening," but a pit, and a *hypha* does not necessarily consist of "an elongated cell." The word *periblem* means the young cortex itself, not "that part of the root of the host-plant which lies beneath the cortex," while *sterigma* is certainly *not* "the same as basidium."

The eight plates contain a great number of good figures, many original, others taken from the works of de Bary Brefeld, Woronin, &c.

A list of the authors quoted is given, and the book is especially well provided with indices, which are three in number. The first, a very useful one, gives the names of all the host-plants of the Uredineæ and Ustilagineæ respectively. Then we have a general biological index; and, lastly, an index of species, including all the synonyms.

The book is exceedingly well got up, but we must protest against the vivid yellow of the cover, presumably intended to recall the colour of the uredospores! Perhaps the decorous brown of the teleutospores would have been more becoming if symbolical colouring was wanted.

D. H. S.

THOMAS ANDREWS.

The Scientific Papers of the late Thomas Andrews, M.D., F.R.S., Vice-President and Professor of Chemistry, Queen's College, Belfast. With a Memoir by P. G. Tait, M.A., Sec. R.S.E., and A. Crum Brown, M.D., F.R.S., Professors in the University of Edinburgh. (London: Macmillan and Co., 1889.)

WE have here in a compact form the biography and scientific works of a man who has left his mark on the science of his time.

Born at Belfast in 1813, Thomas Andrews after acquiring the rudiments of his education at two excellent public schools in his native town, went at the age of fifteen to the University of Glasgow, where he attended the classes of chemistry and natural philosophy for one or two sessions; and in the following years he continued his studies at Paris, Dublin, and Edinburgh, taking the degree of M.D. at Edinburgh in 1835. He immediately began to practice as a physician at Belfast, and also to teach chemistry as Professor in the Belfast College, which was a higher department of the Belfast Academical Insti-

tution. In 1845, the scheme for the creation of the Queen's Colleges was launched, and their Presidents and Vice-Presidents were appointed as a preparatory step to the building of the Colleges. Andrews at this time received his appointment as Vice-President, and he was the first Professor of Chemistry, both which offices he retained till the failure of his health in 1879. His whole life-time was thus—with the partial exception of his medical practice from 1836 to 1845—occupied in scientific teaching and investigation; and from the early age of fifteen, when he published in the *Philosophical Magazine* a paper on the action of a blowpipe flame on other flames, he never ceased to devote himself to original research.

He was never in a hurry to rush into print, but took care to be accurate and thorough in an investigation before announcing his results. Regularly day by day he was to be found at work for hours in his laboratory, patiently conducting with his own hands every detail of his elaborate observations.

The most important of his researches relate to heat of combination, the nature and properties of ozone, and the transition of such substances as carbonic acid from the gaseous to the liquid state. But besides these, we find in the present collection brief papers on a variety of subjects. One contains an account of experiments on the conducting power of flame for electricity, showing that the current from a single cell could be transmitted through a circuit part of which consisted of an alcohol flame. Another describes the attainment of a very high vacuum by a good ordinary air-pump aided by the introduction of carbonic acid into the receiver and the absorption of the last traces of this gas and of aqueous vapour by caustic potash and sulphuric acid. Another gives a comparison of the conducting powers of different gases for heat, as shown by their cooling action on a platinum wire kept incandescent by a current. In all these subjects he was early in the field, and obtained results much in advance of those obtained by his predecessors.

An instance of his careful criticism is afforded by one of the latest papers in the volume—a lecture on recent improvements in magneto-electric machines—in which he points out that Paccinotti's machine, if the inventor's original description of it can be relied on, makes its contacts (for collecting the currents from the ring) in the wrong places. The criticism is certainly justified by the figure and accompanying description which are reproduced from Paccinotti's paper; but from inquiries which we made at the Paris Electrical Exhibition, where the machine was on view, we believe the fault was in the description and not in the machine itself.

As regards ozone, Andrews appears to have been the first to establish the following points:—

(1) That the peculiar substance obtained by the action of the electric spark on oxygen is identical with that obtained in the electrolysis of water, and with that obtained in the slow oxidation of phosphorus.

(2) That it is not a compound body, but is oxygen in an altered or allotropic condition.

In subsequent experiments, with the assistance of Prof. Tait (who was at that time Professor of Mathematics in Belfast), he compared the amount of contraction produced by the partial conversion of oxygen into ozone with the amount of ozone thus obtained as tested by chemical action, and hence deduced the density of ozone.

His researches in various branches of the subject of heat of combination were spread over many years, and were, for the most part, conducted at a date when an accurate thermometer for measuring small differences of temperature could only be obtained by making it for oneself. The subsequent researches of Favre and Silbermann, wherever they differed to any large extent from his, have since been shown to be erroneous, and his results agree fairly well with the latest and best determinations yet obtained.

But his permanent fame will rest mainly on his discovery of the continuous transition which can be made from the gaseous to the liquid state of a substance, or from the liquid to the gaseous. The main result which he established is best set forth by the geometrical illustration employed by his colleague, Prof. James Thomson. Let the volume, pressure, and temperature of a given mass of carbonic acid be represented by the three rectangular co-ordinates of a surface; volume being represented by height, while the pressure and temperature co-ordinates are horizontal. The surface will resemble the side of a mountain which is precipitous in one part, but in another part furnishes a gradual ascent by which the summit can be reached. The ground-plan of the precipice is the curve of boiling-points, and the height of the precipice at each point of the curve represents the increase of volume in passing from the liquid state to the gaseous. As the temperature increases, the precipice diminishes in height, and finally runs off to nothing at a point whose horizontal co-ordinates are the "critical temperature" and "critical pressure." At higher temperatures there is no boiling-point, and in place of the precipice there is a gradual ascent, by means of which the precipice can be rounded and the summit attained. Starting from the ground below the precipice (that is, from the liquid state), the ground above the precipice (that is, the gaseous state) can thus be attained without any kind of discontinuity.

Cagniard de Latour and Drion, who preceded Andrews in this field of research, failed to obtain this result, because their method of experiment placed only one independent variable at their disposal. The substance was inclosed in a sealed tube, and there was no way of altering its pressure except by altering its temperature. Andrews used a screw plunger, which enabled him to increase and diminish the volume independently of the temperature. By making simultaneous measures of volume, pressure, and temperature for various values of the two independent variables, he was able to map out the surface, and Prof. J. Thomson constructed a wooden model of it from the data thus obtained.

In subsequent researches he investigated the effect of mixing various quantities of nitrogen with carbonic acid, and found that the critical point was largely shifted by such admixtures.

Shortly before his health broke down, he devised an ingenious apparatus for making successive additions of a known column of mercury to the pressure of a gas confined in a long tube, hoping in this way to be able to test departures from Boyle's law at very high pressures without employing a column of mercury of unwieldy length. In

the reference to this subject in the preface there appears to be an oversight. The effect of a certain cycle of operations to be performed with the apparatus is described and then we read :—

"A connected series of vessels of this kind will enable the experimenter to apply a measured pressure of an amount depending on the number of vessels."

Instead of a connected series of vessels, it is only necessary to repeat, time after time, with the one vessel, the cycle of operations which has been described; and this we understood to be Dr. Andrews's intention. The apparatus was not brought into actual use, nor even constructed; preliminary trials having shown that screw plungers working in mercury (which were an essential part of the design) could not be prevented from leaking.

The various papers in this volume, and especially the Presidential Address, show Dr. Andrews to have been not only an accurate and original worker, but a man of wide culture and refined literary taste. The editors have done their work carefully and well.

J. D. E.

MACH'S "HISTORY OF MECHANICS."

Die Mechanik in ihrer Entwickelung historisch-critisch dargestellt. (An Historical and Critical Sketch of the Development of the Principles of Mechanics.) By Dr. E. Mach, Professor of Physics in the University of Prague. Second Edition. (Leipzig: F. A. Brockhaus, 1889.)

THE first edition of this work, which forms Vol. LIX. of the "International Scientific Series," appeared in 1883. With the exception of a few short appendices and the correction of misprints, it is identical with the original edition; but we are glad to take the present opportunity of calling attention to a book which, while unpretentious in form, is one of exceptional value to students, and especially to teachers, of the subject with which it deals.

The book has not been translated into English, and we understand that the English publishers did not consider it sufficiently popular in form to be included in the English series. This is much to be regretted. The work is one which certainly ought to be translated, as it would be most helpful to a large class of students and teachers who are unable to read it in German.

In the course of rather fewer than 500 pages the author gives his readers a well-constructed outline of the development of the science of mechanics from Archimedes down to the present time, accompanied by well-reasoned criticisms and discussions of the significance and relative importance of the various steps which he chronicles. The first chapter is devoted to the development of the principles of statics, and we would specially direct attention to the masterly manner in which the author shows the fallacies underlying the attempts of some of the early philosophers to derive the principle of the parallelogram of forces, or an equivalent one, from *a priori* notions, without appeal to experiment. The proposition commonly known as the parallelogram of forces may either be proved by direct experiment or by deduction from some such experimental principle as Newton's second law of motion. The advantage of the latter method consists, as the author points out, in the fact that he nature and extent of the experimental evidence for Newton's second law, or its equivalent, cause it to carry with it a greater certainty of its accuracy than is possible for a direct experimental demonstration of the proposition. This is a point to which it is most important to call attention, for, although Thomson and Tait have long since cleared away from the better class of text-books, and from the minds of the higher class of students, the fog which had accumulated around this essentially simple proposition, much of our school teaching is still enshrouded by it.

The second chapter treats of the growth of the principles of dynamics, understanding this in the more restricted sense of what Thomson and Tait called kinetics. This is of great interest and value throughout, but there are one or two points to which we would direct special attention.

The deduction of the approximate time of swing of a simple pendulum vibrating in a small arc, from a rectilinear simple harmonic motion, is, or at any rate should be, well known to students who have had the advantage of instruction from a Professor at one of our Universities; but it is quite time that this very simple method of obtaining an important relation should take the place of the artificial and cumbrous methods which still disfigure some of the elementary text-books in common use. The criticism of Newton's exposition of the ideas of time, space, motion, and mass, is also worthy of careful study. These two chapters are of quite an elementary character, and may be read with advantage even by students whose mathematical acquirements are of the slenderest.

The third chapter treats of the further application of principles, and the deductive development of mechanics. It does not, like the first two chapters, appeal to the beginner, but will be most helpful to a student who has already made some progress in the subject.

The fifth chapter bears the heading, "The Formal Development of Mechanics." It contains an interesting discussion of isoperimetric problems, and a brief account of the analytical method of treatment introduced by Lagrange. It also contains a section mainly devoted to an account of the theological vagaries of some of the great mathematicians and natural philosophers. This section is not of very great interest or value, and may have been inserted merely to give a popular flavour to what is essentially a scientific book.

The volume concludes with a very brief chapter on the relations of mechanics to other branches of knowledge.

G. W. DE T.

OUR BOOK SHELF.

Das Klima des ausser-tropischen Südafrika, mit Berücksichtigung der geographischen und wirtschaftlichen Beziehungen nach klimatischen Provinzen dargestellt. Von Dr. Karl Dove. 160 pp. and 3 charts. (Göttingen: Vandenhoeck and Ruprecht, 1888.)

METEOROLOGISTS must welcome the reappearance of the name of Dove among the contributors to climatological knowledge, and the present work does no discredit to the name. It is an endeavour to give a conspectus of the climate of South Africa as a whole; and the author ekes out the actual meteorological results, which are somewhat scanty in parts, by evidence derived chiefly from the indigenous flora of the several districts, which

he has collected from the published records of various travellers, such as Livingstone, Serpa Pinto, Fritsch, and others.

He limits the area of his discussion by biological considerations, as he defines the extreme southern limit of tropical Africa to be that fixed by the cultivation of the date-palm and the existence of the tsetse fly.

We have said that the records of observations are somewhat scanty, and this remark will be justified when we point out that from many stations the results for two years, or even less, are printed. The figures, such as they are, have been, however, most conscientiously discussed.

The area is divided into four great districts, classified according to the period of occurrence of the rainy season, viz. (1) the winter rains, (2) the intermediate region of spring and autumn rains, (3) the heavy summer rains, (4) the West Coast. Under (1), as subdivisions, we have the South-West Province, the Western Karroo, and the Little Namaqua Land. Under (2), the South Coast, South Karroo, North Karroo, and the South-East Mountain Land. Under (3), the Table-land of the Upper Orange River, the North Transvaal, the Kalahari, and the Great Namaqua and Damara Land.

After treating of these several regions at considerable length, Dr. Dove proceeds to discuss the possible development of agriculture in the different districts. His panacea for the Kalahari and some other tracts, with pure sandy surface, in the northern part of the area, is to introduce the date-palm.

He concludes the work with a discussion of the rainfall and its distribution, with some remarks on the question of the alleged deterioration of the climate by the drying up of the country. This effect he considers, with Mr. Gamble, to be merely the outcome of reckless forest destruction.

He points out the brilliant results obtained, at comparatively small cost, by the construction of reservoirs, as at Beaufort and at Van Wyk's Vley. R. H. S.

Chambers's Encyclopædia. New Edition. Vol. III. (London and Edinburgh: W. and R. Chambers, 1889.).

It may be enough to say of the third volume of the new edition of "Chambers's Encyclopædia" that it falls in no respect below the high level maintained in the preceding volumes. The editor is working upon a well-conceived plan, and he has every reason to be satisfied with the manner in which individual subjects are dealt with by his contributors. Scientific subjects continue to receive the attention which properly belongs to them in such a work as this. Tbe treatment of coal, coral islands, and geology generally has been intrusted to Prof. James Geikie, and his articles are admirable examples of compact and lucid exposition. Mr. J. Arthur Thomson writes of caterpillars, cells, crabs, &c.; Dr. Leonard Dobbin, of chemistry; Dr. Alexander Buchan, of climate; Mr. R. T. Omond, of clouds; and Dr. R. A. Lundie, of colour-blindness. Mr. C. J. Woodward has an article on crystallography, and Dr. W. Peddie treats of dew and diffusion. Of the articles on Darwin and the Darwinian theory, the former is contributed by Mr. Grant Allen, the latter by Prof. Patrick Geddes. There are a good many geographical articles, among which we may especially note the article on China, by Prof. Legge; that on the Congo, by Sir Francis de Winton; and that on Constantinople, by Mr. Stanley Lane-Poole. So far as we have been able to test the various papers, we have found them carefully written and thoroughly trustworthy.

The Elementary Principles of Electric Lighting. By A. A. C. Swinton. Second Edition. (London: Lockwood.)

The author explains generally the different apparatus used in electric lighting, and the broad princples of their working, using the "water-works" theory of the electric current, but at the same time carefully explaining that this is only done for the sake of convenience. An unfortunate mistake has been made in the diagram of the continuous-current dynamo (p. 24), where the coils are shown as wound in a different *sense* on the two limbs of the field-magnet. The book is, however, a remarkably clear exposition of the subject, and at the same time a model of conciseness.

The Natural History and Epidemiology of Cholera. By Sir J. Fayrer. (London: Churchill, 1888.)

The above formed the subject of the annual oration delivered by Sir Joseph Fayrer before the Fellows of the Medical Society.

The author deals at length in a most interesting way with the history of the disease, and then proceeds to enlarge upon its geographical distribution, habits, conditions, and epidemic movement. The ætiology of cholera is then dealt with, together with a review of those general and special precautionary measures it is desirable to adopt.

Throughout, the essay is written in a clear and interesting manner, and from the vast experience of the author in the subject the oration will well repay a careful perusal. William Robert Smith.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Halo and Mock Suns.

This morning a very distinct halo accompanied by mock suns on either side was seen here. As the latter, owing to the altitude of the sun, were at a considerable distance outside the halo, I think the following details are worth putting on record. At 11h. 12m., Berne time, the sun's altitude being 48° 30′, the distance from the halo to the left-hand mock sun was 9° 15′. The parhelic circle was plainly visible, reaching from the sun slightly beyond the mock suns. Each of the latter consisted of a reddish patch shading off into white and then into blue on the side away from the sun. From the brightest red to the brightest blue was about 2°, and the measurement 9° 15′ was taken from half-way between these to the nearest point of the circle dividing the red from the blue of the halo. It is difficult or impossible to measure such faint objects with the sextant. So I held a pencil at *both* arms' length, and noted the length on the pencil corresponding to the desired angle. Holding the pencil with both hands gives it a very definite distance from the eye, provided the position of the body and the altitude of the object be not much altered. Paying attention to these points I measured the angle subtended at my eye by a certain length on the side of a house, both with the pencil and a sextant. The angle 9° 15′ was found thence by simple proportion. I think the error of this measurement can hardly exceed 30′. The halo of course was the common one of 22°. James C. McConnel.

Davos Platz, April 5.

On the Connection between Earth Currents and Changes in Solar Activity.

May it not be that, in the recent experiments of Mr. Hertz on the effect of ultra-violet light on electric discharge, we have an explanation of the relation existing between disturbances on the solar surface and disturbances in earth currents?

The evidence for such a connection is obtained from the Greenwich records.

If we make the not very violent assumption that two clouds differ in potential from each other and from the earth, it will be seen that the earth will act as a condenser, and underneath each cloud will be collected a charge of opposite sign.

With sunlight, Hertz failed to find any marked effect, prob-

ably on account of absorption in the cloud regions of our atmosphere, which, as Langley has shown, takes up with great avidity the violet and ultra-violet rays.

May it not be that in clouds we have conditions especially favourable to the production of the Hertz effect? If so, the discharge from one cloud to another would be accompanied by an earth current in the opposite direction, as in the theory proposed by Prof. Stokes, in which a decrease of resistance is produced by an increase of heat from the sun.

Hertz found his effect (*Wied. Ann.*, xxxi. p. 993) much more marked in a medium under diminished pressure.

Under 300 millimetres of mercury, he finds that the ultra-violet radiation will nearly *quadruple* the length of spark obtained without it, while under ordinary atmospheric pressure it would scarcely *double* it. But this is the very circumstance which is realized in the case of clouds.

There is also reason to think that solar outbursts are especially rich in these rays of short wave-length which are required to explain the phenomena. HENRY CREW.

Haverford College, U.S.A., March 22.

Hertz's Equations in the Field of a Rectilinear Vibrator.

RECURRING to Hertz's equations for the field of the rectilinear vibrator, it appears to me that, while his conclusions are sound as regards the forces at points very distant from the vibrator, they require modification for the rest of the field. In fact, the principles upon which the question is investigated require that the electromotive force in the direction of z should become evanescent close to the vibrator (the axis of z).

The general form of Π is either—

$$\frac{\mathrm{M}\sin\frac{\rho}{\lambda}}{\rho}\cdot\sin nt,\ \text{or}\ \frac{\mathrm{M}\cos\frac{\rho}{\lambda}}{\rho}\cdot\sin nt,$$

where λ large, and $\lambda n = \frac{1}{\mathrm{A}}$, or, of course, the sum of the two forms.

In assuming for points near the origin (say the middle point of the vibrator) the approximate expression—

$$\frac{\mathrm{M}}{\rho}\sin nt,$$

Hertz, in point of fact, takes the second of the above forms for Π, for this reduces to $\frac{\mathrm{M}}{\lambda}\cdot\sin nt$ when $\frac{\rho}{\lambda}$ is very small.

But this assumption makes both Π and Z infinitely great close to the vibrator. Whereas, by assuming the former of the two forms, or—

$$\frac{\mathrm{M}\sin\frac{\rho}{\lambda}}{\rho}\cdot\sin nt,$$

i.e. near the origin $\Pi = \frac{\mathrm{M}}{\lambda}\sin nt$, we get, as a general expression for Z—

$$\mathrm{Z} = \mathrm{M}\left\{\left(\frac{1}{\rho^3} - \frac{3z^2}{\rho^5} + \frac{z^2}{\lambda^2\rho^3} - \frac{1}{\lambda^2\rho}\right)\sin\frac{\rho}{\lambda} - \left(\frac{1}{\lambda\rho^2} - \frac{3z^2}{\lambda\rho^4}\right)\cos\frac{\rho}{\lambda}\right\}\sin nt,$$

and, as ρ is indefinitely diminished, this reduces to—

$$-\frac{2}{3}\frac{\mathrm{M}}{\lambda^3}\sin nt$$

as a limiting value.

For distant portions of the field, Hertz's results as to the laws and amplitudes of the forces electric and magnetic remain unaltered.

Of course, the whole investigation, with such a simple assumption as to the nature of the field, must be regarded as only approximate. For any given form of vibrator—as, for example, a straight wire connecting two spheres—the exact treatment will be very difficult. In the simplest conceivable case of a spherical metal sheet with an induced Q_n distribution left to itself, the analysis is intricate (see a paper by Prof. J. J. Thomson to the Mathematical Society of London, January 1884). H. W. WATSON.

Berkswell, March 29.

Early History of Lightning-Conductors.

CAN any of your readers refer me to the sources of some of the late Mr. Richard Anderson's information with regard to the early history of the lightning-conductor? (1) On p. 27 of the third edition (1885) of his book, "Lightning-Conductors," he states that Franklin, in the 1758 issue of "Poor Richard," gave directions for the erection of lightning-conductors. (2) On p. 25 he refers to Prof. Winthorp, of Boston, having, in 1755, defended the lightning-conductor against a parson who had attributed a Massachusetts earthquake to the innovation. I should be much obliged for any reference to a library where a copy of "Poor Richard" for 1758 could be found; or, again, for any information with regard to Winthorp's defence of the lightning-conductor.

Prof. Meidinger, of Karlsruhe, who is preparing a second edition of his "History of Lightning-Conductors," is extremely desirous of verifying these details of their early history, and I should be glad if any of your readers could supply me with information for him on these points. KARL PEARSON.

University College, April 9.

The Satellite of Procyon.

MR. J. M. BARR's suggestion (NATURE, March 28, p. 510), as to the use of photography to ascertain whether there is any close companion or satellite to Procyon, would be considered a very desirable one by astronomers, in order to set at rest the question whether a companion can actually be discovered near the assumed place of the hypothetical one, of which the elements were given by Dr. Auwers in 1861, from investigations of the irregularity in the proper motion of Procyon observed by Bessel in 1844, and by Mädler in 1851. The orbit was computed on the assumption of a circular motion in a plane perpendicular to the line of sight round a point about 1″·2 distant, having a period of about 40 years, the position angle for 1873 being about 90°, so that the present angle would be about 234°, or about 9° per annum.

I fear, however, serious instrumental difficulties would arise in obscuring such a brilliant object as Procyon in a large telescope by a screen, so as to get the impress on a plate of a probably faint companion at the extremely close distance of two to three seconds of arc.

This difficulty, no doubt, must have presented itself to the minds of the astronomers at the Lick Observatory, California, or they would have tried the sensitive plate with the 34-inch photo lens of the great refractor, instead of examining Procyon visually with the 36-inch glass, as was done by Mr. S. W. Burnham on the early morning of November 18 last, with the following record:—"*Procyon.*—Carefully examined with all powers up to 3300 on the 36-inch under favourable conditions. Large star single, and no near companion."

If this means that no companion was seen within 10″ or 12″ radius, it makes the matter very perplexing, as Otto Struve measured a supposed new companion in 1873 with the 15-inch refractor at Pulkowa—the mean of several measures for March 28 being P. angle 90°·24, and distance 12″·49, and for 1874 (April 10) P. angle 99°·6, and distance 11″·67. This companion was looked for at Washington with the 26-inch refractor on several occasions from November 1873 till January 1876, and by the three Clarks (father and two sons) with the McCormick 26½-inch refractor, then completed at Cambridgeport, Massachusetts, but Struve's companion could not be seen with either instrument, and I am not aware that it has since been seen by Struve himself with the new Russian 30-inch refractor. The Washington observers at that time, however, gave estimated places for three new companions, supposed to be seen by them as follows:—

No. 1. Position angle, about 10°, and distance about 6″.
,, 2. ,, ,, ,, 36° ,, ,, ,, 8″·8
,, 3. ,, ,, ,, 50° ,, ,, ,, 10″

These appear (if they have an existence at all) to have been missed with the 36-inch glass at the Lick Observatory, as above referred to.

It is a singular coincidence that the position-angles of the companion supposed to have been seen by Otto Struve in 1873 and 1874 agreed with the orbital places computed by Dr. Auwers, but its distance involved the assumption of an enormous mass to Procyon for the parallax assigned to the principal star. ISAAC W. WARD.

Belfast, April 1.

Factors of Numbers.

THE processes given by Mr. Busk at p. 413 of NATURE are an interesting step towards the *practical* solution of the difficult problem of finding the factors of any number. In this article the processes are put in an algebraic form, which both shows more clearly the nature of the processes, and brings out the conditions necessary for their *practical* success (*i.e.* with any moderate labour): it will appear that with high numbers the labour involved would be prohibitory except in[1] favourable cases.

Let N be the number to be resolved into factors. Rejecting even numbers as obviously divisible by 2, *odd numbers only* require to be considered. If two integers, A, B, can be found such that—

$$N = A^2 - B^2,$$

the problem is solved, the factors being $(A + B)$, $(A - B)$. There is one universal solution which includes primes, viz.

$$A + B = N, \quad A - B = 1; \quad A = \tfrac{1}{2}(N + 1), \quad B = \tfrac{1}{2}(N - 1).$$

The problem is to find other solutions, if any exist. Certain limits may be at once assigned to A, B, viz.

(1) A, B are *minima* together, viz.

$A = \sqrt{N}$, $B = 0$, when N is a perfect square.

$A = \sqrt{N + \alpha}$ (the integer next $> \sqrt{N}$), and $B = \sqrt{A^2 - N} = \alpha$, when N is not a perfect square.

(2) A, B are *maxima* together, viz. when they are successive integers. This gives the universal solution above.

This gives a very wide range, wider for B than for A, viz.

$$A \text{ from } \sqrt{N} \text{ to } \tfrac{1}{2}(N + 1), \quad B \text{ from } 0 \text{ to } \tfrac{1}{2}(N - 1).$$

The two processes of Mr. Busk, somewhat generalized, amount virtually to this. Try first if N be a perfect square: if so, the factors are $\sqrt{N}$, $\sqrt{N}$. Next, if N be not a perfect square, assume any trial integer value for either A or B (within above limits, of course). Then, if either $(A^2 - N)$, $(B^2 + N)$ be a perfect square, it is the other sought square B^2 or A^2, and the thing is done.

But, if not, let A be increased, or let B be decreased by some integer r, such that $(A + r)$, $B - r)$ lie within above limits; then, if either $\{(A + r)^2 - N\}$ or $\{B - r)^2 + N\}$ be a perfect square, it is the other sought square, viz. B^2 or A^2, and the thing is done.

To do this thoroughly, *i.e.* to make *certain of not missing* the right value of $(A + r)$ or $(B - r)$, it seems absolutely necessary to work systematically, *i.e.* either—

(i.) begin with the *minimum* value A = integer next $> \sqrt{N}$, and work upwards, or—

(ii.) begin with the *maximum* value $B = \tfrac{1}{2}(N - 1)$, and work downwards,

trying *all* integer values of r in succession, $r = 1, 2, 3$, &c., until a perfect square is reached, or until, finally, the maximum value of r is reached, given by—

(i.) $A + r = \tfrac{1}{2}(N + 1)$, which gives $B = \tfrac{1}{2}(N - 1)$,

(ii.) $B - r = 0$, which gives $A^2 = N$, which is by hypothesis not a perfect square,

which ends the process, and shows conclusively—if no perfect square be reached earlier—that N is a prime.

An important practical help in working either process is given by Mr. Busk, in a simple way of forming the successive quantities $\{(A + r)^2 - N\}$, $\{(B - r)^2 + N\}$ by the successive addition or subtraction of a series of simple "differences," thus—

(0) Write down the starting quantity, $(A^2 - N)$ or $(B^2 + N)$.

(1) Add $(2A + 1)$ or subtract $(2B - 1)$, giving results $\{(A + 1)^2 - N\}$ or $\{(B - 1)^2 + N\}$,

(2) Add $(2A + 3)$ or subtract $(2B - 3)$ *more*, giving results $\{(A + 2)^2 - N\}$ or $\{(B - 2)^2 + N\}$,

and so on; and as the rth step—

(r) Add $(2A + \overline{2r - 1})$ or subtract $(2B - \overline{2r - 1})$ *more*, giving results $\{(A + r)^2 - N\}$ or $\{(B - r)^2 + N\}$.

Nothing simpler could be wished than this as a process, especially as it is exactly suited to be done mechanically upon an arithmometer.

The labour liable to be involved in the work is a serious practical drawback. Both processes are rapid when r is small, and

[1] Mr. Busk's examples are favourable cases.

tedious when r is large. Process (i.) is most rapid when the factors are nearly equal, and process (ii.) when they are extremely unequal; but as these conditions cannot be recognized *a priori*, selection of either process is only guesswork. A *suitable* selection of the starting numbers A, B, *i.e.* by taking A higher than the minimum (and yet not too high), or by taking B lower than the maximum (and yet not too low), *may* of course immensely shorten the process; but such selection is at present pure[1] guesswork. In fact, if with such arbitrary starting values of A, B, a perfect square is not reached by the end of the process, *no conclusion can be drawn*, but the process must be tried again with values of A, B nearer to the really safe starting values. Both processes are most tedious of all for prime numbers, when the number of steps (r) required is—

$$\text{In (i.), } r = \tfrac{1}{2}(N + 1) - \sqrt{N + \alpha}; \text{ in (ii.), } r = \tfrac{1}{2}(N - 1),$$

a number so large as to be practically prohibitory for high numbers.

Some shortening process is much required. One such is proposed (on p. 414) for odd numbers, but (unless it has been misunderstood by the writer) it is certainly not so *in general*. It appears to amount to this:—

If N be not a perfect square, subtract it from the two next higher squares, thus forming $\{(A + 1)^2 - N\}$ and $\{A^2 - N\}$. If either of these be perfect squares, the question is solved by what precedes; but, if not, subtract them from any two successive higher squares of say $(C + 1)$, C, such that $(C - A)$ is an odd number, thus forming—

$$[(C + 1)^2 - \{(A + 1)^2 - N\}] \text{ and } [C^2 - (A^2 - N)],$$

and divide each of these by their difference, *i.e.* by $2(A - C)$.

If they be not evenly divisible, increase the number C by the even integers, 2, 4, 6, &c., successively, trying the divisions again at each step, until after say m steps, the two results

$$[(C + 2m + 1)^2 - \{(A + 1)^2 - N\}], \quad [(C + 2m)^2 - (A^2 - N)],$$

are both evenly divisible by their difference, *i.e.* by $2(A - \overline{C + 2m})$. To the quotients so formed add the original quantity $(A + 1)$ or A, as the case may be.

The two resulting quantities will be found (on reduction) to reduce alike to the simple form—

$$\tfrac{1}{2}\left(\frac{N}{P} + P\right), \text{ where } P = (A - \overline{C + 2m}) \text{ for shortness,}$$

and this turns out to be actually the larger of the two numbers whose square is sought, since its square exceeds N by a perfect square, for—

$$\left[\tfrac{1}{2}\left(\frac{N}{P} + P\right)\right]^2 - N = \left[\tfrac{1}{2}\left(\frac{N}{P} - P\right)\right]^2 \text{ a perfect square,}$$

and the two factors are now seen to be $\frac{N}{P}$ and P.

The process thus appears to be really a roundabout way of finding by repeated trial the smaller factor P or $(A - \overline{C + 2m})$. Direct trial division of N by the series of factors A, $(A - 2)$, $(A - 4)$, &c., would *probably be simpler*. In applying the author's process it seems essential—in order to *avoid missing the right value* of $(C + 2m)$—to start with the lowest value $C = 0$ or 1 (according as A is odd or even), and work steadily on until an even division by $(A - \overline{C + 2m})$ is reached, ending finally with the value $A - \overline{C + 2m} = 1$, which would show conclusively—if no even division be reached earlier—that N is a prime; but if the start be made with a higher value of C, and no even division be met with till the final step of $A - \overline{C + 2m} = 1$, then no[2] conclusion can be drawn, and a fresh start must be made with a lower value of C.

The process will be rapid when m is small—*i.e.* when the

[1] Mr. Busk's example of process (ii.) (NATURE, p. 415) is a good instance of a purely *lucky* success in starting with B = integer next $< \sqrt{N}$. Let the same be tried on N = 69, 93, 123, &c., and it will fail (such a start being, in fact, illegitimate). Mr. W. H. H. Hudson's statement (NATURE, p. 511), that process (ii.) is "not one of general application," failing, for instance, for N = 323171, is a mistake: it fails solely from starting with B too low. The values in process (ii.) are: A = 2250, $B - r = 2177$, and $N = 4427 \times 73$; this process will of course fail if started with a value of B < 2177. This is a good instance of a case very tedious by either process: in fact, the number of steps necessary (if worked without guesswork) will be found to be $r = 1681$ by process (i.) and 159.408 by process (ii.), which are practically prohibitory.

[2] Mr. Busk's example on p. 414 of NATURE is a good instance of this. Applying it to the number N = 73, the start is made with the value C = 6; the process ends really with showing that $73 = 37^2 - 36^2$, and does not (of itself) warrant the inference that 73 is a prime.

factors are nearly equal, and will be tedious when m is large—*i.e.* when the factors are very unequal; and most tedious of all when N is a prime, when the number of steps (m) required will be $m = \frac{1}{2}(A - 1)$ or $\frac{1}{2}(A - 2)$, according as A is odd or even, which is obviously a very high number for high numbers N.

A different "shortening process" is proposed (by Mr. Hudson) on p. 511 of NATURE, which amounts to this. When the two numbers $(A + r)$ and $\{(A + r)^2 - N\}$, or, again, when the two numbers $(B - r)$ and $\{(B - r)^2 + N\}$, have a common measure, that common measure is (as is easily seen) one of the factors of N; and, if it can be recognized, at once solves the question. Unfortunately, this will be in general of little *practical* help, except when one of the four numbers operated on is quite small, as otherwise it is not easy to recognize (quickly) the fact of there being a common measure.

ALLAN CUNNINGHAM,
Lieut.-Col. R.E.

Chatham, March 30.

THE GEOGRAPHICAL RESULTS OF MR. STANLEY'S EXPEDITION.

IT is evident from Mr. Stanley's stirring letters, which during the past week have cast all other topics into the shade, that pioneering in Africa is not yet at an end, and that that strange continent has not yielded up its last wonder to knowledge. The letters are suggestive of many things. Much could be said in admiration of the heroism and generalship displayed; much as to the difficulties encountered and the sufferings and losses sustained; much as to the route selected, and much as to the conduct of the party left at Yambuya. But in the first place this is hardly the proper place to speak of these aspects of the expedition, and in the second place it is only fair to wait for the full narrative before venturing upon criticism. No one who knows Mr. Stanley had ever any doubt of his success, or could ever believe that he would allow himself to die before accomplishing his work. It is clear that to anyone who has it in him to do heroic deeds there is still ample scope in Africa.

What we have to do with here are the geographical results of Mr. Stanley's expedition. And here again we are met by the fact that the expedition was not properly one of exploration; at least, this feature was only secondary to the main object of the expedition, the "relief" of Emin Pasha, himself a contributor to science of high rank. Again, even the communication to the Royal Geographical Society can only be regarded as a few preliminary notes on the additions made to our knowledge of one of the most interesting regions in Africa; for the full results, which cannot but be of high value and interest, we must wait for Mr. Stanley's full narrative, which will doubtless include the results obtained by the scientific members of his staff. As the region through which the expedition passed was previously entirely unknown, fresh additions to our knowledge were inevitable. As to the character of this region, it is evident that, so far as time and danger and difficulties are concerned, no worse route could have been chosen. It is now well known that the Committee and Mr. Stanley yielded to influences which ought not to have weighed with them, in view of the main purpose of the Expedition, and that Mr. Stanley's own preference would have been for the East Coast route. Had this route been selected, no doubt there might have been difficulties with the Masai; forests would have had to be traversed, deserts crossed, and swamps trudged through; but all these obstacles combined would have been trifling compared with the terrors of the Aruwimi jungles, and their suspicious and ferocious inhabitants. However, Science has nothing to complain of: the gain has been all on her side.

Mr. Stanley has passed through one of the great blanks of Central Africa. Much of it was untrodden even by the deadly foot of the Arab slaver. Dr. Junker just touched its northern fringe; he had reached the Nepoko River apparently in its upper course; but from about 3° N. to about 4° S., and between the Upper Congo on the west and the lakes on the east, we have virtually a great blank. It is the northern part of this blank which Mr. Stanley has enabled us to fill in; and when he comes home he will probably be able to tell us more than we yet know. In the particular region with which he was concerned we wanted to know the course of the Aruwimi and its tributaries; the character of the country and people through which it passes; the position and extent of the lake (Muta Nzigé) to the south of Albert Nyanza, and its relation either to the Nile or the Congo. Some of these problems Mr. Stanley has solved; others, no doubt, he will have solved by this time.

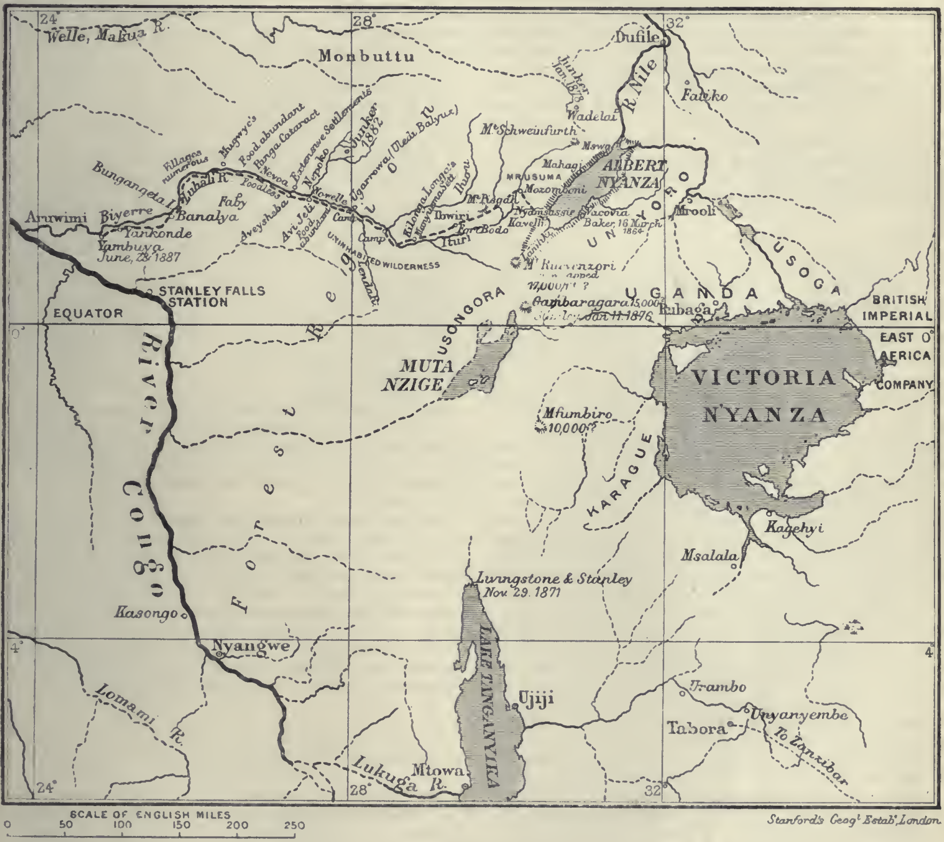
One thing is clear, the Expedition passed through the northern section of what is probably the greatest forest region in Africa, extending from about 3° N. to 4° S., and from about 23° to 30° E. Junker met with it on the Nepoko, and Livingstone in his weary journey from Tanganyika to Nyangwe. It was dense enough in both cases, but nothing apparently compared with what Stanley found it to be on the Aruwimi. The route, he tells us, was covered with creepers varying from $\frac{1}{4}$ of an inch to 15 inches in thickness, swinging across the path in bowlines or loops, sometimes matted and twisted together; also of a low, dense brush occupying the sites of old clearings which had to be carved through before a passage was possible. Where the clearings had been abandoned for some years was found a young forest, the spaces between the trees choked with climbing plants and vegetable creepers. This had to be tunnelled through before an inch of progress could be made. Mr. Stanley's description of the character and extent of this forest in his letter to Mr. Bruce is quite worth quoting:—

"Take a thick Scottish copse, dripping with rain; imagine this copse to be a mere undergrowth, nourished under the impenetrable shade of ancient trees, ranging from 100 to 180 feet high; briars and thorns abundant; lazy creeks meandering through the depths of the jungle, and sometimes a deep affluent of a great river. Imagine this forest and jungle in all stages of decay and growth—old trees falling, leaning perilously over, fallen prostrate; ants and insects of all kinds, sizes, and colours murmuring around, monkeys and chimpanzees above, queer noises of birds and animals, crashes in the jungle as troops of elephants rush away; dwarfs with poisoned arrows securely hidden behind some buttress or in some dark recess; strong brown-bodied aborigines with terribly sharp spears, standing poised, still as dead stumps; rain pattering down on you every other day in the year; an impure atmosphere, with its dread consequences, fever and dysentery; gloom throughout the day, and darkness almost palpable throughout the night; and then, if you will imagine such a forest extending the entire distance from Plymouth to Peterhead, you will have a fair idea of some of the inconveniences endured by us from June 28 to December 5, 1887, and from June 1, 1888, to the present date, to continue again from the present date till about December 10, 1888, when I hope then to say a last farewell to the Congo forest."

Here, then, we have a forest region very different from any other forest region of any extent in Africa. Prof. Drummond, in his recent book on Africa, describes very clearly the typical forest of Central and Southern Africa; the trees mostly standing apart, with very little brushwood, and in many places no difficulty in penetrating it even with a Cape cart. The rank exuberance of the Aruwimi forest can hardly be due to the abundance of water in the shape of lakes and rivers; for away south in the region recently traversed by Mr. Arnot, the region described by Livingstone as a great sponge, where the feeders of the Zambesi, the Congo, and other great rivers, take their rise, and on the east of which lie Tanganyika and Bangweolo

lakes, we find, so far as we know at present, no such dense bush, though the grass is high, and rank, and thick enough. Mr. Stanley attempts to account for the abundance of water and the thickness of the forest by the moisture carried over the continent from the wide Atlantic, by the winds which blow landwards through a great part of the year. But as a comparatively cold current sweeps along the coast from the south, these winds may be colder than the surface of the land over which they pass, and so may decline to part with their moisture. But this is a point for careful investigation; and it may after all be found that the rain of the rainiest region of Africa comes not from the Atlantic but the Indian Ocean, with its moisture-laden monsoons; and so we should have here a phenomenon analogous to that which prevails in the South American continent, the forests of which resemble in many features those of the region through which Mr. Stanley has passed.

The forest itself is not more interesting than its human denizens. Mr. Stanley mentions the names of many tribes living along the river, and judging from their names they seem all more or less of Bantu affinities. But we are here



verging on the limits of the Negro peoples, so that when we obtain full information it may be found that the Aruwimi tribes are much mixed. But it will be of the greatest interest to ascertain what has been the effect upon these peoples of their sad and depressing and ever-saturated surroundings; and to compare the results with what we find to be the case in more open country with people of the same type. That there have been changes in the population of the region is evident from the great heaps of oyster-shells met with by Mr. Stanley, some of them covered by several feet of earth. One important piece of information Mr. Stanley gives us concerning these forest tribes. Nejambi Rapids, about 250 miles above the junction of the Aruwimi and the Congo, marks the division between two different kinds of architecture and language. Below, the cone huts are to be found; above the rapids we have villages, long and straight, of detached square huts surrounded by tall logs, which form separate courts, and add materially to the strength of the village. Many precautions are adopted against attacks by poisoned arrows. Mr. Stanley lost several men by these arrows, and Lieutenant

Stairs had a narrow escape. It was afterwards found that the poison is manufactured from the dried bodies of red ants or pismires ground into powder, cooked in palm-oil, and smeared over the wooden points of the arrows. As might have been expected, the forest is haunted by myriads of insects of every variety, and it is to be hoped that a harvest of these have been gathered for the delight of the entomologists at home.

Mr. Stanley's description of the daily course of things in the forest region is worth quoting:—

"The mornings generally were stern and sombre, the sky covered with lowering and heavy clouds, at other times thick mist buried everything, clearing off about 9 a.m., sometimes not till 11 a.m. Nothing stirs then; insect life is still asleep, the forest is still as death, the dark river, darkened by lofty walls of thick forest and vegetation, is silent as a grave; our heart-throbs seem almost clamorous, and our inmost thoughts loud. If no rain follows this darkness, the sun appears from behind the cloudy masses, the mist disappears, life wakens up before its brilliancy. Butterflies scurry through the air, a solitary ibis croaks an alarm, a diver flies across the stream, the forest is full of a strange murmur, and somewhere up-river booms the alarum drum. The quick-sighted natives have seen us, voices vociferate challenges, there is a flash of spears, and hostile passions are aroused."

As to the river itself, the Aruwimi, or Ituri (it has several other names), is, with its windings, about 800 miles long, from its mouth in the Congo to its source almost on the edge of Albert Nyanza, though the course in a direct line is probably not more than 400 miles. The banks of the river, covered with forest from the Congo to the Nepoko (which is, after all, only a branch of the main river), are uniformly low, here and there rising to about 40 feet. Above the Nepoko, hills begin to crop up more frequently, palms are more numerous, and the woods show the tall, white-stemmed trees so characteristic of the slopes of the Lower Congo. While there are rapids at several places above Yambuya, above the Nepoko navigation becomes much more difficult, and rapids more frequent, while two considerable falls are met with. The land rises steadily until about 400 miles above Yambuya, the river is contracted into a rushing stream about 100 yards wide, banked by the steep walls of a cañon, the slopes and summits of which are clothed with wood. Whatever changes the face of the land may show, the forest covers peak, hill, ridge, valley, plain,—everywhere it is continuous, never broken, except at such clearings as man has made. Mr. Stanley very graphically compares the country traversed by his expedition to the long glacis of a fort rising from the Congo to a height of 5000 to 6000 feet; down the slope flows the Aruwimi, one of whose feeders runs almost within sight of Albert Nyanza, to which there is a sudden drop of 2900 feet.

"The main Ituri, at the distance of 680 miles from its mouth, is 125 yards wide, 9 feet deep, and has a current of 3 knots. It appears to run parallel with the Nyanza. Near that group of cones and hills, affectionately named Mount Schweinfurth, Mount Junker, and Mount Speke, I would place its highest source. Draw three or four respectable streams draining into it from the crest of plateau overlooking the Albert Nyanza, and two or three respectable streams flowing into it from north-westerly; let the main stream flow south-west to near N. lat. 1°; give it a bow-like form N. lat. 1° to N. lat. 1° 50′; then let it flow with curves and bends down to N. lat. 1° 17′ near Yambuya, and you have a sketch of the course of the Aruwimi or Ituri from the highest source down to its mouth, and the length of this Congo tributary will be 800 miles."

Here, then, we have remarkable hydrographical conditions. Only a few minutes' walk separates the feeders of the Congo and the Nile in this particular region. On the other side, again, are found streams flowing into the south of Victoria Nyanza rising close to others which run into Lake Tanganyika, which again, through the Lukuga, is believed to be a feeder of the Congo. Still further south are found the main Congo stream and its feeders rising in such close proximity to the source of the Zambesi that it is difficult to discriminate between the one and the other. Mr. Stanley's own lake, the Muta Nzige, of which he heard again when in the neighbourhood, very probably belongs not to the Nile but the Congo. All this is full of interest, and geographers will look with impatience for the publication of Mr. Stanley's detailed narrative.

Another fact of great interest Mr. Stanley refers to—the existence of a snowy mountain which may rival Kilimanjaro (19,000 feet), in the neighbourhood of Mount Gambaragara, or Gordon Bennett, between Albert Nyanza and Muta Nzige. This may be Mount Gordon Bennett itself, but Mr. Stanley does not think so, and he is supported by the few data which he furnishes. It would be quite in accordance with what we find in other parts of the world that a group of high peaks should be found together.

One other point of geographical interest is Mr. Stanley's observation that the Albert Nyanza is rapidly decreasing in size. A century or perhaps more ago, the lake must have been twelve or fifteen miles longer, and considerably broader opposite Mbakovia, than it is now. With the wearing away of the reefs obstructing the Nile below Wadelai, the lake has rapidly receded, and is still doing so, to the astonishment of Emin Pasha, who first saw Lake Albert seven or eight years ago. It is to be hoped that Mr. Stanley will find time further to investigate this subject, as well as to explore the country between the Albert Nyanza and Muta Nzige, settle the position and outline of the latter, and ascertain precisely to what river system it belongs.

The abruptness with which the forest comes to an end and the rich grass lands begin, about eighty miles from Albert Nyanza, is another point deserving special attention, and can only be explained when we have accurate observations of the rainfall and other conditions that go to form climate.

Such are some of the more important geographical results of Mr. Stanley's expedition, so far as we can gather from his preliminary letters; others may be derived from the map which accompanies his papers. More will no doubt follow. It is to be hoped that the rumour of Emin's return is not true, or at least that if he is coming to Europe he has left his province in efficient hands. In the interests of science as well as of humanity, it is important that the province which Emin has held so long may not be allowed to relapse into barbarism.

J. S. K.

A NEW PERMIAN RHYNCHOCEPHALIAN REPTILE.[1]

AMONG the many publications which have recently startled the palæontological world, one of the most important is unquestionably Dr. Hermann Credner's description of *Palæohatteria*, a new Permian Rhynchocephalian from the Plauen beds near Dresden—beds which have supplied the same author with copious material of Stegocephalians, both in the perfect and larval stages, the subject of his well-known admirable monographs. Great interest attaches to the present discovery from a purely zoological point of view, owing to the close relationship of this, one of the earliest of Reptiles, to the existing New Zealand *Sphenodon* (or *Hatteria*), the anatomy of which was first made known some twenty years ago by Dr. Günther in his classical paper in the Philosophical Trans-

[1] H. Credner, "Die Stegocephalen und Saurier aus dem Rothliegenden des Plauenschen Grundes bei Dresden," vii. Theil. *Palæohatteria longicaudata* (*Zeitschr. Deutsch. Geol. Ges.*, 1888, pp. 487–557, Pl. xxiv.-xxvi.).

actions (vol. clvii., 1867). Since that time *Sphenodon* (of which very few specimens were then known, and which was even supposed to be nearly extinct) has been found in abundance on various small islands in the Bay of Plenty, and has come into the hands of many anatomists, to the great benefit of reptilian morphology. An investigation of the development of this type is, unfortunately, still a desideratum, which, when supplied, cannot fail to throw great light upon the phylogeny of the Reptilia.

On the ground of its osteological structure and of the absence of copulatory organs, *Sphenodon* was recognized by Dr. Günther as the type of a distinct order, the *Rhynchocephalia*, a view in which he has been followed by Prof. Cope, who even goes further, and, very correctly as we think, approximates them to the *Plesiosauria* and *Chelonia*. However, the authority which attaches to the views of Prof. Huxley, who demurred to the ordinal separation of the *Rhynchocephalia* from the *Lacertilia*, has deterred a great number of systematists from accepting the order, and among these we find Dr. Credner still terming *Hatteria* a Saurian. Now, if the Saurians are to include the Rhynchocephalians, it seems unnecessary to divide the Reptiles into orders at all; we may safely say that, as far as our present knowledge goes, the difference between the Rhynchocephalians and the Lacertilians is ten times greater than that between the former and the Plesiosaurians, or between Crocodilians and Dinosaurians, and many times more so than between *Lacertilia* and *Ophidia*. The two latter are accepted as orders by those who refuse that rank to the *Rhynchocephalia*, but they hardly deserve to be looked upon as more than sub-orders in a group to be termed, in virtue of the law of priority, the *Squamata*. The *Rhynchocephalia* must be regarded as the most generalized of all recent and, perhaps, of all known Reptiles; in many points they approach the Stegocephalous Batrachians, and it is possible that the common ancestors of the *Chelonia*, the *Plesiosauria*, and the *Lacertilia* would fall in this order.

The following is Dr. Credner's definition of the new genus *Palæohatteria*:—

Habitus, that of a long-tailed lizard, 16 to 18 inches long, with robust limbs.

Vertebral column consisting of about six cervical, twenty dorsal, three or four distinct sacral, and fifty to fifty-five caudal vertebræ. Vertebral centra, solid amphicœlous sheaths which constrict but do not interrupt the notochord. Neural arches united to the centra by suture. Dorsal vertebræ with long anterior, caudal vertebræ with long posterior articular processes; no transverse processes; spinous processes of dorsal vertebræ elevated, with rounded upper border, decreasing rapidly on the tail to small tubercles, more and more posterior in position, and finally entirely disappearing. Small wedge-shaped intercentra between all præ-caudal and the anterior caudal centra; from the sixth caudal vertebra they are modified into chevrons. All præ-sacral, sacral, and the seven anterior caudal vertebræ with ribs. Dorsal ribs long and curved; cervicals straight; last dorsals short and feebly curved; sacrals short and stout; caudals short, hooked. Proximal extremity of ribs expanded, not divided into capitulum and tuberculum.

Skull pointed and compressed; orbits large and circular, with sclerotic ring; nostrils small, anterior; latero-temporal fossæ comparatively small. Dentition acrodont, the teeth acute and conical, slightly curved backwards at the extremity; a thin coating of dentine, which on the inner side of the basal third shows slight grooves. Præ-maxillaries distinct, each with three or four slender somewhat more strongly-curved teeth. Maxillary extending high up, armed with sixteen to eighteen teeth, of which the sixth and seventh are enlarged. Nasals nearly as long as the frontals. A large lachrymal between præ-frontal and maxillary. Jugal bordering the orbit inferiorly, bifurcating posteriorly into an ascending and a horizontal branch; the former forms with the post-orbital and the post-frontal a vertical post-orbital bar, the latter a horizontal bar with the quadrate.[1] Squamosal curved, fan-shaped, in contact anteriorly with the post-orbital, posteriorly with the horizontal branch of the jugal and with the quadrate. Basisphenoid a trapezoid plate with short lateral processes, with two small perforations near its anterior extremity, which tapers to the pointed præ-sphenoid. Vomer with hatchet-shaped groups of small teeth. Palatines with a series of teeth, parallel to the maxillaries, on the outer border. Mandibular ramus slender, straight, without coronoid process, formed of articular, angular, supra-angular, dentary, and probably also opercular and splenial.

Pectoral arch consisting of a long styliform episternum [interclavicle], which expands anteriorly into a small rhombic plate; two elbow-bent clavicles, overlapping the inner side of the episternal expansion; two crescentic scapulæ, truncate at each end and strongly thickened on the posterior border; and two non-perforated roundish coracoids.

Pelvis consisting of three paired elements, viz. a short massive ilium, with crest-like upper expansion and two diverging lower processes; a triangular posteriorly produced ischium; and a transversely oval, plate-shaped pubis with obturator foramen.

Limbs strong and stout, the posterior a little longer than the anterior. Distal extremity of humerus much expanded, with ectepicondylar foramen. Carpus with eight or nine ossified elements; tarsus formed of calcaneum, astragalus, and five tarsalia; five metacarpals and five metatarsals; five digits to both limbs, the first with two, the second with three, the third with four, the fourth with five, and the fifth with three phalanges, of which the distal is a sharp curved claw.

Abdominal ribs probably present, and formed of numerous small filiform bones.

An *armour* of small oat-seed-shaped scales, forming posteriorly diverging series, restricted to the ventral region between both pairs of limbs.

Among the most salient features in the structure of the new Reptile, as compared with other Rhynchocephalians, are the pelvis and the tarsus. The crest-like expansion of the costal border of the ilium and the bifurcation of its acetabular extremity, are, to a certain extent, Crocodilian or Dinosaurian, whilst the pubis and ischium appear to us to bear the greatest resemblance to the same in Plesiosaurians. It is also in the latter group that we have to look for so primitive and Batrachian-like a tarsus; for the tarsus of *Palæohatteria* affords an exact repetition of that of the likewise Permo-Carboniferous Plesiosaurian *Stereosternum*, which, on the ground of its five distal tarsalia has been made the type of an order, *Proganosauria*, by Dr. Baur. The close similarity of the dentition of *Palæohatteria* and that of certain contemporary Stegocephalians, especially *Dendrerpeton* and *Hylonomus*, is highly suggestive of relationship, and we are not surprised to hear from Dr. Credner himself of his having at first felt uncertain as to the class to which the fossil should be referred. Although unquestionably related to *Sphenodon*, *Palæohatteria* has, we venture to think, yet hardly a claim to enter the *Hatteriidæ*, and it would have been better had the author established for it a new family. The archaic condition of the humerus with both ent- and ect-epicondylar foramens, the presence of uncinate processes to the ribs, the absence of a ventral armour, the presence of a coronoid process in the mandible, and the share taken by the maxillary in the formation of the border of the orbit, a character common to the Chelonians and Plesiosaurians and certain Lizards, but not found in the Stegocephalians, the Ichthyosaurians, the Crocodilians, nor, we believe, in the other Rhynchocephalians, are

[1] What Dr. Credner calls "quadrate" is in reality quadrate + quadrato-jugal.

sufficient grounds for regarding the *Hatteriidæ*, with the single genus *Sphenodon*, as a different family.

Dr. Credner's paper also contains, incidentally, information on *Proterosaurus*, the structure of which is still, in spite of Prof. Seeley's recent investigations, very imperfectly known. In an example preserved in Freiberg, the author has discovered the interclavicle and clavicles, the former element closely resembling the same in *Palæohatteria*, whilst the latter is distinguished by its plate-like proximal expansion, which bears special resemblance to the so-called lateral pectoral plates of certain Stegocephalians. It appears almost certain that *Proterosaurus* was a Rhynchocephalian, but in many respects more specialized than *Palæohatteria*, intercentra being present only between the anterior cervical vertebræ, and the tarsus containing only six elements—three in the proximal and three in the distal row. G. A. BOULENGER.

THE SPECTRUM OF THE RINGS OF SATURN.

AN interesting note on the spectrum of Saturn's rings was communicated to the Royal Society on February 7 by Mr. Norman Lockyer. It has long been known that the rings are considerably more luminous than the planet, and the photographs by the Brothers Henry show that this is truer for the blue light than the more visible rays. It is therefore possible that they shine partly by their own light, and since it is now universally acknowledged that they consist of small bodies in motion, their spectrum has an important bearing on the meteoric hypothesis. Mr. Lockyer suggested that the additional luminosity might be due to collisions, and in order to determine whether the collisions were of sufficient intensity to produce incandescent vapours or not, he asked one of his assistants, Mr. Porter, to obtain a photograph of the spectrum. This was done at the Astronomical Laboratory at South Kensington, with a spectroscope having two prisms of 60° attached to the eye-end of the 10-inch equatorial. The photograph was taken with an exposure of about two hours, and shows decided indications of bright lines. Mr. Lockyer says:—"It is altogether too early to announce this as an established fact, but I think it well to send this note, in order that other observers with more powerful optical appliances and a better climate than that of London may investigate the question."

It is therefore very desirable that further inquiry should be made, both by photographic and eye observations. The bright flutings of carbon at wave-lengths 517, 474, and 564 should receive particular attention, the flutings being easily obtained for comparison from the flame of a spirit-lamp or wax vesta. Brightnesses may possibly occur also in the positions of the magnesium flutings at λ 500 and 521, the lead fluting at λ 546, and the manganese fluting at λ 558, all of which may be conveniently obtained for comparison by volatilizing the chlorides of these substances in the flame of a spirit-lamp or Bunsen burner.

It may be expected that the brightenings will be very feeble, owing to the masking effects of the more abundant solar light, so that the photographic method will probably give the best results on account of its power of integration.

In the same note, Mr. Lockyer states that "other considerations point to the possibility that bright lines or bands may be found in the spectrum of Uranus." A. F.

ON THE SPEED OF THE ELECTRIC TRANSMISSION OF SIGNALS THROUGH SUBMARINE CABLES AND LAND WIRES.

ELECTRO-TELEGRAPHIC operations for the determination of differences of longitude are usually so arranged as to furnish determinations of the speed of transmission of the electric signals. Each of two stations which are telegraphically connected is provided with a clock, and usually with a chronograph also; thus the clock-times at either station may be registered at will on the chronographs at both stations. The difference between the times indicated by the two clocks at any moment is thus readily ascertained, and two values of it will be obtained, one with the current transmitted in one direction, the other with it transmitted in the opposite direction. The difference between these two values indicates the sum of the speeds in both directions; and half the difference is usually called the "retardation on the line," as it indicates the amount by which every signal, on arrival at its destination, is slow on the time of its inception.

This method of determining the velocity is very simple and very exact; it does not require a knowledge of the errors of the clocks, or even of their rates, for the rates cannot sensibly alter in the brief interval between the signals with reversed currents, which need never exceed a few minutes.

The operations of two officers of the Indian Survey, Lieut.-Colonel Campbell, R.E., and Major Heaviside, R.E., for determining the differences of longitude between Bombay, Suez, and Aden,[1] furnish measures of the speed through two submarine cables which happen to be practically identical, though one cable was 355 knots, or as much as one-fourth, longer than the other cable. I gave the figures to Mr. W. H. Preece, of the Postal Telegraph Department, and he has found that they are very closely accordant with the theoretical speeds, calculated with due recognition of the different electrical conditions of the two cables. This is shown in the following table, in which Mr. Preece also gives the corresponding values by calculation and observation for the French Atlantic cable:—

Cable.	Length (knots).	Resistance (R) per knot.	Capacity (K) per knot.	KR per knot.	$L^2 \times KR$ per knot.	Thomson's constant, $a = {}^{\cdot}0232 \times KR$.	Apparatus time const. $a \times 1{}^{\cdot}55$.	Observed speed.
						sec.	sec.	sec.

For the speed of electric transmission through land lines, German geodesists have constructed an empirical formula on the assumption that the speed $= xl + yl^2$, l being the length of the line, and x and y two constants to be determined by observation. It is shown in the *Astronomische-geodätische Arbeiten* for the years 1883–84 and 1885–86, that, expressing l in kilometres,

$$\text{the speed} = 0{\cdot}0000208\text{s.}\ l + 0{\cdot}0000000206\text{s.}\ l^2$$

on the evidence of seventeen longitudinal arcs; and that on employing this formula to calculate the corresponding speeds in six arcs subsequently measured, the values obtained were found to differ 38 per cent. on the average from the observed speeds, and were generally quicker. This formula, however, takes no account of any differences in the electrical conditions of the lines. It gives 0·206s. and 0·302s. as the speeds of transmission through land lines 2700 and 3360 kilometres long, the lengths of the cables Suez-Aden and Aden-Bombay. The formula, however, cannot be legitimately applied to such long lines, for the longest of the seventeen on which the speeds were determined by observation, that from Berlin to Paris, was only 1230 kilometres. J. T. WALKER.

13 Cromwell Road, London, April 3.

NOTES.

THE Bakerian Lecture will be delivered to-day before the Royal Society by Profs. Rücker, F.R.S., and Thorpe, F.R.S. The subject is the Magnetic Survey of the British Isles for the epoch January 1, 1886, on which these gentlemen have been engaged for five years. They have made observations at more than two hundred stations, and have thus completed the first survey of the United Kingdom in which all three elements—the declination, dip, and horizontal force—have been determined for all parts. In addition to the general survey by means of which the directions of the isogonals, isoclinals, and lines of equal horizontal force have been found, special surveys have been made of selected districts in order to investigate the magnitude, direction, and causes of local magnetic disturbance. The principles which are justified by these inquiries have been applied to the whole country, with results which are likely to prove of interest both to physicists and geologists. We hope to give an account of the lecture in an early number.

PROF. MENDELEEF, the celebrated Russian chemist, has accepted the invitation of the Council of the Chemical Society to deliver the Faraday Lecture; he will probably give his mature views on the Periodic Law of the Elements, with which his name is so indissolubly connected. The lecture will be delivered by permission of the Managers of the Royal Institution in their theatre, on the evening of June 4. The Fellows of the Society will entertain Prof. Mendeleef at a dinner at the Holborn Restaurant the next evening; and the President, Dr. W. J. Russell, F.R.S., will hold a reception at the Grosvenor Gallery on June 7.

M. CHEVREUL, the famous French chemist, died on the morning of April 9 at the age of 102. He was born at Angers in 1786. During his long life he held many official appointments, and by his work as a chemist he secured an eminent place among the men of science of the present century. He constantly kept in view the possible applications of science to industry. Some of his discoveries have exercised an important influence on the manufacture of silk, and his researches relating to "fatty bodies of animal origin" marked an era in the development of various industries dependent on organic chemistry. M. Chevreul was a man of active and cheerful temperament, and extreme old age did not prevent him from continuing the studies in which he had found a perennial source of interest.

THE death is announced of the Finnish botanist, Prof. Sextus Otto Lindberg; and of Dr. Hermann Theodor Geyler, Director of the Botanical Gardens at Frankfurt. Dr. Geyler was born at Schwarzbach, in Saxe-Weimar, on January 15, 1835.

IN the House of Commons, on Tuesday, in connection with the vote for expenses incurred in the erection and maintenance of the buildings of the Department of Science and Art, Mr. Acland called attention to the inadequacy of the buildings used by the Normal School of Science. Mr. Acland's appeal, which was in no way exaggerated, received the cordial support of Sir H. Roscoe, who spoke of the condition of the buildings as "really a disgrace." Hon. members, he said, were hoping before long to have a technical Bill; but what would be the good of it unless proper teachers were provided? And proper teachers it was impossible to obtain unless their schools were what they ought to be. In almost every centre of population in foreign countries these normal schools were to be found, but there was only one in England. This had been built for one purpose, and converted to quite different purposes for which it was unfitted. The honour of the country was at stake, and this state of things had been borne quite long enough. Mr. Plunket, in his reply, declined to give any definite pledge about the matter. He had visited the buildings several times, and as one of the results of the debate of last year, the First Lord of the Treasury, the Chancellor of the Exchequer, the Vice-President of the Council, himself, and others made a most careful visit to every part of the building. One of the conclusions arrtved at was, that before additional buildings were erected it would be a good thing to get rid of a good deal of the material filling up the galleries at the present time. A Committee, consisting, among others, of Sir H. Roscoe, Lord Rayleigh, Sir B. Samuelson, and Lord F. Hervey, had been appointed for the purpose of weeding out those galleries in the science collections alone. Until that Committee had reported, it was impossible to take any further steps or to come to any definite decision with reference to increased expenditure to extend the buildings which at present existed.

A DEPUTATION from the National Association for the Promotion of Technical Education waited on Sir William Hart Dyke on Monday afternoon in the Conference Room at the House of Commons. In answer to the deputation, which was introduced by Lord Hartington, as President of the Association, Sir William Hart Dyke said the Government had the cause of technical education very much at heart, and would do their utmost to pass a Bill dealing with the subject during the present session. They would take into careful consideration the recommendations of the Association. He promised, meanwhile, that he would lay on the table of the House of Commons a memorandum explaining some of the difficult points of the Code in special reference to the instructions to be given to inspectors in carrying out the new provisions of the Code. He also promised that the subjects in which instruction might be given in evening schools should be increased from two to four.

AT the thirtieth session of the Institution of Naval Architects, yesterday, an important paper on the designs for the new battle-ships was read by Mr. W. H. White, F.R.S., Assistant Controller of the Navy and Director of Naval Construction.

THE Zoological Museum at Leyden, one of the most considerable on the Continent, has narrowly escaped a terrible disaster. On Monday, the 1st of this month, a fire broke out, and all the resources of the officials and of the town were taxed to extinguish it. Indeed, it was not got under until a considerable portion of the collection of specimens of hollow-horned Ruminants had been destroyed. Had the accident, which arose from the defect of a flue, taken place at night instead of in the afternoon, when plenty of assistance was promptly at hand, it is believed that the whole Museum would have perished. The authorities of other Museums, especially those which contain many spirit preparations, should not neglect this warning.

WE have already mentioned that an international meeting of zoologists will be held in Paris in August. The President will be M. Milne-Edwards, and some important questions will be submitted for consideration. Among them will be the question of the unification of the language of zoology in classification and specific denotation. M. R. Blanchard has prepared an important report on the subject, which will be published shortly in the *Revue Scientifique*, and form the basis for the discussions at the Congress.

THE Physiological Congress which is to be held in Basle in September will be attended by many French physiologists, if all those who propose to go are able to carry out their intention.

THE King of Sweden has selected Herr Ehrenheim, ex-Minister of State, as President of the forthcoming Oriental Congress in Stockholm. It is announced that Prof. R. L.

Beasley will represent the University of Cambridge; Oxford has not yet chosen its representative. The Shah and several Indian princes will send representatives.

THE Central Society of Agriculture of France has conferred upon Prof. J. C. Ewart the title of honorary member in recognition of the services he has rendered to the fishery industry by his "many and eminent labours."

THE *Kew Bulletin* for April 1888 contained a list of new garden plants described to the end of the year 1887. The *Bulletin* for the present month consists of a list of those described and published during the year 1888. The list has been extended to include the descriptions of new plants (and name alterations) which have appeared in several horticultural periodicals, that were not included in the former list. The number of new garden plants annually described in various English and foreign periodicals renders it a matter of considerable difficulty to botanists and horticulturists to keep them in view. The publication of a complete annual list of new garden plants is, therefore, as the editor explains, indispensable to the maintenance of a correct nomenclature, especially in the smaller botanical establishments in correspondence with Kew, as these, for the most part, are only scantily provided with horticultural periodicals. The editor also points out that such a list will afford information respecting new plants under cultivation at Kew, many of which will be distributed in the regular course of exchange.

A SEVERE shock of earthquake was noticed over the whole of South-East Japan on February 18. At Yokohama and at Tokio many houses were damaged. The shock continued for 6m. 12s., and was felt at Sendai, a town 45 geographical miles to the north of Tokio.

ON March 20, about 10 p.m., a slight shock of earthquake was felt near Carlstad, in Sweden. It was followed by a more severe shock at 3 a.m.

SEVERAL meteors have been observed recently in Scandinavia. On the evening of March 14, a brilliant meteor was seen at Molde, in North-West Norway, bluish-white in colour, and going in an easterly direction; and on March 21, at about 10 p.m., another was seen at Sarpsborg, on the Christiania fjord. It radiated in the west, and went in a southerly direction, displaying, during its passage, rainbow colours, and leaving a reddish trail behind. What may have been the same meteor was seen off the coast of Gothenburg, at 10.22 p.m., a considerable distance further south. It was very brilliant, and bluish-green in colour, and its passage—in a direction south-west-north—occupied fifty seconds.

THE atomic weight of chromium has been redetermined by Mr. Rawson, of University College, Liverpool. Previous determinations, of which there have been many, have resulted in placing the value somewhere between 52·0 and 52·5. The method employed by Mr. Rawson appears to have been an exceptionally accurate one, there being no transference from one vessel to another, no filtrations and consequently no burning of filter papers. The plan of operations consisted in first reducing a known weight of pure ammonium dichromate with alcohol and hydrochloric acid to chromic chloride, and subsequent estimation of the oxide produced by direct precipitation with ammonia. The purest obtainable ammonium dichromate, $(NH_4)_2Cr_2O_7$, was repeatedly recrystallized, dried for a couple of days at 100° C., and finally for a fortnight in a desiccator. The water used in the estimations was trebly distilled, and, on evaporation of 100 cubic centimetres, no residue was obtained. The purest commercial hydrochloric acid was redistilled, and the distillate in like manner gave no residue on evaporation. Similarly, the ammonia solution and the absolute alcohol were redistilled, until absolutely free from impurities. The method of vibrations was employed in weighing, and the platinum dish used in the operations was counterpoised by a similar dish of nearly equal weight, the slight difference being made up by a piece of platinum-foil. The two dishes were always treated alike: when one was placed on the water-bath, the other was also placed on a water-bath, and for the same time; they were both ignited for the same length of time, and, after ignition, were simultaneously placed in desiccators. In this way the usual errors in weighing platinum after such treatment were eliminated. During the experiments, the dishes were protected by covers of platinum-foil, which were not, however, weighed with them. In the actual experiments, the finely ground ammonium dichromate was weighed in one of the dishes, 10 c.c. of water added, and when the salt had dissolved 10 c.c. of hydrochloric acid. In small quantities at a time, 10 c.c. of the alcohol were subsequently added, and the whole evaporated to complete dryness on the water-bath. After repetition of this treatment to insure complete reduction, the residue was dissolved in 10 c.c. of water and 2 c.c. of the ammonia added; after an interval another 10 c.c. of water and 3 c.c. of ammonia were added, and the whole evaporated again to complete dryness. The dish was then heated in an air-bath to 140° for five hours, and afterwards to redness for an hour in a muffle furnace. The residual oxide, after weighing till constant, was found to be perfectly pure, and of a fine green colour; on washing with water and evaporating the washings, no residue was obtained. In calculating the results, to which all the known corrections were applied, it was assumed that $O = 15·96$ and $N = 14·02$, both well-determined numbers. The mean of the values from six experiments, the maximum difference between which was only 0·120, gives for the atomic weight of chromium 52·061. Hence chromium appears likely to possess a whole-number atomic weight, and it cannot but be admitted as remarkable that so many of the later stœchiometrical investigations, conducted with all the modern experimental refinements, have yielded values approximating to true multiples of the atomic weight of hydrogen.

MR. W. E. BEALE writes to the *Times* from Folkington Manor, Polegate, Sussex, April 4:—"On this estate is to be seen a nest, which has evidently been built partly by a thrush and partly by a hedge-sparrow. The nest itself is of the ordinary size of the thrush's nest; but, instead of being lined with mud, it is lined with horsehair, wool, and moss. The birds seem to have been good friends during the laying of their eggs. On Monday last there were three sparrow's eggs in the nest, and five thrush's. But on visiting the nest to-day it was found that the sparrow's eggs had been destroyed. The birds appear to have quarrelled when it came to the question of which should sit on them, and the thrush asserted its rights, not, however, without a struggle on the part of the sparrow, one of the thrush's eggs being broken, one missing, and three being perfect."

ACCORDING to the *American Field*, wild boars have become very numerous in the deep recesses of the Shawangunk Mountains, that border Orange and Sullivan Counties, N.Y. They are the genuine Black Forest wild boars of Europe, the descendants of nine formidable and ferocious boars and sows which Mr. Otto Plock, of New York, imported some few years ago for the purpose of annihilating the snakes and vermin that infested his estate near the Shawangunk Mountains. After the boars had eaten up all the snakes and vermin in the inclosure, they longed for more, and dug under the wire fencing and escaped to the mountains, where they have since bred and multiplied. They are so ferocious that the most daring hunter is said to hesitate before attacking them. They have immense heads, huge tusks and shoulders, and lank hind-parts.

Mr. T. Workman writes to us from Belfast that, having fallen into a doze on the afternoon of Friday, March 29, he was awakened by the undoubted hum of a mosquito, and thought himself back in Singapore, where he was about fourteen months ago. His first impulse was to drive away the nuisance, but curiosity to know whether it really was what he thought made him forbear, and he was soon rewarded by its settling on his right eyebrow and inserting its stiletto, with the usual sharp result, both to him and to it. Mr. Workman incloses in his letter a sketch of the insect. A mosquito in March in the north-east of Ireland is certainly a rare phenomenon.

The first part of the Transactions of the meeting held in August 1888, in Paris, for the study of tuberculosis in man and animals, has just been published by M. Masson. It is a volume of 500 pages, and contains much interesting matter.

Messrs. Macmillan and Co. have issued the second part of vol. ii. of the new and thoroughly revised edition of "A Treatise on Chemistry," by Sir H. E. Roscoe, F.R.S., and C. Schorlemmer, F.R.S. In this volume, the authors treat of metals and their compounds.

A valuable list of the Coleopterous fauna of the Liverpool district, by Mr. John W. Ellis, has been reprinted from the Proceedings of the Liverpool Biological Society. The list contains nearly 30 per cent. of the British beetles.

The second part of Prof. E. Strasburger's "Histologische Beiträge" (Jena, G. Fischer) has been published. In this part, which is illustrated with four lithographic plates, the author deals with the growth of vegetable cellular membranes.

Messrs. G. Bell and Sons are about to publish "Names and Synonyms of British Plants," by the Rev. G. Egerton-Warburton. This is a complete alphabetical list of known British plants, giving, under each, references to its description in Sowerby's "English Botany" (Syme Boswell), "The London Catalogue of Plants," and the "Floras" of Babington, Bentham, and Hooker. The correct pronunciation of the names is indicated by accents. A list of the most usual synonyms is appended.

We have received vol. ii., No. 2, of the Proceedings of the Tokio Physical Society. It is worthy of note that the report of the Society is printed in Japanese, in Roman letters, while the various papers are in English. Amongst the contributions in the present number are: effects of stress on magnetization of nickel, by H. Nagaoka; thermal conductivity of marble, by K. Yamagawa; an apparatus for purifying mercury, by H. Nagaoka.

The next Congress and Exhibition of the Sanitary Institute will be held in Worcester at the end of September. Arrangements are in progress, and will be published shortly.

At the Central Institution of the City and Guilds of London Institute, Mr. T. Bolas will deliver a course of six lectures on photography, on Wednesday evenings, at 7.30, beginning on May 8. Lectures I. and II. will deal with the use of artificial light in photography; lectures III. and IV. with photo-mechanical printing methods; and lectures V. and VI. with direct contact printing methods.

The London Geological Field Class under the direction of Prof. H. G. Seeley, F.R.S., will begin the summer excursions this year on May 4, and will continue them on Saturday afternoons thereafter till the end of June. Intending students should apply at once for tickets to the Honorary Secretary, Mr. Walter Lewinton, Lundy House, Willoughby Road, Hampstead, N.W.

The additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♀) from India, presented by Mrs. Cox; a Sinaitic Ibex (*Capra sinaitica*) from Mount Sinai, presented by Sir James Anderson; four Black Swans (*Cygnus atratus*) from Australia, presented by Messrs. James and Alex. Brown; a Raven (*Corvus corax*), British, presented by Mr. G. F. Hastings; a Collared Fruit Bat (*Cynonycteris collaris*), a Side-striped Jackal (*Canis lateralis*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

The Luminosity of Venus.—Venus being now favourably situated, it is a convenient time for making observations with reference to the question of the cause of the recorded so-called phosphorescence. If there be any extensive phosphorescence, as first suggested by Sir William Herschel, or if there be an atmosphere occasionally illuminated by electrical discharges similar to those which produce auroræ in our own atmosphere, or even if there be a meteoritic bombardment, the light observed may possibly give indications of a spectrum of bright lines or bands.

The Spectra of R Leonis and R Hydræ.—A *Wolsingham Observatory Circular* (No. 23, April 2, 1889), by Mr. Espin, states that: "The spectra of R Leonis and R Hydræ contain bright (hydrogen?) lines, first seen on February 25. Observations confirmed, through the kindness of Mr. Common, by Mr. Taylor, at Ealing, who sees two in R Leonis and one in R Hydræ." The spectra of these two important variables have hitherto been simply described as being of Group II (Lockyer), indicating, according to Mr. Lockyer, carbon-fluting radiation and metallic-fluting absorption. Mr. Espin's observations are of very great interest in connection with the meteoric theory as to the cause of variability in this class of stars. It will be remembered that the variability is ascribed to the effects of a cometic swarm revolving round a central one, the maximum occurring at periastron passage, when the revolving swarm passes through the outliers of the central one. It was predicted that, under these conditions, bright lines would make their appearance, and the prediction has now been verified in the most complete manner. Both the stars observed by Mr. Espin were near their maxima, that of R Leonis occurring on March 23, and that of R Hydræ on February 17 (*Ann. du Bur. des Long.*, 1889). It may also be remembered that bright lines have been seen in R Cygni and *o* Ceti when near their maxima. The meteoric theory is therefore greatly strengthened by these observations. The importance of making further observations of these stars, with special reference to the disappearance of the bright lines, is obvious.

The Sun-spot Minimum.—Prof. Tacchini has recently communicated to the *Lyncei* of Rome (vol. v. series 4*a*, March 3, 1889), a note by Prof. Riccò on the days on which the solar surface was entirely free from spots, during the years 1885–6–7–8. It appears from the tables given that in 1885 there were only six days on which no spots were visible, whilst there were fifty-one in 1886, ninety-eight in 1887, and 140 in 1888. The maximum number of blank days occurring in one month was in November 1886, there being no spots on twenty-six days of that month. There were twenty blank days in October 1886, eighteen in July, and sixteen in May of the same year. A second ta le is given, showing the total numbers of days on which no sp s were visible during the years 1872–88 inclusive, and also the greatest number of consecutive days on which there were no spots during the same years. From this it appears that the greatest number of blank days was 248 in 1878, the last minimum period, whilst in 1872, 1882, and 1884, spots were visible every day. It is suggested that the approaching minimum will occur in 1889–90. In 1879 there were thirty-nine consecutive days on which no spots were recorded, this being the maximum number in any one year; the greatest number since then was seventeen in 1888.

Discovery of a New Comet.—A faint comet was discovered by Mr. E. E. Barnard, Lick Observatory, on March 31. The position of the object was as follows:—

March 31, 17h. 19m. G.M.T., R.A. 5h. 20m. 50s.; N.P.D. 73° 53′ 0″.

It has since been observed at Copenhagen:—

April 4, 8h. 51m. G.M.T.; R.A = 5h. 17m. 56s.; N.P.D. = 74° 0′ 55″.

Observations of Variable Stars in 1888.—Mr. Sawyer publishes the results of his observations of variable stars made in 1888, in *Gould's Astronomical Journal*, No. 190. Amongst the principal of these were U Orionis (Gore's variable), observed at maximum 1888 December 26; Mira Ceti at maximum 1887 November 10; W. Cygni at minimum 1889 January 1, since when it has brightened fast. ρ Persei was considered as having been at minimum, 1888 November 7; ε Aurigæ about 1889 January 15. R Scuti seems to have been just three weeks in advance of the ephemeris in Nature; R Lyræ and U Monocerotis corresponded to the predicted times pretty closely. R Virginis also was estimated to be at maximum only one day later than given by the ephemeris; *g* Herculis was recorded as at maximum 1888 June 3 and September 11, and at minimum July 18.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 *APRIL* 14–20.

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on April 14

Sun rises, 5h. 7m.; souths, 12h. 0m. 11·5s.; sets, 18h. 53m.: right asc. on meridian, 1h. 31·6m.; decl. 9° 35′ N. Sidereal Time at Sunset, 8h. 25m.

Moon (Full on April 15, 22h.) rises, 17h. 3m.; souths, 23h. 20m.; sets, 5h. 21m.*: right asc. on meridian, 12h. 52·9m.; decl. 0° 14′ S.

GEOGRAPHICAL NOTES.

The Founder's Medal of the Royal Geographical Society has been awarded to Mr. A. D. Carey, of the India Civil Service, for his remarkable journey in Central Asia, at his own risk and expense, during which he travelled over a distance of 4750 miles, through regions which have never before been visited by an Englishman, and very rarely by any European. The Patron's Medal has been awarded to Dr. G. Radde, Director of the Natural History Museum, Tiflis, for a life devoted to the promotion of scientific geography, as a traveller, observer, and author. The Murchison Grant has been given to Mr. F. S. Arnot, towards providing and conveying a suitable present to the Chief Chitambo, of Ilala, as a recompense for his services in connection with the removal of the body and personal property of Dr. Livingstone in 1872. Mr. Arnot also receives the Cuthbert Peek Grant, in recognition of the interest and value of his seven years' travels in Central Africa. The Back Premium has been awarded to Mr. F. C. Selous, in acknowledgment of the geographical work accomplished by him in his recent journey in Mashona Land and north of the Zambesi; and the Gill Memorial to Mr. M. J. Ogle, of the Indian Survey Department, in recognition of his excellent survey work in Eastern Assam, in Manipur, and in Northern and Western Burma. The three new honorary corresponding members are Captain Dutton, of the U.S. Survey; M. Maunoir, secretary of the Paris Geographical Society; and Dr. Ballivian, a Bolivian geographer. Sir Mountstuart Grant Duff will succeed General Richard Strachey as President.

On Monday night Mr. Harold W. Topham read to the Royal Geographical Society an account of his visit last summer to the Glaciers of Alaska and Mount St. Elias. Speaking of Glacier Bay, near Sitka, Mr. Topham said that into it many large glaciers descend, only one of which, the Muir, has been explored. It is thirty miles long, and its breadth, where it runs out into the sea, is one mile. It is decreasing very rapidly, so rapidly, indeed, that the sailors assert that they can, year by year, distinguish the difference in its size. The height of the ice wall at the foot of the glacier, where it is washed by the sea, was 319 feet in 1886, whilst last year it was 266 feet, a decrease of 53 feet. A cairn which had been erected to ascertain the rate of motion of the glacier, was found almost overthrown into a crevasse. Mr. Topham speaks of the magnificence of the mountain range stretching from Cross Sound to Yakatat. The peaks reach up 16,000 feet, the whole of which height is at once presented to the view. Their bases are washed by the sea, into which their glaciers descend. Many of these glaciers are singularly free from moraine. They are exceedingly steep, and are broken up into innumerable ice falls. The St. Elias Alps, from Cross Sound to Fairweather, run close to the sea. They then curve inland, and sweep round Yakatat Bay at a distance of about thirty miles from the water. There are many fine peaks in the range, and the eye wanders on from summit to summit till it rests upon the finest of all, Mount St. Elias, at the far north-west of the range. Lieutenant Allen stated this peak to be 19,500 feet high. It is the highest mountain in North America. To the north and west of Yakatat Bay all is ice. It is a vast plain of ice, stretching back sixty miles or more, and running eighty miles along the coast. At a place fifty miles up the glacier from the bay, the party found they were only 650 feet above the sea. This gives a fall of only 13 feet to the mile. The rate of progress, therefore, of the ice, must be very small, and this is proved by the quantity of scrub and trees which grow upon the terminal moraine upon the top of the ice. The moraine is several miles broad, and is covered with brush of alder and willow and spruce. The party proceeded by boat from Yakatat to opposite Mount St. Elias. They proceed up the Yahtsétah River. Seven miles from the sea, the river issues from beneath the ice, and it brings with it such a quantity of dirt, that the water is of a greyish-white. The river, where it issues from the ice, is about 50 feet broad, but it divides and subdivides to such an extent that at its mouth it is about seven miles in width. The west bank is composed entirely of ice. Where the river issues from under the ice, the latter is 500 feet thick, and possesses a moraine several miles wide, the last mile of which, the one nearest the edge of the glacier, is covered with thick brush. Through this brush they had some difficulty in forcing their way to the open glacier beyond. The best way of describing the moraines upon the Malaspina Glacier is to liken the

surface of the ice to a very choppy sea, on to which has rained innumerable stones and rocks. The depressions are often 100 feet deep. On this moraine were found shale and slate granite quartz, with sulphates and pyrites and copper. After several ineffectual attempts Mr. Topham and his companions decided to ascend St. Elias on the south-west side, west of the Chaix Hills. The party ultimately, from their camp 1500 feet high, reached the brink of the crater, 7600 feet above sea-level and 5000 above the Tyndall glacier; another six hours found them at a height of 11,461 feet. They were then on the northern and upper rim of the crater, and judged the summit to be another seven or eight thousand feet above. The crater is full of ice, and upon its precipitous cliffs are a number of overhanging glaciers, splashed, as it were, upon the rocks and unattached from the snow-fields above. This is characteristic of a number of the glaciers in the neighbourhood. There they are —right on the rocks, with yawning crevices upon them broken up and ready to topple over upon you. Perhaps in a few years they will have melted entirely away. Everything, Mr. Topham states, around St. Elias bears evidence to the conclusion that the long period of ice through which the land has been passing is now coming to an end; a conclusion which is certainly rash. Mr. Topham gave a detailed description of the panorama to be seen from the highest point reached. There is, he states, vegetation upon the south-east slopes of the hills to a height of 1500 feet above the glacier. The greatest height at which he found vegetation, exclusive of lichens, was 4500 feet above the sea, but the place was exposed to the full glare of the sun, and no other vegetation was found for an interval of 1500 feet below. A characteristic of the Alaskan glaciers is the curious way in which small isolated bits of moraine show up here and there above the ice. For example, you may walk down the centre of the Tyndall upon white ice without seeing more than a few stones to suggest the existence of a moraine, and suddenly you will come upon an island of *débris*, disconnected from any regular moraine. It springs from nowhere, is quite isolated, and appears to have no reason for being there.

BIOLOGICAL NOTES.

THE RATTLE OF THE RATTLESNAKE.—The habit of sloughing is common to all serpents: a short time before the removal of the old skin takes place, the new epiderm makes its appearance beneath the old. The mode of growth of the new and the removal of the old is the same in all snakes, with the exception that, in those with a rattle, that portion of the slough that covers the tip of the tail is retained to form one of the rings of the rattle. The attachment is simply mechanical; the rings are merely the sloughs off the end of the tail. The terminal bone of the tail is formed of vertebræ that have coalesced and changed in great measure their shape; in the different species the number of vertebræ included in this bone varies considerably, and sometimes it varies in individuals of the same species. With the purpose of indicating the manner of growth of the rattle, and as far as possible determining its origin, Mr. S. Garman has followed up its appearance in several species, full details of which, with figures, have been lately published. In the very young rattlesnake, while the vertebræ are still separate, there is no rattle, but about a week after birth a well-marked button is seen; with the first slough the first ring is set free, the button being pushed forward, and a third button is gradually perfected. In time the traces of the vertebræ in the terminal bone are almost obliterated; the bone becomes thickened, pushed forward at its edges, and otherwise enlarged. In a full-grown rattlesnake the hinder seven of the rings belong to the period of the snake's most rapid growth—they form the "tapering rattle" formerly used in classification of the species; while four of the rings and the button are formed while the gain in size was less rapid, and form the "parallelogrammic rattle" of the old classifiers. Many serpents besides those possessed of a "crepitaculum" are addicted to making a rattling noise by vibrations of the end of their tails. In illustration of the extent to which the tail has been modified in different cases, Mr. Garman figures the tails of several species, among others that of *Ancistrodon contortrix*, Lin., the copperhead of the United States. The tip of its tail is directed downwards as well as a little backwards; most often the button has one or two swellings in a degree resembling those on a ring of the rattle. A living specimen of this snake, kept for a year or more, would take to rattling on the floor whenever it was irritated; the sound was made by the terminal inch of the tail, this part being swung from side to side in the segment of a circle, so that the tip might strike downward. The result was a tolerable imitation of the sound made by a small rattlesnake.—(*Bulletin Museum Comp. Anatomy*, vol. xiii. No. 10, August 1888.)

A NEW SPECIES OF LAMINARIA.—The discovery in the Mediterranean Sea, midway between Marseilles and Algiers, of a Laminaria, not only new to the shores of Europe, but an addition to the group—one, too, neither small in size nor obscure in its characteristics—is a very interesting fact for botanists. *Laminaria rodriguezii* has been described by Dr. Ed. Bornet in a recent number of the Proceedings of the Botanical Society of France. It was taken by M. J. Rodriguez a few miles south of Port Mahon, on a rocky bottom, in a depth of from 125 to 150 metres. It was also taken on the east and north coasts of Minorca. It appeared to be abundant in the first-mentioned of these localities. The fronds grow to a height of 2 metres. In general aspect, consistence, and colour this new species somewhat resembles *L. saccharina*, but it cannot be for a moment confounded with this well-known form. It is attached to the stones upon which it grows by a series of little root-like processes, which emanate from stolons running over the surfaces of the stones. From these stolons the young fronds arise, and in specimens with adult fronds, a whole colony of small fronds will be found springing from the stolons. *Lam. bongardiana* and *L. longipes* of Kamchatka, *L. japonica* from Japan, and *L. sinclairi* from California, are the only known species, with simple fronds, which possess these rooting stolons, but none of these can be confounded with the present new form. Of the five species of Laminariaceæ which have been from time to time recorded as occurring in the Mediterranean, this is the only one that is without any doubt a native. *Phyllaria reniformis* may possibly be indigenous, but *Ph. purpurascens*, *Lam. saccharina*, and *Sac. bulbosa* are almost certainly waifs that have been only met with in the neighbourhood of ports. The *Lam. saccharina*, Ardissone, found growing at Syracuse, in Sicily, proves, however, to be Bornet's new species, which is the sole representative on the Atlantic sea-board of the Pacific Ocean forms above referred to. —(*Bull. de la Soc. Bot. de France*, tome xxxv. pl. 5.)

THE ENVELOPES IN NOSTOCACEÆ.—M. Maurice Gomont has printed a brief abstract of his researches on the investing envelopes of the filamentous Nostocs. The thallus in these consists of the simple row of cells, the trichome, and the protective envelope, more or less marked (the gaine); when the hormogones are dispersed, this latter disappears. In a 33 to a 50 per cent. solution of chromic acid, the gaine becomes swollen and dissolves, leaving only a tube-like pellicle; next the protoplasm of the trichome cells becomes greatly changed, leaving the cell-walls clearly defined. These consist of an external layer, seemingly intermediate between the membrane met with in the hyphæ of Fungi and the cuticle of the higher plants; it has a remarkable power of resisting the action of acids: in a 33 per cent. solution of chromic acid or in concentrated sulphuric acid, it remains unchanged for a space of twenty-four hours; it is insoluble in hydrochloric or acetic acids, or in caustic potash; it is dissolved in a 50 per cent. solution of chromic acid, but only after several hours; with aniline or fuchsine it assumes a brighter hue than ordinary cuticle. The interior layer gives the reactions of cellulose. The chemcal properties of the gaine prove it to be a true cuticle.—(*Journal de Botanique* for 1888.)

THE SCOTTISH METEOROLOGICAL SOCIETY.

AT the half-yearly meeting of the Society, held on Monday, April 1, it was stated in the Report of the Council that new stations had recently been added in the Newington District of Edinburgh, and in the Botanic Garden, these additions to the observing staff being regarded with much satisfaction, particularly in view of the facilities which a somewhat thickly planted series of stations in Midlothian offer, in the observation of the physical data required in investigating the various meteorological gradients, as proposed by the late Mr. T. Stevenson. Dr. Archibald Geikie, Prof. Crum Brown, and Prof. Bayley Balfour were elected Members of Council.

The inspection of the fishery barometers of the Meteorological Council at fifty-four of the fishing ports on the Scottish coasts has now been completed by Mr. Dickson, who gave much

attention, by short lectures to the fishermen, conversations with them, and otherwise, to awaken an interest in weather forecasts and their intelligent interpretation. Though the giving of the lectures is practically limited to the Saturdays, when the fishermen are disengaged, yet opportunity was taken to deliver eleven lectures, which were attended by audiences varying from 40 to 250. The method of proceeding was to give, by the help of weather charts, a short explanation of the law of storms, and an account of the weather of the week immediately preceding the lecture. The fishermen were then invited to ask questions, and raise discussions on the subjects of lecture.

During the winter Prof. Balfour engaged Mr. Turnbull to give fourteen lectures to the *employées* of the Garden on meteorology, in which marked prominence was given to the practical side of the science, explaining and teaching them to handle each instrument—why it is placed in the position it occupies, and not elsewhere; and showing the methods of reducing the observations. The efficient training of a body of men from which the Council largely draws its observers is a matter of no small importance. A suitable site has been procured in Fort William for the proposed low-level observatory, and plans of the buildings prepared by their architect, Mr. Sydney Mitchell, and submitted to the Directors and the Meteorological Council, and approved of. The plans and specifications are at present in the hands of the contractors, and the building will forthwith be commenced.

Mr. Herbertson exhibited to the meeting an instrument, named the stephanome, designed by Prof. Tait, for use at the Ben Nevis Observatory for measuring the angular size of halos, fog-bows, glories, &c.; also a valuable collection of sixteen photographs taken at the Observatory, of which the following are of special interest: a cirrus cloud in the northern horizon, taken at midnight in June, when the clouds are seen to be brightly illuminated; St Elmo's Fire, at 11 p.m. on the top of the stove-pipe; and views of the Observatory after continued fog and strong wind, but no fall of snow, when everything is covered with long crystals of ice formed out of the fog.

Dr. Buchan read a paper on the distribution of storms round the Scottish coasts, based on the observations made at the lighthouses during the past seven years. The year is divided by the equinoxes into two strongly contrasted portions as regards storms of wind. The minimum occurs in July, and the maximum in January. Over the whole country there is an annual average of 431 hours of storm occurrence. Dividing Scotland into seven districts, the following is the order of occurrence: Firth of Clyde, 327 hours; Tweed to Aberdeen, 373 hours; Aberdeen to Caithness, 379 hours; Fort William to Islay, 408 hours; Cape Wrath to Mull, 435 hours; the Irish Sea, 508 hours; and Orkney and Shetland, 562 hours. From a report prepared by Mr. Omond it appears that, on an average of the past five years, the wind at the Ben Nevis Observatory has risen to or exceeded the rate of 45 miles an hour, 849 hours per annum.

Mr. H. N. Dickson read a paper on "The Weather Lore of Scottish Fishermen." The fishermen had a very complete and generally accurate knowledge of weather phenomena as far as it was purely a matter of observation. In the course of his inquiries he had got a great deal of miscellaneous information from them on prognostications. The prognostications which received the greatest acceptance among the fishermen were those of halo, coronæ, and mock sunrises. It is a belief current from Aberdeen to Wick that, if a sun-dog preceded the sun, it was a sign of good weather, but if it followed the sun it was a sign of bad weather. Another very general belief in prognostications was the existence of spiders' webs amongst the cordage of ships and in sails. That was a very general belief all along the coast. There was another prognostication which was currently believed in by the fishermen, taken from the occurrence of broken rainbows, which are called "packmen," from the fact that the packmen sold pieces of coloured ribbon. As regards the cirrus cloud, in Shetland and Orkney and on certain parts of the west coast, but not on the east coast, there was an almost universal belief in "weather-heads." If these "weather-heads" ran in the direction of north-east to south-west, it was a sign of good weather, but if it ran south-east to north-west, it was an unfavourable sign. If the aurora rises in the north, and does not come past the zenith, it is a sign of good weather; but should the streamer extend beyond, a gale of south wind is expected. The only other point with regard to the aurora was that in Shetland it was supposed to be near a very severe gale if the aurora emitted a sound resembling the shaking of a blanket. Another prognostication, very interesting in its way, and which all fishermen had seen, is the "false dawn." The "false dawn" was when the dawn seemed to break, and then disappeared. There was some question as to whether it was a prognostication. At St. Andrews they were almost unanimous in believing it as a prognostication, and in other places he got individuals who believed it was a sign of good or bad weather. It was interesting in this way that he had never heard of the "false dawn" as a prognostication before, and he made some investigations as to whether it was common in other parts of the world, and he found it was also current among the Negroes of South America. In Shetland there was a class of prognostications which did not appear anywhere else. It was a sign of a coming gale if the surface of the water became stiff and bubbles remained in the wake of a boat, and if the wake of a boat remained visible for an unusually long time. Another prognostication was known as "cheepers." A sound was heard as if a lot of little birds were floating above the boat, and gave a sort of cheeping sound. That was also called "foul air" by another class of fishermen. In the Outer Hebrides the state of the air was almost the only thing the men paid attention to. It was current all down the west coast that a heavy surf was the sign of a gale approaching, but on the east coast one did not hear much of the heavy surf. He had found among the fishermen much less superstition than they usually got credit for, especially at the largest stations. In the smaller stations, where the boats were very small, there was still a good deal of superstition. In the larger stations, where the boats were large and the men went far out to sea, there was a great deal of faith in weather prognostications and a strong desire for instruction.

Mr. H. N. Dickson also added a note on the temperature of the water round the east coast of Scotland. The curve of the daily variation of temperature in the North Sea was as nearly as possible symmetrical above and below the mean. That was the case where there was reason to believe the water was almost stationary. In observations taken in the North Atlantic and on the west coast of Scotland in warm currents of water, as long as the curve was below the mean, it was almost quite straight, and when above the mean the maximum was intensified and sharpened. In observations taken in the cold Polar current off the Island of Jan Mayen the opposite was the case, the curve being deep below the mean and flat above it.

Mr. Philip Sewell gave a few notes of a voyage he made to Siberia last summer. From the temperature observations and other information submitted, he considered trading to the mouths of the Obi and Yenissei to be practicable in ordinary summers.

TWO-NOSED CATENARIES.[1]

THE curve to be given to an ideal linear chain or rib under uniform-vertical-load area between itself and a horizontal straight line is well known to be a Transformed Catenary, having its ordinates in a constant ratio to the corresponding ordinates of a Common Catenary inverted, with the horizontal straight line as directrix (Rankine, "Civil Engineering"; Church, "Mechanics of Materials," &c.).

Thus, the equation of the Common Catenary being—

$$\frac{y}{m} = \cosh\frac{x}{m},$$

using the notation of the hyperbolic functions, then the equation of the Transformed Catenary will be—

$$\frac{y}{m} = r\cosh\frac{x}{m},$$

r being a fraction, greater or less than unity.

The authors of this paper appear to have been the first to notice the elegant mathematical fact that, for values of r numerically less than $\frac{1}{3}\sqrt{3} = 0{\cdot}577$, the Transformed Catenary possesses two points, equidistant from the vertex, at which the curvature is a maximum; so that in the practical design of masonry arches, which are almost always made circular, a better

[1] "Two-Nosed Catenaries and their Application to the Design of Segmental Arches." By T. Alexander, C.E., Professor of Engineering, Trinity College, Dublin, and A. W. Thomson, B.Sc., A.M.I.C.E., Lecturer in the Glasgow and West of Scotland Technical College. (From the Transactions of the Royal Irish Academy, vol. xxix. Part 3, 1888.)

approximation to the true theoretical shape of the arch is attained either by taking the "three-point circle," passing through the vertex A and the two points of equal curvature B_2 and B_2', or by taking the "described circle," touching at B_1 and B_1', or by taking the "inscribed circle," touching at A and again internally at B_3 and B_3' beyond the points of maximum curvature B_1 and B_1', instead of taking, as customary, the circle of curvature at the vertex; and the authors show that if an elliptical arch is described, the proper approximation to its shape is obtained from an orthogonal projection of one of these circles.

The points B_1 and B_1' are called the *noses* of the transformed catenary, and give the name to the paper.

The transformed catenary, which may be taken as the line of thrust, is shown to lie below the "described circle," and above the "three-point circle," so that by taking these or similar circles for the boundaries of the ring of the arch, the proper stability of the arch is secured.

The mathematical treatment of the Catenary given by the authors would gain considerably in elegance by the employment of the hyperbolic functions, now no longer to be disregarded; thus, instead of writing—

$$y = r\frac{m}{2}\left(e^{\frac{x}{m}} + e^{-\frac{x}{m}}\right)$$

$$\tan\theta = \frac{dy}{dx} = \frac{r}{2}\left(e^{\frac{x}{m}} - e^{-\frac{x}{m}}\right),$$

the notation—

$$\frac{y}{m} = r\cosh\frac{x}{m},\ \tan\theta = r\sinh\frac{x}{m},$$

should be employed; and for purposes of numerical calculation of these hyperbolic functions, it is only necessary to notice that if $\tan\theta = \sinh u$, $\sec\theta = \cosh u$, then $u = \text{hyp.}\log(\sec\theta + \tan\theta)$; so that the table of u, already calculated by Euler, used in conjunction with the tables of the ordinary circular functions, will give us the numerical values of the hyperbolic fnnctions; for large values of u, when θ denotes an angle being nearly a right angle, the approximate equation—

$$\log\cosh u = \log\sinh u = u\log e - \log 2$$

being sufficient.

Tables of numerical results are given at the end of the paper, with practical illustrations, for the benefit of architects and engineers, and supplementary tables are added for the immediate designing of brick, sandstone, and granite arches, with circular soffits; so that these investigations should prove decidedly useful to those engaged in the design of similar structures.

A. G. G.

SCIENTIFIC SERIALS.

American Journal of Mathematics, vol. xi. No. 3 (Baltimore, April 1889.)—Were it not for the size of the pages, this number might be taken to be a number of the *Mathematische Annalen*, seeing that out of its ninety-eight pages sixty-eight are written in German. The first memoir, by Oskar Bolza (pp. 195–214), is entitled "On the Construction of Intransitive Groups," and touches on points discussed by Jordan ("Traité des Substitutions"), Capelli ("Sopra l'Isomorfismo dei Gruppi di Sostituzioni"), Netto ("Substitutionentheorie"), Cayley ("Theory of Groups"), and Dyck ("Gruppentheoretische Studien"). This is followed by a short note by Karl Heun (pp. 215–20), on "Die herstellung einer linearen Differentialgleichung aus einem gegebenen Element der Integralfunction." Next we have an important memoir by Koenigsberger (pp. 221–82), "Ueber die Reduction von Integralen transcendenter Functionen." The closing note, by Dr. Franklin (pp. 283–92), "On the Double Periodicity of the Elliptic Functions," *inter alia*, proves a theorem of a bicircular quartic, enunciated by Clifford (see Crofton, L.M.Soc. Proc., vol. ii), and also results due to Siebeck and Greenhill, but all are established here from a different point of view.

Rivista Scientifico-Industriale, February 15.—Researches on the thermo-electric conductivity of magnetized iron (concluded), by Prof. Ercole Fossati. From these experiments the author concludes generally that the electric conductivity of iron either suffers no change under transverse magnetization or undergoes some increase; this increase, however, is much less than the diminished conductivity of iron magnetized in the longitudinal direction. This inference agrees perfectly with the deductions he had already arrived at experimenting with iron conductors of varying dimensions.—Some experiments with a new battery, by Prof. Augusto Righi. Excellent results have been obtained from the battery here described, which consists of 108 condensers disposed in six groups of eighteen each, one above the other, in order to obtain high potentials. The outer armatures communicate with the conductors of a Holtz machine, the central with the ground, and a capacitity is thus obtained equal to that of $\frac{18}{6} = 3$ jars, united in a single battery with armatures communicating directly with the two conductors of the machine. The capacity of the whole system is thus 18,810 electrostatic units, or about $\frac{1}{18}$ microfarad.

Rendiconti del Reale Istituto Lombardo, February 28.—Notice of the late Prof. Giuseppe Meneghini, by Prof. T. Taramelli. In this biographic memoir a summary account is given of the services rendered to geological studies by the eminent naturalist, who was born in Padua in 1811, and died in January of the present year. Meneghini is best known as joint translator, with Savi, of Murchison's work on the Alps, Apennines, and Carpathians, and by his systematic monograph on the fossils of the Upper Lias in Lombardy and Central Italy. His last publication was a paper on the Cambrian trilobites of the Iglesiente district, and his name will always be associated rather with the palæontological than the stratigraphic or petrographic side of geology.—Meteorological observations made at the Royal Brera Observatory, Milan, during the month of February.

THE last issue of the *Memoirs of the St. Petersburg Society of Naturalists* (vol. xix., Botany) contains, besides several very interesting short papers in the Proceedings, a new contribution to the flora of Novgorod, by A. Antonoff, which raises the number of species of flowering plants discovered in the Government of Novgorod to 700; a note on the comparative anatomy of the tissues in the leaves of *Salicineæ* as a basis for classification, by V. Dobrovlanski; and a suggestive description of the flora of the Shenkursk and Kholmogory districts of Archangelsk, by N. Kuznetsoff. Owing to the extension of a subsoil of limestone, which is much warmed by the sun during the summer, the flora of the region contains a number of species belonging to a more congenial climate, while several species characteristic of those latitudes are wanting. On the other hand, owing to its proximity to the Urals, and the existence on the west of such a barrier as Lake Onega, the flora contains a considerable number of Siberian species, while many West European species do not appear. M. Kuznetsoff's remarks on the extension of the *Abies sibirica*, which is slowly advancing towards the West, and the lime-tree, which seems to be, on the contrary, disappearing, are very interesting. Both the *Ulmus campestris* and the *U. effusa* were found as far north as the sixty-third degree of latitude. The presence of the *Lymnanthemum nymphoides*, which is found in Lithuania and South-Eastern Russia, but not in Central Russia, save Kursk, is especially remarkable, and M. Kuznetsoff explains the extension of this aquatic plant over Archangelsk by its having spread along the canal which connects the Volga with the Dvina. No fewer than twelve other South Russian plants, which must have migrated along the same canal, are named by the author. As to the *Mulgedium tataricum*, C. A. Mey., which is characteristic of the salt steppes of Astrakhan, it has been found on a shoal of the Dvina, under 64° N. lat. The paper is accompanied by a map, showing the western limits of extension of the *Abies sibirica*.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 14.—"On the Organization of the Fossil Plants of the Coal-Measures. Part xvi." By W. C. Williamson, LL.D., F.R.S., Professor of Botany in the Owens College, Manchester.

In this memoir the author first calls attention to detached observations, made in his earlier memoirs, relating to the manner in which a medullary axis is developed in the interior of each of the primary vascular bundles of the Carboniferous Lycopodiaceæ. He then traces the changes undergone during the development of a small branch-bundle in *Lepidodendron Harcourtii*.

This is followed by a description of a small new species of Lepidodendron.

In a second new species, named *Lepidodendron intermedium*, an apparently early form of exogenous zone is shown to exist. When describing, in his previous memoir, Part xi. (see Plate 49, Fig. 11), the stem now designated *Lepidodendron fuliginosum*, he showed that, in it, we have an example of the most rudimentary and least perfectly developed form of an exogenous xylem yet seen amongst these Carboniferous Cryptogams. In this example, but a few radiating laminæ of vascular tissues make their appearance in the innermost cortex. In the plant now described, though these few laminæ are represented by a continuous cylindrical zone of tracheids, and though the laminæ are arranged in radial order, they are still embedded in a mass of cellular tissue, much in excess of what constitutes the medullary rays in the higher types of Lepidodendroid organization.

A fourth new species of Lepidodendron is described, under the name *L. Spenceri*, in young states of which no medulla is visible, but, in its place, a number of vertically elongated cells and imperfectly lignified scalariform tracheids are seen, inclosed within an outer series of perfectly lignified tracheids.

A fifth new species, *Lepidodendron parvulum*, is also described; after which the author points out the differences between the mode of development of the cellular medulla of these exogenous Cryptogams, and that of the representative organ among the Dicotyledonous Exogens. Amongst the ordinary Exogens, the growing tip of a stem or branch is a mere aggregation of cells, which mass is soon separated into two zones by the development within it of a ring of vascular bundles. The cells inclosed within this ring become the medulla, and those external to it constitute the cortex. Such a pith subsequently undergoes but a very limited enlargement. In most cases a time arrives when it grows less with age, and ultimately disappears; but in the Lepidodendra, though the tip of each growing stem was, in the first instance, also a cellular mass, an axial solid bundle of vessels was developed in the centre of the new growth almost at its very commencement. But it was only after this growth had made some progress, and the twig had become clothed externally with numerous leaves, that the first traces of a medulla began to appear in the centre of the bundle. It is thus clear that the medulla of these Carboniferous Lycopods is not genetically homologous with that of an ordinary exogenous flowering plant.

The axial vascular medullary bundle expanded into a hollow cylinder under the internal pressure of the growing medulla, which latter not only attained to considerable dimensions, but was a persistent organ. The ring inclosing the medulla supplied all the vascular bundles going to leaves and in part to branches. The author demonstrates that the branches are supplied with such bundles in two ways; when the growing stem divides dichotomously, which it does as amongst living Lycopods, the medullary vascular cylinder splits into two equal halves. But, besides this mode, the author shows that very frequently comparatively small segments are cut completely out of the vascular cylinder, in which a gap is thus left where the bark and the medulla meet. The angular segment thus detached develops into a solid cylindrical bundle, in which, in time, a medulla forms as before. The author is inclined to believe that all these latter forms of bundles only supply short abortive lateral branches, which most probably supported Lepidostrobous fruits.

March 21.—"On the Velocity of Transmission through Sea-water of Disturbances of Large Amplitude caused by Explosions." By Richard Threlfall, M.A., Professor of Physics, and John Frederick Adair, M.A., Demonstrator of Physics, University of Sydney. Communicated by Prof. J. J. Thomson, F.R.S.

This paper contains an account of a large number of experiments made with the object of determining the velocity of waves of compression caused by explosions under water.

The method adopted depended on the use of a certain "gauge" devised for the occasion, whereby the arrival of the disturbance at a given point was transmitted to a chronograph.

The disturbances themselves were caused by submarine explosions of dynamite and gun-cotton in quantities varying from nine ounces to four pounds.

The distance over which the velocity was measured was about 200 yards.

The water was that of the Pacific Ocean in the harbour of Port Jackson, New South Wales.

The chronograph was of the falling pendulum description, and fired the charge automatically.

The absolute time was obtained by comparing the chronograph tuning-fork with an astronomical clock.

The distance was obtained in terms of the standard yard of New South Wales by means of trigonometrical survey. The chief results for the range quoted are as follows:—

Class.	Description of explosive.	Number of experiments (each experiment involving two explosions and time measurements).	Velocity found in metres per second.	Temperature C.	Velocity of sound calculated in metres per second.	Excess of velocity as compared with velocity of sound.
						per cent.
A	9 oz. dry gun-cotton	11	1732 ± 22	17°·8	1523	13·75
B	10 oz. No. 1 dynamite	24	1775 ± 27	14·5	1508	17·7
C	18 oz. dry gun-cotton	5	1942 ± 8	18·3	1525	27·3
D	64 oz. dry gun-cotton	3	2013 ± 35	19·0	1528	31·7

The chief portion of the paper is occupied in the description of the details of the precautions taken to make the measurements as accurate as possible. This involves some chronographic improvements. An explanation of the large observed velocity is attempted.

"On an Effect of Light upon Magnetism." By Shelford Bidwell, M.A., F.R.S.

Several experimenters in the early part of the present century tried to magnetize iron and steel by the action of light,[1] but I do not know of any recent attempts in this direction, and of late years the thing has been generally regarded as impossible. Under ordinary circumstances there can be little doubt that this is the case, but, if a certain condition is fulfilled, we might, I think, expect to find some evidence of the action of radiation upon the magnetism of iron.

The condition is that the susceptibility of the bar AB to be operated upon shall be greater (or less) for a magnetic force in the direction AB than for an equal one in the direction BA. This paper contains a short preliminary account of a series of experiments which have been undertaken with iron bars having this property. Much yet remains to be done, which will require a considerable amount of time, and for which special apparatus must be constructed. In the meantime, the results already obtained appear to possess sufficient interest to justify their publication.

The method of preparing the bars is as follows. A piece of soft iron rod, which may conveniently be 10 or 12 cm. long and from 0·5 to 1 cm. in diameter, is raised to a bright yellow heat and slowly cooled. When cold, it is placed inside a solenoid, through which is passed a battery current of sufficient strength to produce a field of about 350 or 400 C.G.S. units. The iron when removed from the coil is found to be permanently magnetized, and its north pole is marked for the sake of distinction with red sealing-wax varnish. The bar is then supported horizontally and in an east and west direction behind a small reflecting magnetometer, and over it is slipped a coil, which is shunted with a rheostat, the resistance of which can be gradually increased from 0 to 26 ohms. The coil can be connected by a key with a single battery cell, which is so arranged as to produce a demagnetizing force inside the coil. The resistance of the rheostat is slowly raised, so that more and more current passes through the coil, the battery key being alternately lifted and depressed until the magnetometer indicates that the iron bar as a whole is perfectly demagnetized. The strength of the demagnetizing force required varies according to circumstances: it is generally about one-thirtieth or one-twenty-fifth of the original magnetizing force.

After this treatment the iron rod does not differ, so far as ordinary tests will show, from one which has never been submitted to magnetic influences. Nevertheless, as is well known, it possesses certain properties which distinguish it from a piece of really virgin iron. In the first place, the magnetization induced by a force acting in such a direction as to make the

[1] Chrystal, "Encyclopædia Britannica," vol. xv. p. 274, mentions the following names: Morichini, Mrs. Somerville, Christie, Riess, and Moser.

marked end a north pole is greater than that caused by an equal force in an opposite direction. Again, if such a bar be held horizontally east and west (to avoid terrestrial influences), and tapped with a mallet, the marked end at once becomes a north pole. A similar effect follows if the rod be warmed in the flame of a spirit-lamp. Lastly, if it be placed inside a coil and subjected to the action of a series of rather feeble magnetic forces, of equal strength but alternating in direction, the marked end will generally become a north pole, even though the last of the alternate forces may have tended to induce the opposite polarity.

A rod treated as above described appears to be remarkably sensitive to the action of light. When such a rod is placed behind the magnetometer, and illuminated by an oxyhydrogen lamp about 70 cm. distant, there occurs an immediate deflection of from 10 to 200 scale-divisions,[1] the magnitude of the effect varying in different specimens of iron. As the action of the light is continued, the deflection slowly increases. When the light is shut off, the magnetometer instantly goes back over a range equal to that of the first sudden deflection, then continues to move slowly in the backward direction towards zero.

The first quick movement I believe may be due to the direct action of radiation, and the subsequent slow movement to the gradually rising temperature of the bar. With a thick rod (1 cm. in diameter) the slow movement is barely perceptible, extending over only one or two scale-divisions in the course of a minute, the spot of light becoming almost stationary after the first sudden jump. With a thin rod the sudden effect is generally smaller, while the slow after-effect is greater, and may continue until the spot of light passes off the scale.

As a general rule the magnetic effect is such as to render the marked end of the rod a north pole: occasionally, however, it becomes a south pole, but in such cases I have always found that the polarity is comparatively feeble. It may even happen[2] that the marked end becomes north when certain portions of the rod are illuminated, and south when the light acts upon other portions. This is probably due to irregular annealing and a consequent local reversal of the direction of maximum susceptibility: it indicates that the light effect is local, and is confined to the illuminated surface. In one remarkable specimen, which happens not to have been annealed at all, the sudden effect and the slow effect are in opposite directions. When the light is turned upon this rod, there is at first a sudden deflection of twenty magnetometer-scale-divisions to the left, the spot afterwards moving slowly and steadily towards the right. When the light is shut off there occurs at once a jump of twenty divisions further towards the right before the spot begins to move back in the zero direction.

Some attempts have been made to repeat the experiments with light polarized by means of a Nicol's prism; but, either because the largest prism at my disposal was too small (its aperture being barely 2 cm.), or because too much of the radiant energy was absorbed by the spar, I failed to get any magnetic effects whatever with the prism in either position.

[Prof. Silvanus Thompson has quite recently been kind enough to lend me a very large and excellent Nicol's prism. From a few experiments already made with this instrument it appears that the action of the light is quite independent of the plane of polarization.]

There can be no doubt whatever of the reality of the effects here described: they are perfectly distinct, and are at any time reproducible with certainty. The only question is how much of them is primarily caused by the action of light, and how much by mere incidental change of temperature. But, taking all the circumstances into consideration, I think the evidence is in favour of the conclusion that the *instantaneous* magnetic change, which occurs when a prepared iron bar is illuminated, is purely and directly an effect of radiation.

[1] The magnetometer mirror was 1 metre distant from the scale, and each division = 0·64 mm. ($\frac{1}{40}$ of an inch).
[2] This has been observed in two specimens.

Physical Society, March 23.—Prof. Reinold, President, in the chair.—Prof. J. V. Jones read notes on the use of Lissajous's figures to determine a rate of rotation, and of a Morse receiver to measure the periodic time of a reed or tuning-fork. In determining resistance absolutely by the B.A. or by Lorenz's method, it is important to know the speed of rotation at the instant when the deflection of the galvanometer needle is observed. To determine this, an arm carrying a mirror is caused to oscillate by a pin placed eccentrically in the end of the spindle, and a Lissajous's figure is obtained by using another mirror mounted on a vibrating reed driven electrically. Equality of period is obtained when the resulting elliptical figure is permanent, and the frequency of the reed is determined subsequently. In making the experiments it is found convenient to control the speed of the disk by braking it either with the finger or a piece of wood. The reed consists of a rectangular steel rod, 100 centimetres long, and section 1·51 × 0·60 centimetres, and the length of the vibrating segment can be altered by sliding it through a clamp. To permit of this change without altering the electrical contacts, the latter are formed by two independent springs, one of which is always in contact with the rod. For determining the frequency of the reed a second pair of contacts are operated by the vibrator and the currents recorded by a Morse receiver, whilst simultaneously the paper receives marks from a pen controlled by a standard clock. The limit of accuracy of this part of the experiment is found to be $\frac{1}{10}$ per cent., due to changes in the reed's frequency. This is a serious defect, and the author of the paper asked for advice as to the precautions necessary to obtain reeds of constant pitch. Prof. Ayrton, whilst recognizing the extreme importance of determining speed accurately, suggested that the inconstancy of the reed may be due to the impulse being given at the end instead of the middle of its swing, and recalled an experiment, shown before the Society by Prof. Perry and himself, in which the pitch of an electrically driven fork was varied greatly by altering the adjustment of the contact screw. Referring to Dr. Thompson's modification, where two tuning-forks drive each other, it was pointed out that the method requires the synchronism of the two forks to be very exact. Mr. Blaikley inquired whether any doors were opened or closed during the experiments, as the pitch of a reed is affected by the size of its resonance chamber. He also stated that the pitch of reeds driven pneumatically could be maintained constant to 1 part in 10,000, and mentioned that two forks nearly in unison influence each other's period when near together. Referring to the two forks mentioned by Prof. Ayrton, Prof. S. P. Thompson said it was advantageous to mount such forks on sounding boxes, for when placed at a suitable distance apart they then exert considerable mutual control. The sketch put on the board by Prof. Jones led Dr. Thompson to suppose that a perfect method of driving forks had been devised, for two springs were shown touching opposite sides of the bar, and such an arrangement might be used to complete the circuit, only when the reed is in the middle position. He also believed that forks give greater constancy than single reeds, and mentioned some recent improvements, in which one prong of an electrically driven fork is made of phosphor bronze. Mr. T. H. Blakesley, reasoning from ideas suggested by Mr. Stroh's experiments on vibrating membranes, concluded that the periods of forks, placed at $\frac{1}{4}$ wave-length apart, would not influence each other. In reply to a question from Mr. F. J. Smith, Prof. Jones thought there could be no "creeping" of the reed through the clamp. He also stated that he had been led to use a reed from the results obtained in Delaney's system of telegraphy, and the fact that Lord Rayleigh considered electrically driven forks satisfactory.—Dr. Hofford read extracts from the following papers:—On the Clark cell as a source of standard currents, by Prof. R. Threlfall and Mr. A. Pollock. The authors find, contrary to ordinary ideas, that Clark cells can be used to send currents of considerable magnitude without the E.M.F. being appreciably changed, and have constructed cells which give 0·001 amperes steadily for half an hour. This result has been obtained by increasing the size of the cell so that each electrode is about 5 square inches in area, and the internal resistance is about 6 ohms. For the ordinary small test-tube cell, the resistance of which may be about 1500 ohms, the current ought not to exceed 0·00001. On closing the circuit the P.D. (potential difference) drops almost instantaneously to its steady value, and when the circuit is opened rises equally rapidly to very nearly the original E.M.F. The cells completely recover in time. If the current sent be too large, the P.D. falls for a time, and afterwards rises and tends towards a fixed value. In this respect Clark's cells are greatly superior to large Daniell's, sending currents through the same resistance. The paper contains several tables and curves, as well as valuable results respecting the close agreement between the E.M.F.'s of a great number of different cells.—On the application of Clark's cell to the construction of a standard galvanometer, by Prof. R. Threlfall. A large cell, as above mentioned, together with a known platinoid resistance, are used to standardize a reflecting galvanometer, constructed with a single

movable coil, sliding in guides so as to vary the constant in known proportions. Two controlling magnets are carried on opposite sides of a sleeve sliding on a central tube, inclosing the long fibre, and a small hollow copper cylinder in oil acts as damper. The tangent law was found by calculation to be practically correct up to 15°, and the scale is curved so as to read tangents on a scale of equal divisions. To give this result the approximate polar equation to the curve is shown to be $r = f(1 + 0{\cdot}207\theta^2 + 0{\cdot}0269\theta^4)$. In standardizing the instrument a known current is sent through it from the Clark cell, and the controlling magnets adjusted till the spot comes to a fiducial mark on the scale. By varying the position of the coil, currents ranging from 0·001 to 0·4 ampere, can be measured.—On the measurement of high specific resistances, by Prof. Threlfall. The chief points dealt with are, the means for producing thin plates of material of known dimensions, the form and methods of magnetizing the needles, and the arrangement of suspension found necessary when great sensibility is required. For producing the plates, two plane platinized brass slabs are used, and kept at a known distance apart by micrometer screws, whilst the material is melted between them. The screws are then withdrawn, and the resistance determined by comparison with a megohm, using different E.M.F.'s in the two cases so as to obtain about equal deflections. As regards the galvanometer, after many unsatisfactory attempts to use one made according to the Messrs. Gray's pattern, the coils of that instrument were mounted in the ordinary way, and used with an astatic combination of magnetized steel disks. Extreme care was taken to obtain disks exactly similar, and a pair of electro-magnets were made to magnetize them *in situ*, so as to obtain great astaticism. For suspending the magnets, quartz fibres were found greatly superior to silk, the zero of the instrument being very indefinite, even with a silk fibre 30 inches long. Considerable difficulty was experienced in attaching the mirror to the needle on account of the distortion produced by ordinary cements; slow drying white paint was ultimately used and found satisfactory.—On the measurement of the resistance of imperfectly purified sulphur, by Prof. Threlfall and Mr. A. Pollock. The apparatus used is described in the previous paper, the galvanometer of 16,000 ohms being arranged to give one division for 2×10^{-12} amperes. A mean of the results obtained gives about 11×10^{13} ohms per cubic centimetre as the specific resistance. In performing the experiments many precautions were required to prevent air currents and magnetic disturbances, and paraffin keys were found to give much better insulation than ebonite ones. In conclusion, the authors enumerate the chief points to which attention should be paid in designing and using very sensitive galvanometers. They consider it desirable to use quartz fibres at least 6 feet long, to provide very fine adjustment for the controlling magnets, whose supports should be independent of the suspension arrangement, and believe that the whole should be placed in a thick soft iron cylinder. Mr. Boys, speaking of attaching mirrors to wires, said he found a very small speck of shellac varnish to be very satisfactory. As regards quartz fibres, Prof. Threlfall's method of producing them differed materially from his, and the fibres were much thicker. He considered it quite unnecessary to use fibres anything like 6 feet long, and thought 15 inches quite sufficient where the weight to be supported was not large. Prof. Ayrton regarded the results obtained from Clark's cells to be of extreme scientific and commercial importance, for they showed that a very convenient standard of E.M.F. could also be used as a standard for current. Prof. Thompson, after commenting on the convenience of good E.M.F. standards, expressed a hope that Prof. Threlfall would be able to suggest a convenient method for producing a standard ampere.

Royal Meteorological Society, March 20.—Dr. W. Marcet, F.R.S., President, in the chair.—Dr. Marcet delivered an address on "The Sun: its Heat and Light," in which he said that the source or origin of all meteorological phenomena is the sun, which sends or radiates its heat to the earth through the molecular vibration of the invisible matter connecting earth with space. If there were no air and moisture we should feel the sun's heat to a much greater extent. After the sun's rays have reached the earth, a portion of the heat they bring with them is absorbed by the earth and terrestrial objects, another is converted into motion, and a third is reflected into space. After describing the various actinometers and other instruments used for determining the amount of solar radiation, Dr. Marcet showed that the temperature of the solar rays falls rapidly when tested at increasing altitudes in a balloon. He then gave an account of some observations made by Mr. Glaisher in the celebrated balloon ascent which he and Mr. Coxwell made at Wolverhampton on September 5, 1862, when they reached a height of about seven miles above the earth's surface. Regarding the transformation of solar heat into motion, a very interesting illustration is afforded by the radiometer, in which the direct influence of the sun's rays causes a light vane to rotate; while another illustration of the mechanical effects of heat upon fluids is their conversion into what is known as the spheroidal condition. In connection with this Dr. Marcet explained how by wetting his hand he could pass it through molten lead without injury. He also related the case of Henry Hall, one of the keepers of the Eddystone Lighthouse, who, on the occasion of the fire which destroyed the lighthouse on December 4, 1755, accidentally swallowed some molten lead, but did not die till several days afterwards, when a piece of lead was taken out of his stomach. Dr. Marcet then briefly drew attention to the sun's light, stating that the passage of the sun's light through our atmosphere alters it in kind to a great and remarkable extent. Light can be decomposed into its elementary colours. In connection with this branch of the subject Dr. Marcet performed a number of experiments, including, among others, that of passing a ray of light through a glass freed from dust, when the ray disappears within the vessel, but reappears on the other side, showing that the power to form light was there, though not the material for this power to act upon. Dr. Marcet concluded his very interesting address by describing the various forms of sunshine recorders.—The meeting was then adjourned in order to afford the Fellows and their friends an opportunity of inspecting the Exhibition of Instruments opened on the previous evening. A full account of this Exhibition has already been given on p. 523.

Geological Society, March 20.—W. T. Blanford, F.R.S., President, in the chair.—The following communications were read:—Supplementary note to a paper on the rocks of the Atlantic coast of Canada, by Sir J. W. Dawson, F.R.S.—The occurrence of colloid silica in the Lower Chalk of Berkshire and Wiltshire, by Mr. W. Hill and Mr. A. J. Jukes-Browne.—Note on the pelvis of *Ornithopsis*, by Prof. H. G. Seeley, F.R.S. The remains preserved in Mr. Leed's collection at Eyebury, and described by Mr. Hulke, are the largest and most perfect pelvic bones of a Saurischian known in this country. An examination showed that the bones of the right and left sides were united in the median line almost throughout their length by a median suture, and that they formed a saddle-shaped surface internally from front to back. After giving a detailed description of the pubis and ischium, the author stated that he was not aware that this type of pelvis had been previously observed. He noted that the antero-posterior concavity between the anterior symphysis of the pubic bones and the posterior symphysis of the ischia was a well-marked characteristic of Saurischian reptiles, but that it remained to be determined to what extent the median union of the pubic bones was developed in the group. It was impossible to judge of the form of the ilium from the imperfect fragment preserved, but it did not make any recognizable approximation to the bone in those American genera which offered the closest resemblance of form to the pubis and ischium. There were several minor differences of proportion between the bones from the Oxford Clay and those from the Wealden of the Isle of Wight, and the former differed in ways pointed out from *Morosaurus*, *Diplodocus*, and *Brontosaurus*, though there were resemblances.

Zoological Society, March 19.—Prof. Flower, F.R.S., President, in the chair.—The Secretary read a list of the fishes collected at Constantinople and sent to the Society by Dr. E. D. Dickson. The species were sixty-six in number, and had been determined by Mr. G. A. Boulenger.—Mr. Tegetmeier exhibited a female Gold Pheasant in male plumage, and a curiously distorted pair of horns of the Ibex of Cashmir.—The Rev. A. H. Cooke read a paper on the position of the land-shells of Australia and the adjacent islands, commonly referred to the genus *Physa*, which it was shown (mainly from an examination of the *radula*) were really more nearly allied to the genus *Limnæa*. Mr. Cooke proposed to refer these species to the genus *Bulinus*, established by Adanson in 1757.—Mr. G. A. Boulenger read notes on some specimens of Lizards belonging to the Zoological Museum of Halle, which had been sent to him for examination. To these notes were appended revised descriptions of two Lizards from the Argentine Republic, *Gymnodactylus horridus* and *Urostrophus scapulatus*.—A communication was read from Prof. W. N. Parker,

containing an account of the occasional persistence of the left posterior cardinal vein in the Frog. This condition, abnormal in the Frog, was shown to be essentially normal in *Protopterus*.—A communication was read from Mr. J. Douglas Ogilby, containing notes on some fishes new to the Australian fauna.—Mr. Oldfield Thomas read a paper giving the description of a new Bornean Monkey belonging to the genus *Semnopithecus*, obtained by Mr. Charles Hose on the north-west coast of Borneo. The author proposed to name it *Semnopithecus hosei*, after its discoverer.

April 2.—Prof. Flower, F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of March 1889, and called attention to a specimen of the Manatee (*Manatus australis*), purchased March 2, being the second example of this Sirenian obtained alive by the Society; to an Oriental Phalanger (*Phalanger orientalis*, var. *breviceps*), presented by Mr. C. M. Woodford, of Sydney; and to a specimen of Owen's Apteryx (*Apteryx oweni*), presented by Captain C. A. Findlay.—Mr. Smith-Woodward exhibited and made remarks on a maxilla of the early Mesozoic Ganoid *Saurichthys*, from the Rhætic formation of Aust Cliff, near Bristol.—A communication was read from Mr. W. K. Parker, on the osteology of *Steatornis caripensis*. The conclusion arrived at as regards the affinities of this isolated form of birds was that *Steatornis* is a waif of an ancient avifauna, of which all the near allies are extinct, and that *Podargus* of Australia is its nearest surviving relative.—Mr. Oldfield Thomas read some preliminary notes on the characters and synonymy of the different species of Otter. The author gave a revised synonymy of the four species of *Lutra* recognized as belonging to the Palæarctic and Indian Regions, and of the two found in the Æthiopian Region. The American Otters, for want of a larger series of specimens, could not at present be satisfactorily worked out.—Mr. E. T. Newton read a paper, entitled "A Contribution to the History of Eocene Siluroid Fishes." Mr. Newton observed that spines of Siluroid fishes from the Bracklesham Beds were described by Dixon in his "Fossils of Sussex" (1850), and referred to the genus *Silurus*. Mr. A. Smith-Woodward had recently shown good reason for referring these specimens, and certain cephalic plates from the same horizon, to the tropical genus *Arius*. The greater part of a skull, from the Eocene Beds of Barton, in the Museum of the Geological Survey, confirmed the latter generic reference. Its close resemblance to a skull of *Arius gagorides* in the British Museum left no room for questioning their generic relationship, while at the same time the fossil differed from any known species of *Arius*. The fortunate discovery of one of the otoliths within the fossil skull, and its resemblance in important points to that of *A. gagorides*, still further confirmed this determination. Some other otoliths from Barton, and one from Madagascar, were also referred to the genus *Arius*.—Mr. A. Smith-Woodward read a note on *Bucklandium diluvii*, a fossil from the London Clay of Sheppey, noticed by König, and hitherto not satisfactorily determined. It was shown that this fossil was a portion of the skull of a Siluroid Fish allied to the existing genus *Auchenoglanis*.—A communication was read from Mr. H. W. Bates, F.R.S., containing descriptions of new species of the Coleopterous family Carabidæ, collected by Mr. J. H. Leech in Kashmir and Baltistan.—A second communication from Mr. Bates gave descriptions of some new species of the Coleopterous families Cicindelidæ and Carabidæ, taken by Mr. Pratt at Chang Yang, near Ichang, in China.

PARIS.

Academy of Sciences, April 1.—M. Des Cloizeaux, President, in the chair.—On regulating the velocity of a dynamo-electric machine serving as a receiver in the transmission of force by electricity, by M. Marcel Deprez. The case is first considered of the magnetic field and of the electromotive force of each machine, which are shown to be functions of the intensity of the general current only when the inducting electros are disposed in a simple series in the principal circuit. Cases are then discussed in which the receiver has a constant magnetic field, and in which the field of the generator is constant.—On the biorthogonal reduction of a lineo-linear form to its canonical form, by Prof. Sylvester. Taking F as a lineo-linear function of two series of letters—

$$x_1, x_2, \ldots, x_n; \xi_1, \xi_2, \ldots, \xi_n;$$

then F will contain n^2 terms. By subjecting the letters x and ξ respectively to two independent orthogonal substitutions, arbitrary quantities are introduced into the transformed form $n^2 - n$, so that by giving them suitable values we should be able to get rid of this number of terms while retaining the n pairs alone, whose arguments will be, for instance,

$$x_1\xi_1, x_2\xi_2, \ldots x_n\xi_n.$$

Prof. Sylvester here calls the multiples of these arguments the *canonical multiplicators*; he gives the rule for determining them, and at the same time for finding the two simultaneous orthogonal substitutions which lead to the canonical form.—On the progress of the Suez Canal, and its state in the year 1888, by M. de Lesseps. Of the works undertaken to widen the Canal from 22 to 65, 75, and in some places even 80 metres, some have already been completed, and for a distance of about 15 kilometres from Port Said vessels have now ample space for passing each other. The depth will be increased to 8·50, and ultimately to 9 metres, and navigation by night is facilitated by luminous buoys and tow-paths, the light being obtained by means of compressed gas. All the sidings have been widened to 100 metres between Suez and Port Said, thus allowing six large vessels to be shunted at the same time in all of them. Ships using the electric light are now able to traverse the Canal in about twenty hours, the time hitherto required being from thirty-five to forty hours. In 1888 the Canal was traversed by 3440 vessels of 6,640,832 tons (2625 of 5,223,254 tons, British), yielding to the Company 65,102,000 francs in tolls, &c.—On an aperiodic balance with direct readings of the last fractional weights, by M. P. Curie. The instrument here described, and illustrated with a vertical section and a general view, has been constructed for the purpose of increasing the rapidity and accuracy of weighing operations in scientific and industrial laboratories.—On transformation and equilibrium in thermodynamics, by M. P. Duhem. It is pointed out that the "new function" spoken of by M. Gouy in a recent communication (*Comptes rendus*, cviii. p. 507), had already been anticipated by Mr. J. W. Gibbs, in 1873, whose views were later explained by M. Duhem in his work on the thermo-dynamic potential.—On the difference of potential at contact of a metal and of a salt of the same metal, by M. H. Pellat. The author's researches lead to a general law thus expressed: The difference of normal potential between a metal and the solution of a salt of the same metal is nil. It also follows that the difference of potential of two salts of the same acid and of different metal at contact, increased by the difference of potential of these metals placed in contact, is proportional to the quantity of heat liberated by the substitution of one of the metals for the other in the salt of the acid in question.—On telephonography, by M. E. Mercadier. The problem of telephonography—that is, the transmission of sound to distances by telegraph lines, for instance—is here studied in connection with the recent improvements of the phonograph by its inventor, Mr. Edison, and by Mr. S. Tainter (graphophone). M. Mercadier's process, which shows good results even with inferior instruments, appears to be much simpler than that by which Mr. Edison has lately succeeded in communicating along the wires between New York and Philadelphia, using for the purpose his new improved phonograph.—Papers were contributed by M. F. Beaulard, on the double elliptical refraction of quartz; by M. Woukoloff, on the law of the solubility of gases; by M. René Drouin, on succinamic nitrile; by M. Albert Colson, on the artificial and natural alkaloids; by MM. P. Langlois and Ch. Richet, on the strength of the respiratory function as affected by anæsthetics; by M. Abel Dutartre, on the action of the poison of the land salamander (*Salamandra maculosa*); and by M. Haug, on the Lias formations in the sub-Alpine ranges between Digne and Gap.

BERLIN.

Meteorological Society, March 12.—Prof. von Bezold, President, in the chair.—Dr. Wagner spoke on the connection between cosmic and meteorological phenomena. After a short review of the earlier attempts to connect meteorological phenomena with the rotation of the sun or with the phases of the moon, he passed on to a consideration of Prof. von Bezold's recently published work, in which it is shown that the storms in Bavaria and Würtemberg have a distinctly recurrent periodicity of 26 days, corresponding to the period (25·84 days) of the sun's rotation. In opposition to this, Köppen had found from his own calculations, based on more extensive data, that the storms are recurrent with a periodicity of 29 and not 26 days, thus corresponding to the synodical period of the moon. The speaker had himself investigated the periodicity of storms, not only in Bavaria

and Würtemberg, but also in Baden, keeping the observations of lightning separate from those of mere rain-storms : this seemed to be necessary, not only inasmuch as von Bezold did not take any account of lightning, but also because the occurrence of lightning at the time of new moon, or during the last quarter of the moon, might give rise to apparent maxima resulting from purely optical causes. He found that the storms possess a periodicity of 29 days, which include three maxima, the chief of these being in the last half-quarter, the next at new moon, and the least at full moon. No physical explanation, or even any idea of any connection between the storms and the phases of the moon, can at present be given.—Dr. Assmann gave an account of a phenomenon which had been observed on the trees in the Thiergarten as a result of the recent heavy snow-fall. The masses of snow which were piled up high on the branches of the trees had slipped down round their sides and hung down like curtains; they possessed a not inconsiderable consistency and glacier-like structure. The superficial thawing which occurred daily about midday had contributed largely to bring about the modification which the snow had undergone.

Physiological Society, March 15.—Prof. du Bois-Reymond, President, in the chair.—Dr. Benda spoke on multinuclear mammalian spermatozoa, and refuted a number of objections which had been raised to his views on spermatogenesis.—Prof. Gad gave an account of experiments which Dr. Piotrowski had made under his direction, on the difference between the conducting power of nerves and their irritability. It was known that under certain conditions, as, for instance, when a nerve is dying or is surrounded by an atmosphere of carbonic acid gas, its power of conducting impulses shows no change, while at the same time the irritability of that part which is surrounded by the gas has disappeared. After confirming the above by renewed experiments, Dr. Piotrowski found that when he surrounded a small stretch of the sciatic nerve with alcohol vapour he obtained a result exactly the reverse to that observed with carbonic acid gas : the nerve was irritable, but could no longer convey impulses coming from its central end. Irritability and conducting power were tested, not only by muscular contractions, but also by the negative variation at the peripheral end of the nerve. Three distinct causes might be assumed for the difference between irritability and conducting power which had been experimentally proved as above. In the first place, irritability and conducting power might be two totally distinct properties of a nerve. But this view must be dismissed, inasmuch as the only possible way of conceiving the propagation of an impulse is to suppose that the impulse is transmitted from one transverse section of the nerve to another, so that the stimulation of one section acts as a stimulus to the rest. In the second place, it might be supposed that the electrical resistance of the nerve-sheath and medullary-sheath had been increased, so that the stimulus, which was applied from the exterior, could not overcome this increased resistance, while at the same time the conducting power of the axis-cylinder remained unchanged. But this view is untenable in face of the fact that alcohol vapour increases the irritability of a nerve but lessens its conducting power. And it is still further opposed by an experiment on the olfactory nerve of the pike. This nerve possesses scarcely any sheath, or at most an extremely thin one, and still it behaved exactly as does a sciatic nerve when surrounded by carbonic acid gas. Finally, mechanical stimuli were just as efficient as electrical, and in this case the resistance of the sheath does not affect the question. A third possible explanation was that nerves possess not only a longitudinal, but also a transverse irritability, and that the latter is diminished by the CO_2, and increased by the alcohol vapour. This last explanation was also rendered probable by an experiment in which the heightened irritability under exposure to alcohol vapour was still further increased when the current used for stimulation was led through the nerve at right angles to its length by means of wide electrodes instead of by means of the wire electrodes usually employed, in which latter case a small longitudinal stretch of the nerve is included between the points of the electrodes. The speaker therefore regards it as proved that the irritability of a nerve can be diminished by the action of CO_2 without its conducting power being simultaneously affected. Further, that by means of alcohol vapour the irritability may be increased, while the conducting power is at the same time considerably diminished, and that nerves possess a distinct transverse irritability. The speaker also regarded it as extremely probable that the effect of CO_2 and alcohol vapour is different upon the transverse and longitudinal conducting powers of a nerve.

Vienna.

Imperial Academy of Sciences, February 7.—The Secretary read a letter by Dr. Ludolf Griesebach on his travels in Turkistan, describing the geology of the environs of Ghazni.—The following papers were read :—On the retinal image of the insect's eye, by Prof. S. Exner.—On the orbit of Winnecke's comet in the years 1858–86, by E. von Haerdtl.—On the relation of atmospheric pressure to electricity (sealed), by T. Altschul.

February 17.—The following papers were read :—On some derivatives of cyanamide, by A. Smolka and A. Friedrich.—On morphine, by Zd. H. Skraup and Dr. Wiegmann.—On the definitive determination of the plane of polarization, by the late L. Kudelka.—On an anomaly of Mendeleeff's periodic system (sealed), by B. Brauner.—On marine Hydrachnida, with some remarks on Midea (Bruz), by R. von Schaub.—On the passage of electricity through bad conductors, by H. Koller.

A CHEMICAL "WRECKER."

Chemical Lecture Notes. By Peter T. Austen, Ph.D., F.C.S., Professor of General and Applied Chemistry, Rutgers College, and the New Jersey State Scientific School. (New York: John Wiley and Sons, 1888.)

THE work of a teacher of chemistry is becoming more difficult and more perplexing every day. The mass of facts of primary importance both to the science and to technology is now so great that the amount of time that can reasonably be devoted to the business of lecturing during an ordinary College course is wholly inadequate to overtake them. The chemical student of to-day is naturally expected to have a wider range of knowledge, and a far higher standard of acquirement, than his brother of five-and-twenty years ago. The wonder is, that one small head can carry all that he is required to know. One inevitable result of this mass of material is seen in the specialization, both in work and in teaching, which is becoming increasingly apparent. There are chemists to whom the chemistry of the carbon compounds is rapidly becoming a sort of "Dark Continent," and who begin to regard the intricacies of a structural formula with much the same feelings as they would look upon the tangled vegetation of a jungle; and, on the other hand, there are men to whom the sesquipedalian names of organic chemistry are as familiar as household words, but who are oblivious to the most ordinary facts of mineral or physical chemistry. Specialism is of course inevitable. The field is far too big to be ranged over by one man if he means to do his fair share of the work of cultivating it. But the question remains, What to teach, and how to teach it? The truth is, that as chemistry is too frequently taught to-day, the facts obscure the view of the principles. We pile up the deck-load when we ought to jettison half the cargo. What we want is, a stricter subordination of facts to principles. We need to import the methods of the statistician into our procedure. Could anything be more deadly dull, or intellectually more depressing, than the courses of so-called "advanced chemistry" professed in some of our Colleges, in which the only stimulus to mental exertion on the part of the teacher and the taught comes from the spur of the inevitable examination at the end? Not one teacher in ten seems to recognize that his first duty is to be interesting. His first duty, he will tell you, is *to pass* his men; and as our systems of examination are at present ordered, the passing is more a question of the facts than of the principles. And yet no one who has listened to the lectures of such men as Liebig or Hofmann or Victor Meyer can doubt for a moment that the teaching of even the most "advanced" chemistry is capable of affording a high intellectual enjoyment. But then, such men are not the slaves of a Syllabus; they are not held in bondage in Burlington Gardens. They are free to develop their own methods and to stamp their own individuality on their work. The revolt in the *Nineteenth Century*, the other day, might have been more successful if it had been more judiciously fought. The chemist who knows, can afford to smile at Mr. Frederic Harrison's sneer at the value of the knowledge of the number of the isomeric amyl alcohols. Of course, the bare fact of the number is not of cardinal importance, but it is evidently not given to Mr. Harrison to know all that is implied by that fact. In this respect at least, Mr. Harrison is a degenerate disciple. The Master's knowledge of chemistry was not bounded by the limits of a volume in the "International Scientific Series": Comte had dabbled sufficiently deep in the science to have appreciated the real worth even of the fact, could he have lived to acquire it. But, although Mr. Harrison may shoot badly, the circumstance that he should have gone to the barricades at all is significant; and every teacher who has a soul above that of a crammer must share in his growing impatience with the present condition of things.

Now there is no doubt, if we may judge from his book, that Prof. Austen would also gladly range himself behind the barricade if Mr. Knowles would only enlist him; but whether his shooting would be of any use, is, as we proceed to show, very questionable.

Dr. Austen writes, as he tells us, for those students who study, "not merely to pass, but to know." His book is not intended to be a text-book: it is simply a collection of notes and observations on topics which his experience as a teacher has shown "often give the student more or less trouble." No attempt has been made "to include all the rocks and shoals on which the chemical student may get wrecked." In short, the book is an attempt to deal with the philosophy of chemistry rather than with the facts; and as such it seemed to us, in view of the ideas to which we have attempted to give utterance at the beginning of this notice, to merit careful examination.

We have, first, a short introduction, in the style of certain well-known lectures, "adapted to a juvenile auditory," which we associate with the classic shades of Albemarle Street. Dr. Austen's sentiments concerning the functions and duties of a teacher are admirable, but they have just as much originality as his attempts to write in the manner of Dr. Tyndall. The introductory paragraphs are, indeed, characteristic of the rest of the book. We have much loose statement, and many faults of expression and of taste, with, now and again, a shrewd practical remark, which Mr. Harrison's clever young examinee, with the "marvellous *flair*," would certainly "spot," like the vulture he is said to resemble. But there is not a single original observation in the work, nor a single new experiment. The iron-filings and the sulphur do their time-honoured duty in illustrating the nature of chemical change, and Hofmann's well-known examples of the volumetric relations of the simple and compound gases are duly set forth, but with nothing of the *verve* of that great expositor. We admit that it is difficult to find anything better in illustration of these particular points; but then, what is the *raison d'être* of Dr. Austen's book? In dealing with such matters as Molecules and Atoms, Valency and Atomicity, Dr. Austen is clearly out of his depth, or rather he is a sufficiently good swimmer to get over the surface indifferently well—but with neither the skill nor the hardihood to get down to the pearls below. He is befogged by the smoke-rings, and muddled among the vortex-atoms. At times he seeks to be interesting, but with what success the following extracts may serve to show.

In the section on Substitution or Replacement we read: —

"It takes but a slight imagination to see in many reactions analogies with the diplomatic methods of human affairs. Thus the reduction of potassium dichromate to chromic chloride in the presence of alcohol and hydrochloric acid, is particularly suggestive of what in politics is called a 'deal,' or in diplomacy an 'understanding.' ... So again, in the case of bleaching by moist chlorine, the reaction $H_2O + Cl_2 = 2HCl + O$ becomes possible if there is some substance to take up the O. Otherwise there is no reaction, as O refuses to be put out and allow H to dissolve their partnership, and unite with Cl, unless provided for. But if an easily-decomposed organic substance can be procured, the reaction can be consummated. The colouring matter is attacked by the O, and the H and Cl unite, all participants being apparently satisfied."

Now if truth be the test of real humour, it follows that this humour, if humour at all, is false. At best it is but a tawdry imitation of the style of "Die Verlobung in der Bleikammer," which Dr. Austen seems to admire.

In a lecture on the Nature of Affinity we are told that "no word has been more abused than 'affinity.' Used in the sense to denote the tendency or desire to combine, the word is proper, and in its right place." And this is how Dr. Austen illustrates the "proper" use of the term:—

"$HBr + Cl = HCl + Br$.

"Assume that H represents a young lady from the High School, Br a bore, and Cl a College student, and the mechanism of the reaction becomes at once apparent." The parable is probably intended to indicate a "rock" or a "shoal" on which the chemical student may get wrecked if he does not take care. Indeed, the too-susceptible Dr. Austen cannot keep the "fair sex" out of his pages. The following burst of eloquence is culled from a lecture "On the Chemical Factor in Human Progress" (p. 62):—"To what an extent is the fair sex indebted to the humble chemist! We have given them the wonderful aniline colours, which would put Solomon in all his glory to shame, and compel the peacock to hide both his head and his tail in bedazzled desuetude." "Bedazzled desuetude" is not bad, and Dr. Austen has prudently copyrighted it, with the rest of the work. We take breath and read on:—"We can make artificial blushes, heart palpitations, and alabaster complexions, ... we can change raven locks to tresses of glinting gold, or *vice versâ;* we can supply eyes of any shade of colour, as well as any number or kind of teeth. In fact, the chemist is to the girl of the epoch what the lamp was to Aladdin—only more so." The "girl of the epoch" is doubtless properly grateful, and we hope "the man of the time" is equally so, when he knows that his "overcoat may have in it the remains of ball dresses and prison shirts. It may have laid on luxurious beds, or in the gutter, or both."

Dr. Austen proceeds to inquire, "what is the effect of the increasing accuracy in chemical analysis upon our civilization. Chemical analysis is the balance-sheet of trade. It establishes responsibility. It says to the cheat, honoured and respected though he may be in the community, and there are countless thousands of them, 'Thou art the man!' It compels accuracy of statement—rigid truth" After this astonishing example of "accuracy of statement," the reader will be prepared for anything, and we might give him a dozen instances of the same kind of "rigid truth" if it were worth while to spend more time on this silly production. We are only too thankful that this uncertificated chemical pilot has not attempted to include more of the rocks and shoals on which the student may get wrecked.

The whole book is a jumble of feeble sentiments, false statements, and mischievous reasoning, thrown together with no attempt at order or connection. The spirit of prophecy was surely on him when Dr. Austen wrote this brilliant passage in "The Chemical Factor," &c. (p. 56): "Tangle your cord ever so intricately, the chemist will cut it at a single stroke, and will prick the bubble of your silly babble." The metaphors are mixed, but the meaning is clear.

In concluding this notice of a book about which it is impossible to say a single good word, we are sufficiently mindful of the Laureate's saying about the satire which has no pity in it to offer Dr. Austen the grain of comfort which is contained in his own statement (p. 48): "The more the world abuses you, the more reason you have to suppose that you have evolved an idea that has some claim to be original."

THE BEST FORAGE CROPS.

The Best Forage Crops. By Drs. Stebler and Schröter. Translated by A. N. McAlpine, B.Sc. Lond. (London: David Nutt, 1889.)

DR. STEBLER'S well-known work, "Die besten Futterpflanzen," has found a translator into English. A French translation is also before us, so that it is now available to everyone who speaks any one of the three great languages of the civilized world. It may be described as a complete account of the herbage which constitutes permanent pasturage and rotation grasses. The precise technical value of the word *Futterpflanzen* we do not attempt to give, although forage or fodder crop appears to be the correct English equivalent. An English agriculturist would, however, be somewhat surprised to find in a work dealing with the best forage crops no mention made of what are looked upon in this country as the best fodder crops. We are accustomed to rank such crops as vetches, rape, winter rye, trifolium, kale, and cabbage, as among the forage crops; and even swedes, mangel, carrots, and parsnips, although separately classed as root crops, would not be improperly included in the same designation. By fodder crops we usually mean plants cultivated for their leafy herbage for forage, and "grass" and "hay" would come under the designation. Dr. Stebler's work deals exclusively with these last sections of the class fodder crops. We therefore consider the title of this work, as rendered into English, too ambitious, as it is scarcely a "complete account" of the best-known forage plants, but an exhaustive treatise upon some of the less-known ones, most of which are included by English farmers under the term pasture or meadow grasses.

These remarks apply to the title only, and are not to be considered as detracting from the value of the book, which is unquestionably very great. The number of facts

and the variety of authorities quoted are extraordinary, and we welcome this addition to the literature of grasses as most opportune. The work is practical as well as theoretical. It deals with hay-making and ensilage, impurities and adulteration, preparation of the soil, time for sowing, quantities of seed, and judging the quality of seed. It also supplies accurate botanical descriptions, describes varieties, and treats of geographical distribution, growth, and development. So far as the list of plants described is concerned, the work is complete; so far as it purports to treat of the "best forage plants," it is incomplete, and ought either to have been preceded, or be followed, by another. As a botanical account of various members of the Gramineæ and Leguminosæ, the book is exceedingly useful. It must, however, be borne in mind that a large proportion of the grasses described are unimportant economically, and are therefore not to be ranked as among the best fodder crops. Take, for example Yorkshire fog (*Holcus lanatus*), false oat grass (*Arrhenatherum elateus*), yellow oat grass (*Avena flavescens*), sweet vernal grass (*Anthoxanthum oderatum*), reed canary grass (*Phalaris arundinaceæ*), upright brome grass (*Bromus erectus*), awnless brome grass (*Bromus inermis*), kidney vetch (*Anthillis vulneraria*), and goat's rue (*Galega officinalis*). These plants are not of any agricultural importance, and yet they occupy about one-third of the attention of the reader.

Dr. Stebler's book is, in fact, a study of pastoral plants rather than of agricultural crops, and its chief students will be found among seedsmen and those who are abandoning agriculture for the simpler processes of pastoral life.

As a manual of grasses it is exhaustive, so far as the plants selected for description are concerned, but the number described is limited, and the order in which they are introduced is curiously unscientific. Why, for instance, is sainfoin interpolated between *Festuca ovina* and *Festuca heterophylla?* and with what object is Alsike clover pitched in between rough-stalked meadow grass and sheep's fescue, and separated from red and white clovers by a number of true grasses?

Somewhat significantly, the first position in this standard work is allotted to perennial rye-grass, and in the light of the present controversy upon the value of this grass it is interesting to know what so high an authority as Dr. Stebler has to say upon its value and permanence. Speaking of it, he says:—"At times over-estimated, at times depreciated, it is yet one of the most valuable grasses. It is more a 'bottom' than a 'top' grass. For pastures on heavy soils it cannot be surpassed. In marshy districts where the soil is good, it forms a large proportion of the herbage, so much so that in such cases experienced agriculturists use only perennial rye-grass and a little white clover. Its duration depends very much on the nature of the soil and the climate: on dry, light soils it disappears after the second year, whilst in moist climates and on good heavy soils, it will persist for seven years or even longer." The word perennial must always be used in a qualified sense, as no grass, unless it be gifted with immortality, can actually be so described. The individuals perish, but their place is taken by fresh generations, and in is sense rye-grass may be considered as a lasting ingredient in pastures. Its occurrence on village greens, where it cannot seed, meadows, and town moors, as well as in almost all pastures, and especially those which are closely grazed, are evidences that rye-grass can hold its own for an indefinite length of time. Our own climate is especially suited to it, especially when the soil is of a heavy nature and of good quality. Dr. Stebler recommends 5 per cent. as the maximum amount in a mixture required for permanent pasture, but on this point we must differ from him. He, in fact, is not quite consistent, as he tells us that 80 per cent., with white clover to complete the mixture, is used for forming the excellent pastures on the alluvial flats of Northern Germany.

In the discussion now occupying the attention of agriculturists as to the value of perennial rye-grass, both sides may adduce arguments based on Dr. Stebler's opinion, but a perusal of the work will show that the relative permanence of the various grasses described is not pointed out with clearness. The subject is, indeed, beset with many difficulties, and the chief argument in favour of the true perennial character of rye-grass is its continual presence in closely-grazed pastures.

The illustrations of seeds and the botanical descriptions are among the most useful features of this excellent work. The analyses and chemistry of the grasses are also instructive. The book is evidently written from actual personal knowledge, and the positions of Dr. Stebler as Director of the Seed Control Station at Zürich, and of Dr. C. Schröter, the Professor of Botany, also at Zürich, are guarantees that the work is thorough and trustworthy.

Prof. McAlpine, who has undertaken the arduous work of translation, is the Botanist to the Highland and Agricultural Society. The work has been printed abroad, and the typography is somewhat cramped and the quality of the paper and binding scarcely worthy of the text. A glaring advertisement on the outside of the cover might well have appeared somewhere else than on a work of such standard merit as that of Drs. Stebler and Schröter.

JOHN WRIGHTSON.

THE ZOOLOGICAL RESULTS OF THE "CHALLENGER" EXPEDITION.

Report on the Scientific Results of the Voyage of H.M.S. "Challenger" during the Years 1873–76, *under the command of Captain George S. Nares, R.N., F.R.S., and the late Captain Frank T. Thomson, R.N.* Prepared under the superintendence of the late Sir C. Wyville Thomson, Knt., F.R.S., &c., Director of the Civilian Staff on board, and now of John Murray, LL.D., Ph.D., &c., one of the Naturalists of the Expedition. Zoology—Vol. XXIX. Published by Order of Her Majesty's Government. (London: Printed for Her Majesty's Stationery Office, and sold by Eyre and Spottiswoode, 1888.)

VOLUME XXIX. contains a Report, by the Rev. Thomas R. R. Stebbing, on the Amphipoda collected during the cruise of the *Challenger;* it forms one of the longest volumes yet issued, consisting of 1774 pages of letterpress, and is illustrated with an atlas of 212 plates.

Of this immense volume, which will always remain a memorial of the patient research and labour of the author, just 640 pages are devoted to the bibliography. It is, perhaps, the most elaborate ever written as a preface to any form of a Report, and meeting one on the first opening of the pages, seems to challenge a few words of comment.

The importance of a bibliography to a student no one will refuse to acknowledge. A list of the works written on the subject of a Report not only shortens the references in the necessary quotations under the genera and species, but, when not required for this purpose, it helps to furnish material for further workers. Whether the list of works published should be arranged under the dates of publication or under the authors' names, alphabetically placed, has been a matter on which differences of treatment have occurred; in the present case they are arranged chronologically. The bibliography begins with the fourth century before Christ, when Aristotle wrote his "De Animalibus Historiæ," and is carried down to the present time, and is illustrated with woodcuts.

Under the date of publication, the author's name, and particulars of his birth and death, are given; these are followed by the full titles of his work, and then comes an analysis of the contents of the work, so far as these relate to Amphipod Crustacea. All of these analyses are of interest; all, or at least most, of them involved great skill and patience in their compilation; and many of them will be of service to future students. But still, it may very legitimately be doubted whether all this enormous mass of details as to the writings of the Milne Edwardses, Spence Bate, Boeck, &c., was necessary in a Report of the nature of the one before us, or whether it be in keeping with the regulations laid down for the guidance of those intrusted with the preparation of these Reports. In the printed suggestions made by the first Superintendent of these Reports, Sir Wyville Thomson, and, to the best of our belief, also approved of by Dr. Murray, was one "that no printing shall be unnecessarily repeated of matter which has already been printed elsewhere." This, it was added, does not apply to the preliminary Reports, leave to print which in various journals had been given.

If the important bibliographical list of Axel Boeck had been brought up to date, the student would have been benefited, and space would have been enormously saved; but the aim of the author seems rather to have been "to produce a record, after the annalistic method, of the progress of knowledge in this branch of natural history"—a very worthy aim, no doubt, and, as far as we can judge, well accomplished, but one outside a Report on the species taken during the *Challenger* cruise.

One hundred and eighty species are described as new, and thirty-one new genera are defined. The author feels sure that our knowledge of the group is still very imperfect, and calls attention to the fact that a few weeks' stay at Kerguelen yielded forty-eight species from this small region, previously supposed to be barren in Amphipods; and still none of the shore-frequenting species, mentioned by Dr. von Willemoes Suhm as "everywhere under stones," were apparently collected, so that still further additions to the Amphipod fauna may be expected.

As to the bathymetrical distribution of the Amphipods, there must be a good deal of uncertainty, as with other groups of animals taken in the trawls and tow-nets; some were undoubtedly taken at or near the bottom, while others were as certainly taken in the surface and subsurface waters: still, there seems some significance in the fact that, of twenty-eight species of the group of the Gammarina, said to be from depths of from 300 to 2300 fathoms, twenty-five genera are represented, of which ten are new, and twenty-six of the twenty-eight species are also new.

Many of the species described as new are as interesting as novel, but the details relating to them do not admit of being particularly referred to. In the introductory remarks, the author states that he believes the two well-known species of Gammarus, *G. pulex* and *G. locusta*, to be the representatives of an ancestral form of Amphipod.

"Far more than any other Amphipod, *Gammarus pulex* appears to have spread itself over the fresh-water streams of the world, and *Gammarus pulex* is connected by the very closest ties with *Gammarus locusta*. It is clear, from the general distribution of the Gammarina, that the chief nurseries whence they issue are the weeds of the coast. From these, the rivers are accessible, as well as the ocean; yet in the rivers the species of Amphipoda are few, while in the ocean they are multitudinous. This admits of a simple explanation, if we accept *Gammarus locusta* as representing the ancestral form which at one time occupied the world without the competition of other species of Amphipoda.

"In order to enable the family to extend its range over the fresh waters of the world, no further change was needed than such as would enable some of the progeny to pass from salt water to brackish, and from brackish to fresh. But, the section of this genus having once obtained command of the rivers, by the capacity of living vigorously in the river water, would have an immense advantage over all rivals attempting in the future to make a lodgment in the stream while their capacity for life therein was in its initial stages and only feebly developed."

There is an atlas of 212 plates, the figures on which have all been drawn by the author in a most satisfactory way. It is to be regretted that there are no detailed descriptions of these plates; perhaps with the 640 pages of bibliography, and sixty of index, this was too much to expect.

OUR BOOK SHELF.

Magnetism and Electricity. By Edward Aveling, D.Sc. (London: Chapman and Hall, 1889.)

As most intending candidates for London Matriculation will be aware, the new regulations affecting the science subjects have been in force since last June. Chemistry and natural philosophy have been replaced by mechanics, which is compulsory, and chemistry, light and heat, or magnetism and electricity, at the option of the student. To meet these new requirements Dr. Aveling has prepared a series of text-books on the specified subjects, of which the book before us is one. The book is of necessity planned on examination lines; and, although the author hopes "that the matter and method may be of service in the introduction of students generally to the subjects considered," we could hardly recommend it to those who do not require it for examination purposes. However, it completely covers the syllabus, and gives accurate, though often scanty, information. In the chapter on "Terrestrial Magnetism," for example, some very useful data are given

but the explanations of the methods of determining them are very meagre. Thus, on p. 22 the declination compass is described, and the explanation given for its use is simply that "the telescope is set in the plane of the geographical meridian, and, as the needle sets in the plane of the magnetic meridian, the angle between the telescope, which always lies over 0° to 180° on the circle, and the needle, is the declination." Again, referring to the determination of dip, it is simply stated "that when the instrument is arranged with the circle in the plane of the magnetic meridian, the angle of inclination can be read off on the circle" (p. 26). We fear that very few students would succeed in getting even approximate values with only these brief statements to guide them if the instruments were put into their hands.

One chapter is devoted to "Examples on Formulæ," which will, no doubt, be of great service to students, although the title is rather suggestive of cramming. The examples given are not less numerous than useful, no less than 52 out of 144 pages being devoted to them. Several of the papers set at previous Matriculation, Science and Art, and other examinations are given.

The book is well illustrated throughout, and although it is more of an epitome of the chief laws and experiments than a text-book, it will, no doubt, be of great service to those for whom it is primarily intended.

Heat and Light. By Edward Aveling, D.Sc. (London: Chapman and Hall, 1889.)

THIS is another text-book of the series referred to in the preceding notice, and follows on the same lines. It is characterized by the same bare outline, the explanations of the methods of determining the various data generally including no suggestion whatever as to difficulties and corrections. This is especially noticeable in the account of Joule's classical experiment (p. 26), in which no mention whatever is made of the corrections for loss of heat due to radiation or for the velocity of the weight on falling. The diagram, too, is seriously wrong, since it simply shows a set of vanes revolving in a vessel of water; without the pierced partitions necessary to prevent the rotation of the water, the experiment is, of course, useless.

The chapter on the composition of white light and the spectrum is perhaps the least satisfactory in the book. The merest outline of the subject is given, and there are two or three very obvious slips. On p. 165, for instance, the electric light and the lime-light are quoted as examples of monochromatic light. and again on p. 166 it is stated that "glowing gases yield spectra with *dark* lines." The idea that the actinic rays are confined to the violet part of the spectrum is rather old-fashioned, and is scarcely likely to be credited by a student who may have happened to experiment in the direction of orthochromatic photography.

Like its predecessor, the book contains numerous examples and illustrations.

The Encyclopædia Britannica. Ninth Edition. Index. (Edinburgh: Adam and Charles Black, 1889.)

THE publication of this volume (of 500 pages) marks the completion of one of the greatest literary undertakings of the present age. As to the necessity for an index there can be no doubt, since, as the editor explains, the plan of the "Encyclopædia Britannica" was that subjects rather than words should be dealt with, and that large subjects should be discussed in a connected way, under general headings, so that the book might be used not only for occasional reference, but for systematic study. This plan was adhered to, and the result is that "many things which a reader may wish to understand are explained, not under their own names, but in the course of a larger discussion." In such cases reference must be made to the index; and this is so full and so accurate that no one who may have occasion to consult it will ever have the slightest difficulty in at once finding what he wants. The index has been compiled by Mr. William Cairns, and arranged and revised by the Rev. George M'Arthur, with the assistance of Miss Emily Stevenson and Mr. J. T. Bealby. The volume contains also a complete list of contributors, with a key to the initial letters affixed to the longer articles. A glance over this list, which includes almost all the foremost writers of the day, suffices to explain the high character of the work as a whole.

Blackie's Modern Cyclopædia of Universal Information. Edited by Charles Annandale, M.A., LL.D. Vol. I. (London: Blackie and Son, 1889.)

IT is intended that the work of which this is the opening volume shall serve as "a convenient work of reference for readers of all classes—comprehensive in scope, handy in size, moderate in price, and generally adapted to the needs of the day." Of course no one who may want to obtain a thorough knowledge of any subject will think of seeking for it in such a work as this; but the editor does not place before himself too high an object of ambition when he expresses a hope that the new Cyclopædia may prove useful to persons who have little time for acquiring information from books in general, though they take an interest in many topics lying outside their own pursuits. The present volume deals with words beginning with the letter A, and with many of those beginning with B. The articles are short but clear, and, so far as they go, accurate. Especial attention has been given to matters which are of living interest in our own day, and we are glad to see that many scientific articles have been written or revised by specialists. The volume contains some good maps and many interesting pictorial illustrations.

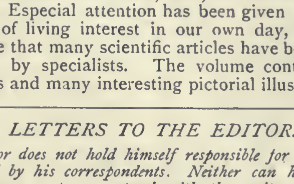
LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Spherical Eggs.

A BIOLOGICAL friend lately asked me for a solution of the problem, How many spherical eggs, 0·03 millimetre in diameter, can be contained in a cubic millimetre?, the whole space occupied by the eggs being large compared with a millimetre. Assuming the eggs as closely packed as possible in a horizontal stratum, their centres will lie at the angular points of a series of equilateral triangles whose sides are equal to a diameter. The number of spheres in this stratum corresponding to a unit of area will thus, on an average, be $\frac{2}{d^2\sqrt{3}}$, d being the diameter.

The next stratum above will have the centres of the spheres placed so that each is at the vertex of a regular tetrahedron,



having alternate equilateral triangles of the lower series as base. Evidently, in a volume of the slice between the two planes of centres, having a unit of area for its base, there will be, on an average, $\frac{2}{d^2\sqrt{3}}$ spheres. But the thickness of the slice is $d\sqrt{\frac{2}{3}}$. Hence, in a unit volume, on an average, there will be $\frac{\sqrt{2}}{d^3}$ spheres, *i.e.* $\sqrt{2}$ times, or about $\frac{7}{5}$, as many as would be contained, assuming their centres at the corners of cubes.

Possibly some of your readers may have considered this problem, and may be able to suggest some other method of packing the spheres. I do not remember to have met with any discussion of it. W. STEADMAN ALDIS.
University College, Auckland, New Zealand, February 4

Temperatures in Lake Huron.

SOME very interesting results observed by Commander Boulton, R.N., on the temperature of the waters of the Georgian Bay, the eastern basin of Lake Huron, have been placed by him in my hands. They appear to establish that the waters of the bottom of the bay are colder than the even deeper waters of the rest of the lake.

Lake Huron in its profound depths forms three great basins—the Georgian Bay, defined along its western outline by the bold cliffs of the Niagara limestones, and the central and southern basins, separated by the subaqueous corniferous escarpment which diagonally crosses the lake in a south-eastern direction from the outline of Lake Michigan. Whilst the southern basin has generally a sandy bottom, and is in many parts comparatively shallow, the central basin has a floor chiefly of clay, and includes the deepest portions of the lake.

The surface temperature necessarily varies with the seasons, and with the continuous or fitful nature of the weather for days preceding the observations. Thus on May 11, 1888, when the ice had but recently broken up, the surface water of the Georgian Bay near Owen Sound registered 34° F., whilst at 15½ fathoms the minimum was 34½° F.

Observations will during the coming summer be continued in this and other lakes, but in the meantime the records given hereunder may be taken as preliminary illustrations of the temperature of the waters of the bay. For comparison, some published observations taken in 1860 by the United States engineers in the central and southern basins are also given.

June 20, 9 *a.m.*

	° F.
Surface	55
45 fathoms (bottom)	52

On August 20, 1886, the temperature of the surface rose from 59¾° F. at 8 a.m., to 62° at 9 a.m., 63¾° at 11.34 a.m., and 65° at 12.38 p.m.

The suggestive explanation of the lower temperature of the Georgian Bay depths is that whilst the more southern and warmer waters of Lake Michigan in their course from the inlet to the outlet do not reach the bay, a considerable portion of the colder waters of Lake Superior find their way into it by the channel north of the Manitoulin Islands. Further, the subaqueous cliffs which block the western side of the bay preclude a free circulation between the deeper waters of the bay and the profound depths of the lake beyond. A. T. DRUMMOND.

Will Fluctuations in the Volume of the Sea account for Horizontal Marine Beds at High Levels?

IN the interesting article "On the Gradual Rise of the Land in Sweden" (NATURE, March 21, pp. 488-92), Nordenskiöld arrives at the conclusion that the small alterations of the relative level of sea and land which observation proves have taken place in Sweden, are due to movements of the land, not to fluctuations of the sea-level. On the other hand, he contends that the extensive horizontal stretches of marine strata found in many places on the earth's surface at heights measured by thousands of feet above the sea-level indicate fluctuations of level in the sea itself. This is certainly reversing the order of things as believed in by most geologists. It is also suggested that the fluctuations of sea-level are due to alternate increase and decrease of the volume of the sea, arising from gaseous and fluid additions from outer space or loss thereto, the alternate gains and losses balancing one another over long periods.

It is not my object in this communication to discuss the physical possibility of such alterations of the volume of the sea having taken place in this way, but to point out that, even if granted, such rising and falling of the sea-level fails to explain the geological phenomena for which it is invoked. Formations horizontal in one place are disturbed in another. They cannot be divided into two hard and fast stratigraphically dissimilar kinds of marine deposits, the *horizontal* and the *folded*, as is attempted by Nordenskiöld. Even the example quoted by him of the Tertiary strata of Spitzbergen shows this, as it is stated, "Near the west coast they are much disturbed, but further inland they form horizontal strata of sand and clay, &c."

The plains of Russia are, as was shown long ago by Murchison, largely occupied by nearly horizontal strata of undisturbed Silurians, while in the Ural Mountains the same formation is thrown up on end. I venture to pronounce this continuity of horizontal with disturbed deposits an almost universal phenomenon, for where plateaus are capped by horizontal strata, as often happens, these cappings are only the remnants left by denudation.

It is a well-known geological fact that as strata recede from a mountain range they become less and less disturbed and more horizontal. Again, there are no horizontal strata of any extent or thickness that are not riven with faults showing that they have been subjected to upthrow or downthrow as the case may be, and these have to be accounted for as well as the level at which the strata occur. Except in the very newest deposits, strata bear very little relation to the levels at which they are now found. Because strata are often horizontal at high levels it is no indication that they have not been upheaved. The Colorado plateaus may be cited as an instance, and such instances may be multiplied to any extent.

There is, however, another difficulty appertaining to the explanation offered by Nordenskiöld. It is this, the general rise of the sea-level over the whole globe to the extent even of 1000 feet would obliterate an enormous area of land. Where, then, would the sediment come from to form the beds appealed to in proof of the rise of the sea-level? Formations are not arranged concentrically at varying levels or, in other words, stratigraphically contoured, as would be the case were they due to this cause. But there is a final and still greater difficulty to be met. Denudation is year by year reducing the height of the land, and if no compensatory elevation excepting over disturbed areas took place, continents instead of growing as they are supposed by some to do, would long ago have been obliterated, and the earth planed down to a uniform level, so that when periods of "high water" recurred all terrestrial life would be destroyed. This contingency no doubt to some minds will be plain demonstration of the truth of Nordenskiöld's theory.

T. MELLARD READE.
Park Corner, Blundellsands, near Liverpool, March 25.

The Meteorological Conditions of the Aruwhimi Forest Tract.

I CANNOT but think that the true explanation of the rank exuberance of the Aruwhimi forests, so graphically described by Mr. Stanley, or rather of the humid climate that fosters them, is different from that suggested either by the great traveller himself or the writer of the notice in last week's NATURE. The source of the winds that feed the rainfall of this region seems to me a question of secondary importance, but since in equatorial regions, as a rule, easterly winds predominate, I am inclined to think, with the writer of the article, that this source is most probably the Indian Ocean.

If, however, this be so, since in the interval between the coast and the Aruwhimi basin they have to pass over some of the highest mountains in the continent, and reach the latter on a descending slope, they would be comparatively dry winds, more or less analogous to the Alpine *föhn*, were there not other conditions present which more than counterbalance the desiccating influence of the eastern mountains. The first and most

important of these conditions I take to be the equatorial position of the Aruwhimi basin; the second that it is situated in the heart of the continent. Both of these, but more particularly the former, determine it as the seat of ascending air-currents, and therefore of their dynamic cooling on a gigantic scale, and it is to this dynamic cooling that the high rainfall of the region is to be ascribed.

Very probably a considerable portion of the precipitated moisture is locally re-evaporated, so that, as suggested long ago by Sir John Herschel in the case of the Brazilian forest rainfall, the same water is precipitated again and again. There are not, I believe, in the lower atmosphere, any steady winds blowing outwards to carry away the evaporation of the damp forest tract, and the main loss of water to be supplied by easterly or other winds is that carried off by the river drainage, probably less than half of the rainfall. The air which has ascended to the higher regions of the atmosphere as a part of the main circulation of the globe, parts with nearly the whole of its vapour in the act of ascending.

We have a case in some respects analogous to that of the Upper Aruwhimi in the very damp and equally forest-clad province of Upper Assam. This too is characterized by a very calm atmosphere, being girt with lofty mountains on the north and east, and also shut off on the south and south-west from the Bay of Bengal by hills of considerable elevation. Such gentle winds as blow in the valley are chiefly from the east or down valley. Yet the rainfall is over 100 inches in the year, and the whole tract is one of marsh and dense forest. It is indeed not situated under the equator, and herein it is less favourably conditioned as a region of excessive rainfall than the basin of the Aruwhimi.

As the result of a long study of the rainfall of India, and perhaps no country affords greater advantages for the purpose, I have become convinced that dynamic cooling, if not the sole cause of rain, is at all events the only cause of any importance, and that all the other causes so frequently appealed to in popular literature on the subject, such as the intermingling of warm and cold air, contact with cold mountain slopes, &c., are either inoperative or relatively insignificant.

Folkestone, April 11. HENRY F. BLANFORD.

"Les Tremblements de Terre."

M. FOUQUÉ'S letter (NATURE, March 28, p. 510) does not meet the main points of my criticism of his book. He thinks that a pendulum swinging in synchronism with the ground's motion is the right thing to use as an absolute seismometer. M. Poincaré's mathematical note, to which he refers as supporting his view, does not support it, but shows why such a pendulum is unsuitable. It is necessary to emphasize this, for it relates to a fundamental matter in the dynamics of earthquake measurement—a matter on which the work done of late years in Japan seems to me to be so intimately based that a misunderstanding about it must be fatal to a proper appreciation of that work. And, in point of fact, I did not find that M. Fouqué gave an appreciative account of what any of the Japanese observers had done. As to his mention of Prof. Ewing's seismograph, in particular, I criticized it not so much because it was meagre as because it was incorrect,—so incorrect as to justify the inference that the author was not acquainted with that instrument.

THE REVIEWER.

Hertz's Equations.

MR. WATSON'S criticism, that Hertz's equations are only true for places at some distance from the oscillator, is no doubt perfectly valid. [There is, by the way, an insignificant and obvious misprint of λ for ρ about the middle of his letter.] But this was entirely recognized by Hertz himself; he treated the oscillator as infinitesimal, knowing that it was nothing of the kind when you got near it, and refrained from drawing his diagram-curves into its neighbourhood, for this very reason.

The fact is surely that, to work out completely the case of electric oscillators in a compound body formed of a couple of spheres joined by a cylinder, would tax the resources of a strong mathematician; and it is impossible that the vibration can be, in any sense, a pure one; all manner of sub-vibrations must be superposed upon the main.

From the physical point of view, some general notion of what was happening at a distance of a wave-length or more from the oscillator was desirable, and this Hertz satisfactorily obtained.

But, to work out what is happening in the immediate neighbourhood of a dumb-bell oscillator must be left, I imagine, to the time when some pure mathematician may devote his attention to this particular shape of conductor, if the case appears to him of sufficient interest. At present I see no special reason why it should be so regarded, but of that Mr. Watson is a better judge. I hope he may see fit to attack the problem.

Grasmere, April 13. OLIVER J. LODGE.

THE COMPRESSIBILITY OF HYDROGEN.

AS stated in the obituary notice that appeared in NATURE (vol. xxxviii. p. 598) at the time of the melancholy accident which caused his death, Wroblewski was engaged in an investigation of the behaviour of hydrogen on compression. The results of this investigation, as far as it had then advanced, have now been made public (*Monatsh. für Chem.*, 1888, p. 1067 *et seq.*). They are of a most important and interesting nature, and form a fitting memorial of the patience and skill of the observer, who most unhappily was not spared to bring this, the last and most complete of a long series of similar investigations, to a close.

Hydrogen has long occupied an exceptional and isolated position among gases. This is due to the fact that, as Regnault first pointed out, hydrogen forms the sole exception to the law that the product of the pressure into the volume, pv, of any gas decreases with increasing pressure,—the exact converse being true in the case of hydrogen, this product showing a regular increase. It is true that, as since shown by Amagat and others, this behaviour of hydrogen becomes general for all gases when the pressure is increased beyond a certain limit, but before reaching this limit the product pv invariably decreases until a minimum is reached for all gases with the exception of hydrogen. For hydrogen neither the decrease nor the minimum have yet been observed, the gas as hitherto examined showing an invariable increase of pv with increasing pressure. The natural inference was, however, that the exception was only apparent, and that the minimum above noted would be found to occur also with hydrogen if the gas were examined at lower pressures than those hitherto investigated—that is to say, at pressures below one atmosphere. But a difficulty in the way of this hypothesis arises from the fact that the critical pressures of all gases are found to be *below* the pressure at which the minimum value for the product of pressure into volume occurs, and therefore on the above reasoning the critical pressure of hydrogen would have to be phenomenally low and considerably beneath one atmosphere.

To gain a further insight into the relation of volume to pressure in the case of hydrogen, Wroblewski decided to investigate this relation through a wide range of temperature. For this purpose he selected as temperatures sufficiently apart, the boiling-point of water, 100° C., the melting-point of ice, 0° C., the boiling-point of liquid ethylene, $-103°.5$ C., and the boiling-point of liquid oxygen, $-183°$ C. The pressures employed varied from one to seventy atmospheres.

The method of experimenting was exceedingly simple. The gas at a known pressure was forced into a bulb of known capacity having a capillary neck, and kept at one of the above four temperatures. A sufficient length of time was allowed for the gas to attain the fixed temperature; it was then transferred to a eudiometer, and its volume measured. It is needless to add that every precaution was taken both in purifying the gas and in applying the necessary corrections.

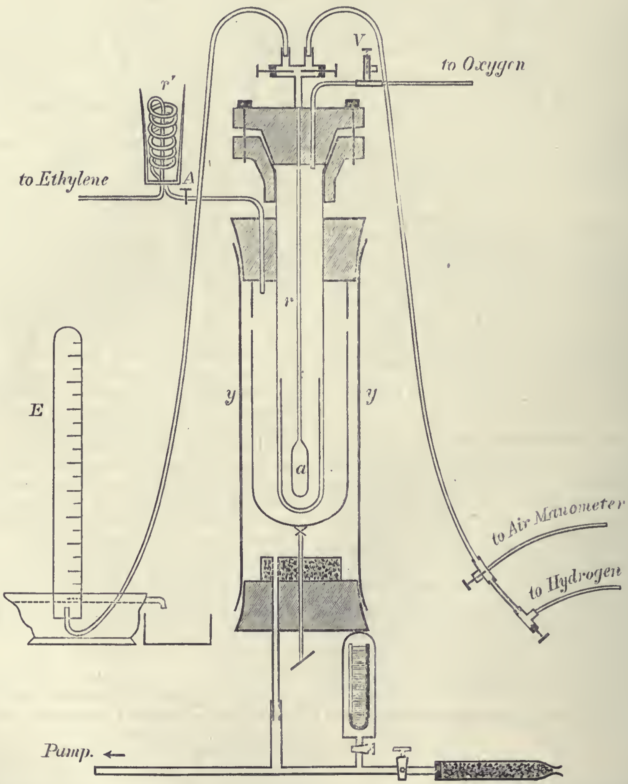
The results with the three first of the above temperatures agree with the behaviour of hydrogen already observed, the product of volume into pressure constantly increasing with the pressure. It was found that for the range of pressures under investigation (one to seventy

atmospheres) the relation between these two quantities may be expressed in all three cases by the general equation $pv = a + bp + cp^2$. The curves which this equation represents have their concave side towards the axis of p. Between the temperatures $-103^\circ\cdot5$ and 100°, then, nothing is observed that contradicts former experience with regard to hydrogen on compression.

But at the temperature of boiling oxygen, -183°, the behaviour of hydrogen is very different. Up to a pressure of about fourteen atmospheres the product pv decreases with rising pressure, and the above equation no longer holds good. At about fourteen atmospheres, however, this decrease has reached a minimum, and from this point the gas behaves in the ordinary way, and the product pv increases with the pressure in accordance with the equation given above. Not the least sign of liquefaction occurs at this temperature at any of the pressures employed.

This is an observation of great importance. It shows that at sufficiently low temperatures hydrogen behaves on compression like all other gases, and has a minimum value of pv occurring, not at some exceptionally low pressure, but at a pressure of fourteen atmospheres.

For the general representation of the four isothermals thus obtained, Wroblewski employs an empirical formula that differs but slightly from one given by Clausius—



In the sketch given of the apparatus used when the gas was cooled by means of liquid oxygen, a is the bulb in which the compression of the hydrogen takes place. The vessel containing this is filled with oxygen under pressure and surrounded by ethylene under evaporation, liquid ethylene being obtained by passing the gas already cooled by a mixture of ice and salt through a worm tube immersed in r' in a mixture of solid carbon dioxide and ether. By suddenly diminishing the pressure on the oxygen by opening the tap V communicating with the outside air, the gas is partially liquefied and the desired temperature is reached. The volume of the gas in a is afterwards measured by allowing it to escape into the eudiometer E.

$$p = \frac{RT}{v - a} - \frac{K}{\epsilon^T v^2},$$

the values of the constants being in the present case R $= \frac{1}{273}$, $a = 0\cdot00111665$, K $= 0\cdot00051017$, and $\epsilon = 1\cdot003892$. This equation serves for the calculation of the critical temperature, pressure, and volume of hydrogen, for which the values are found to be—

$$\theta\epsilon^\theta = \frac{8K}{27Ra}, \ \pi = \frac{RT}{8a}, \text{ and } \phi = 3a,$$

or, substituting the values for the constants, we get—

Critical temperature $\theta = 32\cdot6$ or $-240^\circ\cdot4$ C.,
,, pressure $\pi = 13\cdot3$ atmospheres,
,, volume $\phi = 0\cdot00335$,

from which

Critical density $= 0\cdot027$.

Similar results were obtained by employing other formulæ than the one given above, but this was retained as being in best agreement with the experimental results.

These numbers afford at once an explanation of the ordinary behaviour of hydrogen on compression and the

absence of the minimum of pv at ordinary temperatures, this being due to the fact that hydrogen possesses a very low critical temperature combined with a low critical pressure. For if, instead of taking temperature and pressure in the ordinary units, we take temperature in terms of the critical temperature, and pressure in terms of the critical pressure as units, and then with temperatures as abscissæ and pressures as ordinates construct the curve for the observed minimum points of pv, this curve will be found to be one and the same for all gases. As Wroblewski has shown, it is a continuation of the curve for the vapour pressures at different temperatures of the liquefied gases, pressure and temperature being expressed in terms of the critical. Drawing this curve by the aid of the observations that have already been made with ethylene, carbon dioxide, methane, and other gases, it is found that the pressure for the minimum point rapidly rises with rising temperature, and reaches a maximum of about 3π for a temperature of $1{\cdot}4\theta$. From this point, however, the pressures decrease as the temperature rises, so that, when the temperature is about 3θ, the pressure at which the minimum pv occurs is π, or the critical pressure; and if the temperature be further increased beyond this point the pressure of minimum pv is reduced below the critical, and continues still further to fall as the temperature rises.

Applying this to hydrogen at a temperature of about 3θ, the pressure of minimum pv should be π, the critical pressure, and this as a matter of fact agrees with the result of the above experiments. For 3θ is approximately $-176°$ C., at which point the required pressure should be the critical or 13·3 atmospheres, and observation shows that at $-183°$ C. this pressure is fourteen atmospheres, and as, the temperature being lower, we should expect the pressure to be somewhat higher, this is a very close approximation indeed. At higher temperatures the pressure falls below the critical, and this evidently takes place so rapidly that at $-103°$ C., or for about 5θ, the pressure of minimum pv is so small a fraction of the critical as to be removed outside the range of observation. The critical pressure itself being low of course assists this process.

This, then, explains the behaviour of hydrogen on compression, and why this behaviour differs from that of the other gases. For a gas must be raised to a temperature of over 3θ before it will act like hydrogen, whereas gases have up to the present only been examined at temperatures not far removed from the critical.

The very low critical temperature of hydrogen is remarkable. It confirms the saying of Regnault, that hydrogen at ordinary temperatures is a gas *plus que parfait.* At the same time it shows that no reliance can be put on Pictet's statement that hydrogen was liquefied at about $-140°$ C. under a pressure of 360 atmospheres; and whether the temperature attained in Cailletet's experiments was low enough to actually liquefy the gas must be looked upon as extremely doubtful. At the time of his death Wroblewski was planning experiments for the liquefaction of hydrogen, the only thing necessary to make his work complete.

By cooling hydrogen under a pressure of 110 atmospheres to $-213°{\cdot}8$ C. by the evaporation of liquid nitrogen, and then suddenly diminishing the pressure, as low a temperature as $-223°$ C. was obtained, but the hydrogen still remained in the gaseous state and refused to liquefy.

H. CROMPTON.

THE MANATEE.

THE Zoological Society have added to their living collection in the Regent's Park a young specimen of the Manatee (*Manatus americanus*), which those who wish to have an opportunity of inspecting an extremely curious form of Mammalian life should take an early opportunity of visiting. The Manatees belong to the order *Sirenia* of naturalists, and are sometimes called "herbivorous Cetaceans," although it is, to say the least, very doubtful whether they have any near relationship whatever to the true Whales or order Cetacea. These creatures were abundant in former geological epochs, but since the extermination of the *Rhytina*, or Steller's Sea-cow, at the latter part of the last century, have only two representatives still living on the earth's surface, viz. the Manatee of America and Africa, and the Dugong of the Indian Ocean.

As will be seen by our outline sketch, taken from the Zoological Society's Proceedings, the Manatee is shaped more like a fish than an ordinary mammal. It is formed exclusively for aquatic life, and inhabits the estuaries and rivers of the American and African continents, where it passes its time browsing on the plants beneath the surface and adjacent to the banks. It remains mostly under the water, and only raises its head above the surface to breathe.

The present specimen, which arrived at the Gardens from Liverpool on March 2, is the second example of this singular form that has been received alive by the Society. The first specimen was acquired in August 1875, and lived about a month in the Regent's Park, where it attracted many visitors. When dead, however, it was by no means wasted, as it formed the subject of an excellent article on its anatomy read before the Zoological Society by the late Prof. Garrod, and subsequently published in the tenth volume of the Society's Transactions.[1]

In 1879, a pair of Manatees, received from the Island of Trinidad, lived for several months in the Brighton Aqua-

[1] A complete account of the anatomy of the Manatee was prepared by Dr. Murie in 1872, from the examination of a specimen of this animal imported from Surinam for the Zoological Society, which unfortunately only lived just long enough to reach England. This will be found in the eighth volume of the Zoological Transactions. The attention of residents on the Amazons should be called to the existence in that river of a second species of Manatee (*Manatus inunguis*), discovered by the great Austrian naturalist, Johann Natterer, in 1830, but as yet little known in Europe.

rium, and were the subject of some very interesting notes on their habits, prepared by Miss Agnes Crane, and published in the Zoological Society's Proceedings, from which the following particulars are extracted:—

"Lettuces and endives formed the favourite food of this pair of Manatees; six dozen of these vegetables, weighing 30 pounds, being their average daily allowance. The male would devour at a pinch leaves of the cabbage, turnip, and carrot. Both relished those of the dandelion and the sow-thistle (*Sonchus oleraceus*). Some varieties of a common river-weed were also taken; but this food was abandoned on account of the leeches with which it was found to be infested Sometimes the animals swim gently about, and pursue the leaves floating on the water. At others, the plants are seized in their mouths, drawn down, and eaten under water, the hand-like fore-fins being employed in separating the leaves The food is invariably swallowed below the surface. The masticatory actions of the animal have been so fully and accurately described by Prof. A. H. Garrod, F.R.S. (Trans. Zool. Soc., vol. x. p. 137), that further remark on that subject is unnecessary. The habits of the animals in captivity, while affording occasional evidence of the ease and rapidity with which they move in the water, do not furnish much support to the views of their capability of habitual active progression on land. Yet it must be admitted that, supplied with a sufficiency of nicely-varied food, they have no inducement to leave the water, and that the construction of their straight-walled tank precludes such efforts as a rule. The male, however, has recently been observed to make some slight attempts at terrestrial movement, turning himself round and progressing a few inches when his tank was empty. With jaws and tail-fin pressed closely to the ground, the body of the animal becomes arched, and is moved by a violent lateral effort, aided, and slightly supported, by the fore-paddles, which are stretched out in a line with the mouth. But the effect of these very laboured efforts was not commensurate with their violence; in fact, their relation to active locomotion may be compared to those of a man lying prone with fettered feet and elbows tied to side. Nor does the Manatee seem at all at ease out of water, as he lies apparently oppressed with his own bulk, while he invariably makes off to the deepest corner of his tank directly the water is re-admitted. One point may be regarded as definitely settled. Notwithstanding the predilection they have evinced for land vegetables, they never feed out of water. Food has been repeatedly offered them, but it always remains untouched, although readily devoured when the influx of water set the leaves floating on the surface. Although it is possible that the animals can get out of water and remain so for a short period, as they progress so slowly and do not feed out of water it seems as though they must be acquitted of the garden depredations and prolonged wanderings from their native element with which they have been credited."

The Manatee now in the Zoological Society's Gardens has been placed in one of the large warm-water tanks in the Reptile House, the corresponding tank on the opposite side being occupied by a very fine specimen of the Snapping Turtle (*Macroclemmys temmincki*).

After inspecting the Manatee, those who wish for more information on the subject of the Sirenians should visit the Natural History Museum at South Kensington, and examine the splendid mounted skeleton of the *Rhytina*, or Steller's Sea-cow—a recently extinct gigantic representative of the same order of mammals—in the Palæontological Gallery.

THE ROYAL SOCIETY SELECTED CANDIDATES.

THE following fifteen candidates were selected on Thursday last by the Council of the Royal Society to be recommended for election into the Society. We print with the name of each candidate the statement of his qualifications:—

JOHN AITKEN.

He is an accurate, successful, and highly inventive investigator in Experimental Physics, and for the purpose of his investigations has designed and constructed many ingenious and valuable pieces of apparatus. Has carried out a valuable and instructive research regarding the relations between fog and dust in air, and in connection therewith has devised and used methods for counting the number of dust particles in air. The results of his works were given in numerous papers read by him before the Royal Society of Edinburgh, and published in the Proc. and Trans. Roy. Soc. Edin., during the years from 1875 until the present date. Received from the Roy. Soc. Edin. the Keith Prize for 1883–85, for a paper on "The Formation of Small Clear Spaces in Dusty Air" (1884), being a continuation of the subject of a former paper "On Dust, Fogs, and Clouds" (1880), and for contributions on atmospheric phenomena, the more important of these being a series of papers on "Thermometric Screens" (1884–87).

EDWARD BALLARD, M.D. (Lond.),

Physician in H.M. Civil Service. Eminently distinguished as an Investigator of Causes of Disease, and as a promoter of scientific sanitary administration. Has published, *inter alia*, as follows:—On the Influence of Weather and Season on the Public Health, based on the Statistical Study of 272,000 Cases of Sickness (1857–68); On Vaccination and its Alleged Dangers (1868); A Local Outbreak of Enteric Fever traced to a Local Distribution of Milk (1871); Reports to the Local Government Board, year by year, on particular inquiries, local, or more or less general (1871–88). Of the latter the following may be named:—The Effluvium Nuisances which arise in various manufacturing and other branches of industry, studied as to their Effects on the Public Health, and as to their Preventability (1876–78); various Studies of Outbreaks of Disease referable to Articles of Food (1873, 1880–88); Survey of England as to the Local Preparations against Chlorea (1885-86): Studies of the Causation of Epidemic Infantine Diarrhœa in England and Wales (1882-88).

ALFRED BARNARD BASSET, M.A.,

Barrister-at-Law. Author of a treatise on Hydrodynamics, in two volumes (1888); also papers in the *Quart. Journ. Math.*, *Mess. of Math.*, *Phil. Mag*, Proc. Lond. Math. Soc., Proc. Camb. Phil. Soc., Phil. Trans. Roy. Soc. (1888), and *Amer. Journ. Math.* These papers treat of the Motion of Liquids about Elliptic Cylinders, of Associated Functions and Spherical Harmonics, of Electric Currents of a Sheet rotating in a Field of Magnetic Force, the Potential of a Spherical Bowl, Motion of a Liquid Ellipsoid and Stability of this Motion, Motion of two Spheres in a Liquid, Potentials of Circular Disks, Motion of a Ring in a Liquid, Motion of a Sphere in a Viscous Liquid, and the Steady Motion of an Annular Mass of Rotating Liquid.

HORACE T. BROWN,

F.C.S., F.I.C., F.G.S., Brewer. Distinguished as an investigator of the Carbohydrates, and of the Phenomena of Fermentation; also on account of the services he has rendered in introducing scientific methods into the brewing industry. Author of the following and other papers:—"On the Estimation of Ammonia in Atmospheric Air" (Proc. Roy. Soc., 1870); "On the Influence of Pressure on Fermentation" (Journ. Chem. Soc., Part I., 1872, Part II., 1873); "On the Electrolysis of Sugar Solutions" (*ibid.*, 1872). In conjunction with Mr. Heron:—"Contributions to the History of Starch and its Transformations" (*ibid.*, 1879); "Some Observations on the Hydrolytic Ferments of the Pancreas and Small Intestine" (Proc. Roy. Soc., 1880). In conjunction with Dr. Morris:—"On the Non-crystallizable Products of the Action of Diastase upon Starch" (Journ. Chem. Soc., 1885); "Determination of the Molecular Weights of the Carbohydrates" (*ibid.*, 1888).

LATIMER CLARK,

C.E., F.R.A.S., F.R.G.S., Electrical Engineer. Past President of the Institution of Electrical Engineers. Author of:—"Description of the Britannia and Conway Tubular Bridges;" chapter on "Tides of the Menai Straits," in E. Clark's book on

the Britannia and Conway Bridges; "Elementary Treatise on Electrical Measurement;" and (jointly with R. Sabine) "Electrical Tables and Formulæ." Author of various papers on Electric Measurement, and on various branches of Engineering Science, published in Report of the Brit. Assoc., the Government Report on Submarine Cables, and the Engineering Journals. Introduced a standard voltaic cell of great importance and value for promoting accurate measurement of electric potentials, and presented a paper on this subject to the Royal Society, which was read June 19, 1873. From 1848–51 was Resident Assistant Engineer at the Britannia Tubular Bridge, under the late Robert Stephenson. In 1851 became Engineer to the Electric and International Telegraph Company, and remained in this service for 20 years, part of the time as Engineer-in-Chief. Made important observations on the passage of electricity through long underground lines, of which the results were the subject of Faraday's Bakerian Lecture of 1854, and are given in his "Experimental Researches," with Faraday's own experiments and theory. In 1854 introduced the system of transmitting messages through "pneumatic-despatch tubes" in the Electric Telegraph Company's service. The system is continued in the Postal Telegraph system of the Government, having been found admirably successful and useful.

DAVID DOUGLAS CUNNINGHAM, M.B., C.M. (Edin.).

F.L.S., Surgeon-Major, Beng. Med. Service, Honorary Surgeon to the Viceroy of India. Professor of Physiology, Medical College, Calcutta. Fellow of the University of Calcutta. Distinguished as the author of numerous original scientific memoirs in connection with Animal and Vegetable Physiology and Pathology, among which may be noted:—"On certain Effects of Starvation on Vegetable and Animal Tissues;" "On the Development of certain Microscopic Organisms occurring in the Intestinal Canal;" "On the relation of Cholera to Schizomycete Organisms;" and (in conjunction with the late Dr. T. R. Lewis, F.R.S., elect.) of the following papers relating to the Etiology of Cholera and other Diseases:—"A Report of Microscopical and Physiological Researches into the Nature of the Agent or Agents producing Cholera;" "The Soil in its Relation to Disease;" "Cholera in Relation to certain Physical Phenomena;" "The Fungus Disease of India;" Leprosy in India;" &c., &c. Distinguished as an eminent Indian Physiologist and Pathologist.

LAZARUS FLETCHER, M.A. (Oxon),

F.G.S., F.C.S., Memb. Phys. Soc. President of the Mineralogical Society. Late Scholar of Balliol College, and Fellow of University College, Oxford. Late Millard Lecturer on Physics, Trinity College, and Junior Demonstrator at the Clarendon Laboratory at Oxford. Senior University Mathematical Scholar, 1876. Late Examiner in the Natural Science Schools in Oxford and Cambridge. Keeper of the Mineralogical Department, British Museum. Conducted the re-arrangement of the Minerals in the new Museum at South Kensington, and by his descriptions of these in the "Guides" published by the Trustees of the British Museum, has contributed valuable aid to the students of Crystallography and Mineralogy. Is the Author of many memoirs in the Journal of the Crystallological Society, and recently that of the Mineralogical Society (with which the former Journal has been united) on various minerals, including Copper, Silver, Gold, Bismuth, Sulphur, Nagyagite, Realgar, Zircon, Skutterudite, and Copper Pyrites, and of two important mathematical memoirs on the Dilatation of Crystals on Change of Temperature, in *Phil. Mag.* 1880 and 1885.

WILLIAM BOTTING HEMSLEY,

A.L.S. Assistant for India in the Herbarium of the Royal Gardens, Kew. Entered the Kew Herbarium in 1863; assistance acknowledged by G. Bentham, F.R.S., in preface to Flora Australiensis, 1863; A.L.S., 1875; Lecturer on Botany at St. Mary's Hospital, 1876; author of numerous papers on Systematic Botany, which, together with his larger works, have given him an authoritative position in this branch of science; author of the Botany (5 vols, 4to) of the "Biologia Centrali-Americana," 1879-88; joint author with Brigade-Surgeon Aitchison, F.R.S., of memoirs on the botanical collections of the several Afghan expeditions (Journ. Linn. Soc., xviii. pp. 29-113, 1880; xix. pp. 148-200, 1883; Trans. Linn. Soc, 2nd Ser. III. pp. 1-139, 1888); engaged by sub-committee of the Government Grant Committee to prepare the "Index Floræ Sinensis," an enumeration of all known Chinese plants (in course of publication, Journ. Linn. Soc., xxiii. 1886–88, *et seq.*).

CHARLES THOMAS HUDSON, M.A.,

LL.D. (Cantab.). President of the Royal Microscopical Society (1888). Was 15th Wrangler, 1852. Joint author of Hudson and Gosse's "Rotifera." Discoverer of *Pedalion mirum*, and of numerous new genera and species of Rotifera, described in papers published in the Journ. Roy. Micros. Soc., *Quart. Journ. Micros. Sci.*, and the *Ann. and Mag. Nat. Hist.* from 1869 to the present year. Specially distinguished for his knowledge of the Rotifera, concerning which he is the chief living authority. ["The genus Pedalion discovered and described by Dr. Hudson is one of the most remarkable and important contributions to animal morphology of the past twenty years."—E. R. L.]

THOMAS MCKENNY HUGHES, M.A.

F.G.S., F.S.A. Professorial Fellow of Clare Coll. Camb. Chev. Ord. SS^{rum} Maur. et Lazar. Ital. President Brit. Committee, Internat. Geol. Congress. President Chester Nat. Hist. Soc. Hon. Memb. Soc. Géol. de Belg. Memb. Soc. Géol. de France. Memb. Soc. Geol. d'Italia, &c., &c. Woodwardian Professor of Geology, Cambridge. Author of the following papers:—"On the Junction of the Thanet Sand and the Chalk," &c. (Quart. Journ. Geol. Soc. 1866, vol. xxii. p. 402); "Geology of Parts of Westmoreland and Yorkshire" (Proc. Geol. and Pol. Soc. W. Riding, Yorks. 1867); "Break between Upper and Lower Silurian Rocks, Lake District" (*Geol. Mag.* 1867, p. 346); "The Two Plains of Hertfordshire and their Gravels" (Quart. Journ. Geol. Soc. 1868, vol. xxiv. p. 283); "Part of the Geology of the London Basin" (Mem. Geol. Surv. iv. 1872). Memoirs Geol. Surv.—Explanation of Quarter Sheet 98, N.E., and of ditto S.E. (1872). "Man in the Crag" (*Geol. Mag.* 1872, vol. ix. p. 247); "Exploration of Cave Ha, Yorkshire" (Journ. Anthrop. Inst. 1874); "Felstone Implements in Pontnewydd Cave" (*ibid.*); "Classification of the Sedimentary Rocks" (Brit. Assoc. Rept. 1875); "Geological Measures of Time" (Royal Inst. March, 1876); "Silurian Grits, Corwen, N. Wales" (Quart. Journ. Geol. Soc. 1877, vol. xxxiii. p. 207); "Evidence afforded by Gravels and Brick-earth" (as to remains of Man) (Journ. Anthrop. Inst. 1877); "Pre-Cambrian Rocks of Bangor" (Quart. Journ. Geol. Soc. 1878, vol xxxiv. p. 137); "Relation and Duration of Forms of Life on the Earth to the Breaks in the Sedimentary Rocks" (Proc. Camb. Phil. Soc. 1879); "Silurian Rocks of the Vale of Clwyd" (Quart. Journ. Geol. Soc. vol. xxxv. p. 694); "The Pre-Cambrian Rocks of Caernarvon" (*ibid.*, p. 682; "Transport of Fine Mud, &c., by Conferva" (Camb. Phil. Soc., Feb. 1880); "The Altered Rocks of Anglesea" (*ibid.*); "Evidence of Later Movements of Elevation and Depression in British Isles" (Vict. Inst., March, 1880); "On the Geology of Anglesea" (Quart. Journ. Geol. Soc. 1880, vol. xxxvi. p. 237); "Geology of the Vale of Clwyd" (Chester Soc. Nat. Sci., Nov. 1880); Second Paper on "Geology of Anglesea" (Quart. Journ. Geol. Soc., 1882, vol. xxxviii. p. 16); "On the Brecciated Bed in the Dimetian at St. David's" (*Geol. Mag.* 1883, p. 306); "Report of Excursion of the Geol. Assoc. to Bangor, Snowdon, Holyhead, &c." (Proc. Geol. Assoc. vol. viii., July 1883); "Fossils in Pleistocene Gravels, Barnwell, near Cambridge" (*Geol. Mag.*, 1883, p. 454); "Tracts of Terrestrial and Freshwater Animals" (Quart. Journ. Geol. Soc., 1884); "On so-called '*Spongia paradoxica*' from the Red and White Chalk, Hunstanton" (*ibid.*); Report of the Excursion of the Geol. Assoc. to Cambridge (Proc. Geol. Assoc. 1884); "On some Perched Blocks" (Quart. Journ. Geol. Soc., 1886); "On Caves" (Vict. Inst., 1887); "Drifts of the Vale of Clwyd, in relation to the Caves" (Quart. Journ. Geol. Soc., 1887); "Some Brecciated Rocks in the Archæan of Malvern" (*Geol. Mag.* 1887); "On Bursting Rock Surfaces" (*Geol. Mag.*, Nov. 1887).

EDWARD B. POULTON, M.A. (Oxon.),

F.L.S., F.Z.S., F.G.S. Tutor of Keble College. Lecturer in Natural Science, Jesus College, Oxford. Distinguished as a zoologist, and especially for investigations upon the colours of insects. Author of the following, among other papers:—"The Tongue of *Perameles nasuta*" (*Quart. Journ. Micros. Science*, January 1883); "The Tongue of *Ornithorhynchus paradoxus*" (*Quart. Journ. Micros. Science*, July, 1883); "On the Tongues of Marsupialia" (Proc. Zool. Soc., December, 1883). Papers relating to the subject of colour and marking in insects, in

Trans. Entom. Soc., April 1884, August 1885, and June 1886; Proc. Roy. Soc., No. 237, 1885, and No. 243, 1886; "The Experimental Proof of the Protective Value of Colour and Markings in Insects in reference to their Vertebrate Enemies" (Proc. Zool. Soc., 1887); "An Inquiry into the Cause and Extent of a special colour-relation between certain exposed Lepidopterous Pupæ and the surfaces which immediately surround them" (Phil. Trans., 1887); "Notes in 1886 on Lepidopterous Larvæ" (Trans. Entom. Soc., 1887).

WILLIAM JOHNSON SOLLAS, D.Sc. (Cantab.), Hon. LL.D. (Dubl.)

F.R.S.E., F.G.S. Late Fellow of St. John's College, Cambridge. Professor of Geology in the University of Dublin. Author of numerous papers on Geology, Palæontology, and the Natural History of the Sponges, among which the following may be specially enumerated:—"On the Silurian District of Rhymney, &c." (Quart. Journ. Geol. Soc., vol. xxxv. p. 475); "On a New Species of Plesiosaurus, &c." (*ibid.*, vol. xxxvii. p. 440); "On the Structure and Affinities of the Genus *Siphonia* (*ibid.*, vol. xxxiii. p. 242); "On *Stauronema*, a New Genus of Fossil Hexactinellid Sponges" (*Ann. and Mag. Nat. Hist.*, Ser. 4, vol. xix. p. i.); "On the Flint Nodules of the Trimmingham Chalk" (*ibid.*, Ser. 5, vol. vi. p. 384); "On the Sponge Fauna of Norway" (*ibid.*, Ser. 5, vol. v. p. 130, 5 parts).

CHARLES TODD, M.A. (Camb.), C.M.G.,

F.R.A.S. Postmaster-General, Superintendent of Telegraphs, and Government Astronomer. He has executed important astronomical observations extending over thirty-eight years, including Transit of Venus, Jupiter's Satellites, Determination of Australian Longitudes, &c. He has conducted Meteorological Observations in South Australia extending over thirty years. He has written a Treatise on the Meteorology of South Australia, and other works. He has contributed papers to the Royal Society of South Australia, and was responsible for the erection of the telegraph line across the interior of Australia from Adelaide to Port Darwin, 2000 miles in length, and to Western Australia, 1000 miles in length.

HERBERT TOMLINSON, B.A. (Oxford),

Formerly Junior Student of Christ Church, Oxford. Whitworth Exhibitioner, 1870. Demonstrator of Natural Philosophy in King's College, London. Author of numerous papers on physical subjects published in the Phil. Trans., Proc. Roy. Soc., *Phil. Mag.*, &c., the most important of which relate to the influence of stress and strain on the Physical Properties of Matter. The following may be enumerated:—(1) "Effect of Magnetization on the Electrical Conductivity of Iron" (Proc. Roy. Soc., 1875); (2) "Increase in Resistance to the passage of an Electrical Current produced in certain wires by Stretching" (*ibid.*, 1877); (3) "Alteration of Thermal Conductivity of Iron and Steel caused by Magnetism" (*ibid.*, 1878). The following papers relate to the influence of Stress and Strain, &c.:—(4) "Moduli of Elasticity" (Phil. Trans., 1883); (5) "Electrical Conductivity" (*ibid.*); (6) "Relations between Moduli of Elasticity, Thermal Capacity, and other Physical Constants" (Proc. Roy. Soc., 1885); (7) "Alteration of the Electrical Conductivity of Cobalt, &c., by Longitudinal Traction" (Proc. Roy. Soc., 1885); (8) "Internal Friction of Metals" (Phil. Trans., 1886); (9) "Co-efficient of Viscosity of Air" (*ibid.*); (10) "On Certain Sources of Error in Connection with Experiments on Torsional Vibrations" (*Phil. Mag.*, 1885); (11) "Temporary and Permanent Effects on some of the Physical Properties of Iron produced by raising the Temperature to 100° C." (*ibid.*, 1886); (12) "Effect of Change of Temperature on the Internal Friction and Torsional Elasticity of Metals" (abstr. in Proc. Roy. Soc., 1886); (13) "Effect on Magnetization on the Elasticity and the Internal Friction of Metals" (Phil. Trans., vol. clxxix. p. 1); and other papers.

GERALD F. YEO, M.D. (Dubl.),

F.R.C.S. Professor of Physiology, King's College, London. Researches:—"On the Physiology of the Central Nervous System" (with Prof. Ferrier) (Proc. Roy. Soc., 1881; Phil. Trans., 1884); "On the Physiology of Muscle and Nerve" (with Dr. Cash) (Proc. Royal Soc., 1882 and 1883; Journal of Physiol., 1884); (with Mr. Herroun) (*ibid.*, 1884); "On the Composition of Human Bile" (with Mr. Herroun) (Journ. of Physiol., 1884); "On the Cause of the First Sound of the Heart" (with Dr. Barrett) (*ibid.*, 1884). On Pathological Subjects:—"Diseases of the Kidney" (Dubl. Path. Soc., 1865); "Lymph Glands" (*Med. Jährb. d. Aertze*, in Wien, 1871); "Pleuropneumonia in Cattle" (Report for Roy. Agric. Soc., 1878); and of numerous other papers (Proc. Dubl. Path. Soc.; *Irish Hospital Gazette*; *Dubl. Journ. Med. Sci.*, 1872 to 1875). Author of "Manual of Physiology."

THE SHOOTING-STARS OF APRIL.

In recent years this meteor group has not developed exceptional activity, nor have its annual returns attracted such general observation as the *Perseids* of August; but it is nevertheless a stream that is entitled to a considerable amount of interest, as some of its displays appear to have been noticed in ancient times, and it is identified with the comet described by Thatcher on April 4, 1861. The modern displays of this shower have not justified the anticipations formed of it in regard to its richness because of its periodic character. Of late years the special region of the orbit where the meteorites are clustered in the richest profusion has probably been far removed from the earth. The apparent feebleness of the shower may therefore be regarded as merely temporary. The *Leonids* of November have during the last fifteen years similarly offered a poor spectacle to those who have encouraged the hope that they might attain a prominent degree of activity. But with the parent comet (I. 1866), in distant parts of its path, it is not surprising that comparatively very few of these meteors have been seen. The same remark equally applies to the April meteors. They are chiefly condensed near the comet of 1861, which is now traversing a section of its orbit sufficiently remote from the earth to have withdrawn all the richer parts of the stream from our cognizance. The meteorites lately encountered by the earth upon crossing the node of this comet on about April 20 are simply the outlying and more scattered remnants of the system. It is highly probable, however, that the distribution of the particles is to some extent irregular, and that in certain years the shower attains a more pronounced aspect than the conditions would indicate. Thus in 1884 there was a rather conspicuous display, the number of meteors visible being about 22 per hour for one observer; but this, though representing a striking degree of productiveness relatively to the minor showers, yet falls much below the character of a meteor-stream of first-class importance.

In the present year, the Lyrid showers, if visible, will be most favourably witnessed in the early part of the night, as moonlight will interfere in the morning hours. On April 19 the moon rises at 11h. 53m., on the 20th at 13h., and on the 21st at 13h. 55m. The north-eastern sky should be watched before our satellite emerges from the horizon. The most essential features to be noticed during the progress of the display will be the following:—

(1) The position of the radiant-point on each night of observation. It is very important to note whether this point becomes rapidly displaced to the eastwards, as in 1885 (NATURE, vol. xxxii. p. 5).

(2) The horary number of meteors appearing to one observer, and the proportion radiating from Lyra.

(3) The paths and visible peculiarities of the largest meteors. It is necessary that such data be gathered and utilized in computations of the real paths of those meteors which may be recorded at more than one station.

(4) The duration of the individual meteor-flights. This is an element extremely difficult to estimate with tolerable precision, especially in respect of swift-moving meteors like the Lyrids.

(5) The positions of radiants of the minor streams which furnish meteors at this epoch. Subjoined are the

places of some of the principal of these, which have been ascertained during the last fifteen years:—

No.	R.A.	Decl.	No.	R.A.	Decl.
1	213°	+ 53°	5	286°	+ 24°
2	227	− 1	6	293	+ 43
3	231	+ 17	7	296	± 0
4	272	+ 21	8	302	+ 23

The centre of emanation of the Lyrids is at $270° + 32\frac{1}{2}°$, which lies between the constellations of Hercules and Lyra. It will be very interesting to secure additional observations this year as to the strength and character of this stream, and of the many lesser contemporary displays which manifest themselves at this period. Fortunately the weather is often propitious in the vernal season, and enables researches of this nature to be successfully prosecuted.

W. F. DENNING.

NOTES.

OUR readers may remember that, last autumn, *apropos* of a great patent case of colossal dimensions which was then before the Courts, we published an article urging that, in the interests of speedy justice, no less than for the dignity of science and its professors, it was most desirable that advantage should be taken of the provisions which already exist in our law, and especially in the Judicature Act of 1873 and its amending statutes, and in the rules of the Supreme Court framed under them, for the employment of scientific assessors or experts to aid the judge in strictly scientific cases. It may be remembered that, even in the very case on which we then commented, the tardy employment of Prof. Stokes to aid Mr. Justice Kay was productive of most satisfactory results. We are glad, therefore, to notice that, in a case of some difficulty which came before Lord Coleridge last week, the same eminent man was again called in, and again with the result of relieving the Court from the task of hearing a mass of expert evidence with which no judge and jury are competent to deal satisfactorily. The whole question at issue was whether a certain anemometer, of which one of the parties was patentee and the other the purchaser, came up to the description of its qualities given by the vendor. A considerable array of counsel appeared on both sides, and it was arranged that the services of Prof. Stokes should be called in to the aid of the Court. Seven of the anemometers were submitted to him, and, after an investigation by him, his report was read, and upon it judgment was given. The result is, that the report of the case occupies less than a third of a column of the *Times*. Without the services of Prof. Stokes, or some similar sworn expert, we should have had half-a-dozen or more expert witnesses on one side contradicted by half-a-dozen expert witnesses on the other side; a case which would have lasted three or four days before a wearied judge, conscientiously striving to understand purely technical details, and a perplexed and confused jury; great loss to both parties; an unsatisfactory result; and, as we think, no little scandal to science and scientific men. All this has been prevented by the very simple expedient of calling in an eminent man of science to make a sworn report on the purely technical details, and leaving the rest to the ordinary administration of our Courts. Herein, we are persuaded, lie the proper functions of scientific men in the administration of public justice.

TWO years ago the Dutch Congress of Science and Medicine was founded, and it was decided that it should meet every two years. The first meeting was held at Amsterdam in September 1887. The second meeting will take place at Leyden from the 25th to the 27th of April. The President of the Congress is Prof. Suringar (Leyden), who will deliver the opening address. A large attendance is expected.

THE meetings of the Institution of Naval Architects, last week, were in every way most successful, and the Institution is to be congratulated on the importance and the wide range of the subjects discussed. At the first meeting, on Wednesday, April 11, a remarkable paper on the designs for the new first-class battle-ships was read by Mr. W. H. White, the Director of Naval Construction. The principal object of this paper was to describe the main features of the approved designs for these battle-ships, and to contrast their protection, armament, speed, and coal-endurance with the corresponding features in other battle-ships designed during the last twenty years. Incidentally, Mr. White sought to show that there are good reasons why these ships surpass in size any previously constructed vessels of the Royal Navy. The reading of the paper was followed by a discussion, in which Sir E. J. Reed, Lord Charles Beresford, and others took part. On Thursday, Sir N. Barnaby, late Director of Naval Construction, read a paper on the protection of buoyancy and stability in ships. The next paper was by Captain Penrose Fitzgerald, on the protection of merchant steamers in time of war. The cruiser, *Piemonte*, built for the Italian Government, at Elswick, was described by Mr. P. Watts, of Elswick, her designer; and Mr. J. I. Thorneycroft read a paper on water-tube boilers for war-ships. On Thursday evening, technical papers were read by Mr. John Scott, Mr. J. Macfarlane Gray, and Mr. V. B. Lewes. On Friday, the first paper read was by Mr. Beauchamp Tower, describing an apparatus for providing a steady platform for quick-firing or machine-guns, or a telescope, or a search-light, on board ships at sea. The second paper was by Prof. V. B. Lewes, on the corrosion and fouling of steel and iron ships. Two papers by Mr. R. E. Froude followed, one on the part played in the operations of propulsion by differences in fluid pressure, and the other on Prof. Greenhill's theory of the screw propeller. Technical papers were likewise read by Mr. W. Rundell and Mr. A. F. Hill.

THE general meeting of the Institution of Mechanical Engineers will be held on Wednesday evening, May 1, Thursday evening, May 2, and Friday afternoon, May 3, at 25 Great George Street, Wastminster, by permission of the Council of the Institution of Civil Engineers. The chair will be taken by the President, Mr. Charles Cochrane, at half-past seven p.m., on Wednesday and Thursday evenings, and at half-past two p.m. on Friday afternoon. He will deliver his inaugural address on Wednesday evening. The following papers will be read and discussed as far as time permits:—"Research Committee on Marine-Engine Trials: Report upon Trials of the s.s. *Meteor*," by Prof. Alexander B. W. Kennedy, F.R.S., Chairman; and "Description of an Apparatus for Drying in Vacuum," by Mr. Emil Passburg, of Breslau (Friday afternoon). The anniversary dinner will take place on Friday evening, May 3.

THE public funeral of M. Chevreul, which took place in Paris, on Saturday last, was one of great splendour. This was due in part, no doubt, to the interest excited by M. Chevreul's extraordinary age; but it must also be taken as a striking indication of the respect felt in France for men who achieve eminence in science. In front of the house in which M. Chevreul died, beside the Jardin des Plantes, a tent was fitted up as a chapel; and here the body was placed in state. The procession to the Cathedral of Notre Dame was headed by a detachment of police, who were followed by a platoon of cuirassiers, the 103rd Infantry Regiment, with flags, and a band of ushers, carrying wreaths presented by the Stearine-makers of France, the Stearine-makers of Lyons, the Friendly Society of Natives of Anjou, living in Paris, and a large number of other public and private bodies. Last of all came a wreath sent by the Gobelin Works, surrounded by a woollen fringe dyed by M. Chevreul himself. The pall-bearers were MM. Fallières,

Minister of Public Instruction, Louis Passy, President of the Society of Agriculture, Chaumeton, President of the Students' Association, Des Cloizeaux, of the Academy of Sciences, Quatrefages, of the Academy of Sciences, Chautemps, President of the Municipal Council of Paris, and Roy, Manager of the Society of Arts and Manufactures. Next came the members of M. Chevreul's family, grandchildren and great-grandchildren; and they were followed by the representatives of the President of the Republic, by several of the Ministers, the Presidents of the Senate and the Chamber, and representatives of all the great educational and scientific bodies and administrative departments. At Notre Dame there was an impressive religious service. The interior of the church was hung with black, and over the porch, which was also hung with black, was a scroll bearing the dates "1786–1889." In the centre of the choir was a catafalque resting on silver columns, and surmounted by a canopy with bands of ermine. After the religious ceremony, the body was removed to L'Hay, and interred in the family vault. In compliance with M. Chevreul's last wishes, no speech was made over his grave.

MR. FRANCIS ARTHUR HERON, B.A., of New College, Oxford, has been appointed, after competitive examination, to the Assistantship in the Geological Department of the British Museum, vacant by the resignation of Mr. Arthur Dendy, now Demonstrator of Biology in the University of Melbourne.

WE are glad to see that female art students have now the opportunity of studying the scientific basis of their profession, as Bedford College for Ladies has instituted a well-arranged course of lectures to be given this spring by the Professor of Physics, Mr. Wornack, on light and colour. That an artist should have, at least, an elementary knowledge of the physics of light and colour there can be no doubt.

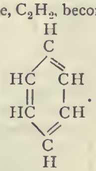
THE Liverpool Marine Biology Committee have arranged to have a four days' dredging expedition at Easter in the Liverpool Salvage Association's steamer *Hyæna*. The ground expected to be covered on this cruise is from the south end of the Isle of Man southwards to Anglesey, and along the north coast of Anglesey to Puffin Island. The submarine electric light will again be used as an attraction in tow-nets let down to the bottom, and this method of capturing some of the more active Crustacea which appear to escape the dredge, will be tried in considerably deeper water than in last year's *Hyæna* Expedition. Mr. Hoyle's new tow-net, which can be opened and closed at any required depth, and Mr. W. S. McMillan's large bottom net, will also be used.

THE extraordinary meeting of the Société Géologique de France, which will be held this year in Paris, beginning on August 18, promises to be one of great interest. During the week devoted to the meeting, the collections in Paris will be visited, and there will be a series of excursions to places of interest within easy reach of that city. In the week following the meeting, excursions will be made to more distant localities—among others to the Auvergne and Brittany, that to the former district under the guidance of M. Michel-Lévy, and that to Brittany conducted by M. C. Barrois. Arrangements will be made with the railway authorities for a reduction of 50 per cent. upon the fares; but in order to secure this advantage the names of persons intending to attend must be sent to the secretaries of the Society before July 1. British geologists, and especially Fellows of the Geological Society of London, are cordially invited to be present.

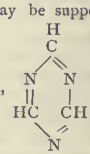
THE April number of *Himmel und Erde*, the magazine of the Gesellschaft Urania (Berlin), contains an interesting article on the Norwegian North Sea Expedition, by Prof. Mohn, Director of the Norwegian Meteorological Institute, Christiania. There is also a good article on the famous hot springs of the Yellowstone Park, by Prof. Zittel, which is illustrated by a map of the neighbourhood and a beautiful photogravure of the terraces. The Copernican theory is discoursed upon by Dr. William Meyer, and two drawings comparing the supposed paths of Mars on the old and new theories very forcibly illustrate its beauty and simplicity. Dr. Ernst Wagner contributes an article on the eruption of Krakatão, particularly referring to the work of the Krakatão Committee of the Royal Society. Besides these, there are also particulars of the various astronomical phenomena for the month.

PROF. KIKUCHI, of Tokio, Japan, has completed his work (in Japanese) entitled "Elements of Plane Geometry" by a second volume, which contains "Book iv., Ratio and Proportion; Book v., Geometrical Applications."

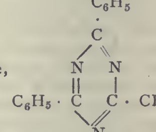
A SERIES of derivatives of the unknown tri-hydrocyanic acid, $H_3C_3N_3$, have been prepared by Prof. Krafft and Dr. von Hansen, of Heidelberg. Tri-cyanogen chloride, $C_3N_3Cl_3$, and the corresponding bromide have long been known, and the radicle C_3N_3 is supposed to exist in the ferro- and ferri-cyanides. Hence it has been expected that some day the hydride itself would be obtained, and although this has not yet been accomplished, a very close approach has been effected by the Heidelberg chemists, who have succeeded in preparing derivatives containing organic radicles instead of hydrogen. Tri-cyanogen hydride may be regarded as bearing the same relation to prussic acid as benzene does to acetylene. On passing a current of acetylene gas through a considerable length of platinum tubing heated to redness, condensation occurs, and benzene, together with other heavier hydrocarbons, is produced; three molecules of acetylene, C_2H_2, become locked up together in the closed chain of C_6H_6,



. In the same way three molecules of prussic acid, HCN, may be supposed to condense into the closed chain of $H_3C_3N_3$,



. The first compound of the new series is methyl-diphenyl tri-cyanide,



.

Two parts of aluminium chloride, Al_2Cl_6, were added to a mixture of five parts of benzonitrile, $C_6H_5 . CN$, and two parts of acetyl chloride, $CH_3 . COCl$, keeping the temperature down to 0° C. The mixture was warmed upon a water-bath, when the aluminium chloride gradually passed into solution, and hydrochloric acid gas was copiously evolved. The yellow liquid thus obtained was poured into iced water, upon which a yellowish waxy substance separated endowed with a powerful tear-producing odour. The dried wax was next dissolved in ether, and after filtration of the solution and subsequent evaporation of the ether, was subjected to fractional distillation under reduced pressure. A quantity of benzonitrile passed over first; then benzoic acid, and finally, at a pressure of 15 millimetres and temperature of 220°–230°, corresponding to 370° under

ordinary pressure, methyl diphenyl tricyanide, which solidified in the receiver to a white mass of crystals. By recrystallization from alcohol, it was obtained in long needles About 50 grammes were obtained for every 100 grammes of acetyl chloride used. The crystals melted at 110°. When hydrochloric acid gas was passed through a solution of the needles in benzene, crystals of the hydrochloride separated. Upon similarly treating a warm alcoholic solution, and adding a warm solution of platinum chloride in alcohol, ruby-red crystals of the platinochloride were obtained on cooling, analyses of which confirmed the above formula, which had been independently established empirically by analyses of the base itself. A vapour-density at 444° also pointed to the corresponding molecular weight. The proof of its constitution was afforded by the products of saponification, which were found to be simply acetic and benzoic acids and ammonia. When propionyl chloride was substituted for acetyl chloride, the corresponding ethyl compound was obtained, and likewise the propyl compound by use of normal butyryl chloride.

SEVERE oscillations of the ground were noticed at Athens during the evening of April 3.

IN the *Meteorologische Zeitschrift* for March, Dr. J. Hann summarizes the results of the meteorological observations made during the French International Polar Expedition to Cape Horn in 1882-83. These observations are specially interesting, both on account of the locality and of their fulness, as they embrace several subjects not generally included in the other expeditions. The principal features of the climate are a relatively mild temperature, a high degree of humidity, precipitation in the form of rain, snow, and hail at all seasons, an almost continually cloudy sky, and sudden and very violent storms, especially in summertime. Storms occur in summer every four or five days, and decrease in number and intensity as winter advances. Nine times out of ten they approach from between north-west and south-south-west. Storms from the north-east are very rare. Thunderstorms rarely occur; distant thunder was only heard five times during summer, and lightning was seen only twice. No observations were made at Orange Bay during the month of September, but Dr. Hann has interpolated values from observations taken at Ushuaia, about a degree further northward.

THE New England Meteorological Society, following the custom of the Royal Meteorological Society of London, held an Exhibition of Instruments at Boston, in January last. Among the more interesting articles exhibited we may mention: (1) A registering actinometer, by Richard Brothers, of Paris, consisting of a bright and black globe, each containing a thermometer which registers on a drum. (2) A Watkin aneroid for mountain use, in which the hand travels three times round the dial in registering from 23 to 31 inches, so that the open scale is not sacrificed to the size of the instrument. (3) A portable anemometer, as designed by Mr. F. Galton for the Meteorological Office. In it, the Robinson cups are geared to a dial, but can be disconnected by inverting a sand-glass after a run of two minutes, and the wind's velocity in miles per hour can be read off at leisure. (4) A form of the Jordan sunshine-recorder, modified by Prof. Pickering. It consists of two half-cylinders, each with its axis parallel to the earth's axis. The sun shines through holes, the latter being shifted slightly each day, so that one sheet of sensitized paper lasts a week. (5) The Chief Signal Office exhibited a very delicate anemometer, with conical cups made of aluminium, used to determine the constants of the anemometers of the service. Among the curiosities of the Exhibition were a bottle and a saucer fused together by lightning, and a piece of window-glass which had been ground translucent by the sand-bearing winds of Cape Cod.

MR. C. CARUS-WILSON writes to us that he has devised a simple and effective dry method by which the denser minerals—zircon, rutile, tourmaline, &c.—may be separated from sand. A piece of cardboard about 2 feet long is bent in the form of a shoot or trough (it must not be allowed to break), and held in this form by elastic bands at either end; this must then be held, or fixed, at an angle sufficiently inclined to allow the sand to travel slowly down the shoot on being gently tapped. A small quantity of the sand to be treated is now placed at the head of the trough, which is then tapped with the finger. When the trough is tapped, the sand travels slowly down, and in doing so, the denser grains lag behind, forming a dark mass in the rear of the stream; this dark mass increases as the sand flows on, and must be collected and placed in a receptacle just the moment before the last tap would cause it to fall off the trough. When a sufficient quantity of this denser sand has been thus collected, it should be placed in the lid of a cardboard box (about 12 inches by 6), and gently shaken to and fro at a slightly inclined angle, the mass being at the same time gently blown upon with the breath. The finer quartz grains will thus be blown away, and hardly any but the denser grains will remain.

AT a recent meeting of the Northern Antiquarian Society of Copenhagen, Dr. L. Zinck drew attention to the remarkable graves from the Stone Age found in the northern part of Seeland. In one grave 52 bodies were found, and upwards of 175 ornaments. From the number of graves in one locality he came to the conclusion that the occupants had dwelt there. Certain bone implements showed that they had reared sheep, whilst their cooking-pots were exactly like those now in use by the peasants, called "Jutland" pots.

DURING last year the archæological researches that have been carried out in Norway were extended as far north as 70° 15′ lat. N. The results appear to show that the islands and the coast were well populated in prehistoric times, but that the cultivation of the soil did not begin until a late date. Numerous burial-places were found, and among the weapons and implements discovered were schist arrow-heads, knives of three kinds, and chisels. No stone axes like those found in the south were discovered. From the fact that no bronze objects have ever been found in the north of Norway, it is concluded that the inhabitants of the Stone Age, on coming in contact with those of the early Iron Age, adopted the use of iron, and never learnt the use of bronze. It is worthy of note that all the implements from the Stone Age are of schist, none being of flint, as in the south.

ATTENTION has lately been called by an American physician (Dr. Lindsey) to the therapeutic value of regions below the sea level, for asthmatical or consumptive patients, who there have continuously higher atmospheric pressure than at the sea-level. Excellent effects have been thus obtained in the valley of Conchilla, near Los Angeles in California, about 273 feet under the sea (barometric pressure only about 7 mm. higher). The most noteworthy place of the kind on the earth's surface is probably the Dead Sea district (–1289 feet), and the following are some others: Lake Asal in East Africa (–639 feet), the oasis of Araj in the desert of Lybia (–270 feet), the Arroyo del Muerto in California (–230 feet), the oasis of Siwah in Lybia (–123 feet), the borders of the Caspian (–86 feet).

IN the Report of the Acting Administrator of British Bechuanaland for the past year, presented to the Houses of Parliament, it is said that the forests of that region are of considerable extent, but they are being rapidly destroyed for the timber and firewood required at Kimberley. Both natives and Europeans are engaged in denuding one of the finest forest tracts in the world, which might be protected by a small yearly expenditure. The system at present employed is that any person on payment of a small fee is allowed to cut down timber without any check being put upon

him. The Surveyor-General suggests that a ranger be employed by the Crown to sell, on behalf of the Crown, fuel and timber that has reached maturity. With regard to the trigonometrical survey of the country, the piles built extend over 4000 square miles, and the final results deduced from observations made over 2600 square miles have been recorded. It was intended to commence a geological survey during the past year, with the object chiefly of examining the districts in which gold, coal, lead, and other minerals have been found, but considerations of economy have led to the abandonment of this scheme for the present.

THE present state and the history of the flora of the province of St. Petersburg were lately the subjects of a very interesting communication by Dr. R. Regel at a meeting of the St. Petersburg Society of Naturalists (*Mémoires*, vol. xix.). The influence of man in the introduction of new species is most marked in so populous a province. Several species have been unconsciously imported by man from South-Eastern Europe, the Mediterranean coast, and Asia; and many garden plants, such as *Bellis perennis*, *Impatiens parviflora*, and *Aster præcox*, have become regular members of the wild-growing flora. Some of them have spread with astonishing rapidity. The recently imported *Erigeron canadense* has now penetrated as far as the Altai Mountains; the *Matricaria discoidea*, imported from America thirty years ago, is found all over the region; while the *Sambucus racemosa* grows even in the wildest marshes of Schlusselburg. Plants imported by man are dispersed by birds, water, and wind over a wide space, and a great many species, such as *Elodea canadensis*, *Corydalis bracteata*, *Scilla cernua*, &c., have spread during the last ten years. Dr. Regel insists upon the necessity of such species being carefully mentioned, because a few years after their introduction the botanist may not be able to explain how they appeared in the region, and may suppose that they have been merely overlooked.

ANOTHER interesting feature of the St. Petersburg flora which has been pointed out by Dr. Regel, is the frequency of white colour in the case of such flowers as are coloured pink or blue in Central Europe. The prevalence of white in the north is thus confirmed. The *Polygala vulgaris*, *Lychnis viscaria*, *L. Flos-cuculi*, *Centaurea phrygia*, *Jasione montana*, *Campanula glomerata*, *C. Trachelium*, *C. latifolia*, *C. rotundifolia*, *C. patula*, *Calluna vulgaris*, *Arctostaphylos Uva-ursi*, *Thymus serpyllum*, *Brunella vulgaris*, *Gymnadenia conopsea*, *Orchis maculata*, *O. Traunsteineri*, and others were found with white flowers. In accordance with Dr. Masters's views, Dr. Regel sees in this fact a pathological phenomenon due to unfavourable climatic conditions. The colouring pigment does not disappear, but more intercellular spaces appear, and being filled with air, they permit the full reflection of light. In fact, several white flowers of *Campanula patula* became blue when dried, the pressure exerted upon them evidently having compressed and reduced the intercellular spaces.

THE following are the lecture arrangements at the Royal Institution after Easter, so far as they relate to science:—Prof. E. Ray Lankester, four lectures on some recent biological discoveries; Mr. Eadweard Muybridge, of Pennsylvania, two lectures on the science of animal locomotion in its relation to design in art (illustrated by the zoopraxiscope); Prof. Dewar, five experimental lectures on chemical affinity; Prof. W. Knight, of St. Andrews, three lectures on (1) the classification of the sciences, historical and critical; (2) idealism and experience, in philosophy and literature; (3) idealism and experience, in art and life (the Tyndall lectures). The Friday evening meetings will be resumed on May 3, when a discourse will be given by Sir Henry Roscoe, M.P., on aluminium; succeeding discourses will probably be given by Prof. Dewar, Prof. Silvanus P. Thompson, the Rev. S. J. Perry, Prof. D. Mendeleef, Mr. A. Geikie, Mr. C. V. Boys, and other gentlemen.

THE Registrar of the University of London desires us to call attention to the fact that the June examination for matriculation is, in the present and future years, to be held a week earlier than heretofore.

IN the list of English and American Corresponding Members of the French Academy of Sciences, printed in NATURE, January 24 (p. 312), Prof. A. Agassiz was inadvertently omitted from the list of names under "Anatomy and Zoology."

THE additions to the Zoological Society's Gardens during the past week include a Green Monkey (*Cercopithecus callitrichus*) from Barbadoes, presented by the West Indian Natural History Exploration Committee; a Kinkajou (*Cercoleptes caudivolvulus*) from Demerara, presented by Mrs. Marian FitzSimons; a Grey Squirrel (*Sciurus griseus*) from North America, presented by Miss Vokes; a Shag (*Phalacrocorax gracilis*), British, presented by Mr. Henry Reynold's; a Black Tortoise (*Testudo carbonaria*) from Trinidad, a —— Cayman (*Jacare*, sp. inc.) from Demerara, presented by Colonel Fielden, F.Z.S.

OUR ASTRONOMICAL COLUMN.

MELBOURNE OBSERVATORY.—The twenty-third Annual Report of the Board of Visitors to this Observatory, together with the Annual Report of the Government Astronomer, have just reached us. The visitation took place on October 4, 1888, and the Astronomer's Report is for the year ending June 30, 1888. The principal points of interest in the Reports are those referring to the great reflector and to the new photographic telescope. The mirrors of the former instrument had become so dull that their repolishing was rendered imperative, and the work was to be done at the Observatory itself, the risk and cost of sending them to England being prohibitory. With a view to this important operation, a number of small mirrors have been repolished, in order that the necessary experience might be acquired before the great mirrors were taken in hand. The new telescope for the photographic survey was well advanced, and Mr. Ellery expected that Melbourne would be ready to enter on her share of the work as soon, if not sooner, than the other associated Observatories. The Government of Victoria, besides supplying the necessary funds to enable the Observatory to take part in the photographic survey, had granted £2300 for the erection of a dwelling-house for the Director within the Observatory grounds. The new transit-circle and the two equatorials had been in constant use, and were in good order; 2962 observations of right ascension, and 1434 of Polar distance, having been obtained with the former during the year. The photoheliograph had been subjected to a slight alteration, the front lens of the secondary magnifier having been previously too close to the primary focus, so that much trouble was caused from the magnified images of any particles of dust which might lodge upon it. The sun-pictures had, in consequence of the time employed over this alteration, not been so numerous as usual, a record of the sun's surface being only obtained on 129 days. With the great telescope, eighty-one nebulæ were observed or searched for.

Mr. Ellery reports that the meteorological department, especially with regard to the Inter-Colonial Weather Service, increases in importance and efficiency every year, and that he proposed to call a conference of the several Meteorological Directors of the Australian Colonies, with the view of assimilating their methods of reporting, and of still further improving meteorological work in Australia.

COMET 1889 *b* (BARNARD, MARCH 31).—Herr von Hepperger has computed the following elements and ephemeris for this object from observations of dates March 31, April 4 and 8:—

$$T = 1889 \text{ July } 27{\cdot}4812 \text{ Berlin M.T.}$$

$$\left.\begin{aligned} \omega &= 257^\circ\ 27'\ 28'' \\ \Omega &= 308\ \ 29\ \ 41 \\ \iota &= 162\ \ 46\ \ 20 \end{aligned}\right\} \text{Mean Eq. } 1889{\cdot}0.$$

$$\log q = 0{\cdot}29519$$

Error of middle place (O – C.).

$\Delta\lambda \cos\beta = -11''$. $\Delta\beta = 0''$.

Ephemeris for Berlin Midnight.

1889.	R.A. h. m. s.	Decl. ° ′	Brightness.
April 18	5 10 18	15 30·6 N.	0·92

26	5 7 53	15 15·2	0·91
30	5 7 4	15 7·5 N.	0·90

The brightness at discovery is taken as unity.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 *APRIL* 21–27.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on April 21

Sun rises, 4h. 53m.; souths, 11h. 58m. 35·0s.; sets. 19h. 5m.: right asc. on meridian, 1h. 57·6m.; decl. 12° 1′ N. Sidereal Time at Sunset, 9h. 5m.

Moon (at Last Quarter on April 22, 14h.) rises, 1h. 0m.; souths. 5h. 0m.; sets, 9h. 0m.: right asc. on meridian, 18h. 58·1m.; decl. 22° 38′ S.

Planet.	Rises. h. m.	Souths. h. m.	Sets. h. m.	Right asc. and declination on meridian. h. m.	° ′

GEOGRAPHICAL NOTES.

To the current number of the Proceedings of the Royal Geographical Society, Mr. George Taylor contributes a valuable paper on Formosa and its aborigines. Mr. Taylor, while resident on the south coast of Formosa, had good opportunities of studying the natives, and the information which he has otherwise collected renders his paper the best summary of our knowledge of Formosa which we have at present. Mr. Taylor thus summarizes the geography of Formosa. On the western side, the land is composed of low level plains, extending from the sea-shore to some distance into the interior, the country appearing flat up to the more pronounced elevations which precede the steeper mountain slopes. The splendid watershed from the central mountains shows in the numerous rivulets which spread like a network over the plains, and renders them especially suitable for the cultivation of rice and sugar-cane. The western sea-board partakes of the nature of the land, the coast being lined with mud and sand-sanks intersected by channels, this formation extending some distance out to sea. Within, Formosa is comparatively hilly, but large areas are covered with tea plantations, which form the principal industry. The east coast is rugged, precipitous, and exposed to the full fury of the north-east monsoon, which blows hard throughout eight months of the year; therefore, except in the Pilam plain and a few small valleys, little attempt is made at cultivation. To the south, the land terminates in huge masses of coral limestone, and coral branches may be traced in peaks elevated 2000 feet above sea-level. The sea-shore is lined with a semi-vitrified conglomeration of clay, sand, and coral, which presents a serrated surface so sharp and ragged as to be impassable to all beasts; and the natives, when fishing, are obliged to protect their feet with sandals composed of many folds of boar-skin. Mr. Taylor's account of the aborigines is specially valuable. While the pure aborigines from the interior are of an essentially Malayan type, still there is extraordinary diversity of features, indicating a considerable mixture of types. Among the Paiwang, probably the earliest settlers, head-hunting prevails. The Tipuns, again, seem to be of northern origin. To the naturalist—whether geologist, botanist, or zoologist—the interior of Formosa offers an almost virgin paradise.

ACCOUNTS are to hand of M. W. Delcommune's recent exploration of the Lomami, one of the most important southern tributaries of the Congo. Both Cameron and Wissmann met with the Lomami far to the south, and the latter connected it with the Sankuru. M. Delcommune, however, navigated the river from its mouth in the Congo, about 100 miles below Stanley Falls, for a distance of 580 miles, to a point only three days' journey from Nyangwé in the Lualaba. The river is reported to traverse a magnificent country, to be free from all obstructions, and to all appearance it continues to be navigable for some distance beyond M. Delcommune's farthest point.

MESSRS. W. AND A. K. JOHNSTON have sent us a copy of the third edition of their small map of Central Africa, in which Mr. Stanley's recent route is laid down in red. The next edition ought to have the Lomami delineated in accordance with M. Delcommune's recent exploration.

AFRICA fills a large place in the new number of *Petermann's Mitteilungen*. Dr. K. W. Schmidt has an article which deserves serious attention on the surface or soil conditions of German East Africa. Dr. Schmidt writes from careful personal observation, and his estimate of the capabilities of the German sphere is not very encouraging. Freiherr von Steinächer contributes some useful notes on German South-West Africa, with a map of Herreo Land and neighbouring regions. Dr. R. Lüddecke describes at some length the features of the new map of Africa, in six sheets, which has been prepared for the new edition of Stieler's "Hand-Atlas."

IN an interesting account in *Les Missions Catholiques* of a missionary's journey through Ecuador, it is stated that of the many towns and village, as Archidona, Canelos, &c., the names of which appear on maps of the country, scarcely one exists. The natives do not live in villages, and even where there is a church, they live miles away in the forest in small solitary communities. Hitherto the missionaries have failed in inducing the natives to take to communal or social life.

M. ROGOZINSKI, who has been in Europe for some time, has returned to Fernando Po, and intends to resume his explorations in the Cameroons region, and especially to endeavour to ascertain the existence or non-existence of the Lake Liba, which still figures mysteriously in maps of Africa.

THE death is announced of M. V. A. Malte-Brun, son of the great geographer of that name, and who himself for the last forty years had been a student of and writer on geography.

AFFORESTATION IN CHINA.

THE question of afforestation in China is at the present time attracting a great deal of attention. China is a treeless country, and to this, perhaps, are due the devastating floods which work such ruin there, and the fearful seasons of drought, which are almost as destructive as the floods. The timber used

in various ways is all imported—chiefly from the United States of America, and from Hainan and Formosa. Till the overflow of the Yellow River some time ago, no one paid the least attention to this question; but now a proclamation of the liberal Viceroy, Li Hung Chang, to the people of his thickly-populated provinces, shows that the subject will receive the attention it deserves. His Excellency says that one of the first principles in governing a State is to watch over the agriculture of the State, so that it may benefit both the individuals who till it and the State. In one of the provinces over which he rules—namely, that of Chihli—arboriculture is rendered especially easy by the softness and fertility of its alluvial plains. If we omit the various species of fruit-trees, such as the apple, pear, and apricot, other kinds of trees are very rarely seen, and in consequence vast tracts of fertile plains are left barren. Some slight attempts have been made to plant these extensive tracts with forest trees; but the strong northerly winds which prevail soon uprooted trees which had not been planted to a sufficient depth nor in well-chosen places. Amongst the peasants, the Viceroy says, the principles of arboriculture are unknown, and therefore their previous efforts have only resulted in labour and money uselessly expended. In recent years the Viceroy has ordered the planting of willow-trees along the banks of the streams and rivers in Chihli, with the object of protecting and strengthening the embankments.

If successful methods, His Excellency asks, have been found for cultivating trees in salt lands, how much more easy ought they to be found in the rich level plains of Chihli? Accordingly, the authorities of the various prefectures and sub-prefectures of Chihli are instructed to procure the necessary seed trees, and to inform the people in their respective districts of the eight directions for tree-planting and the ten benefits to be derived from the same. Steps are to be taken by the authorities to encourage the people in their efforts at planting, but official agents, who might oppress the people, are not to be sent among them. At the end of each year a statement is to be submitted to the authorities, by every person who has tried planting, of the number of trees he has received, the number successful, the species which have thriven best, &c., so that the Government may reward those who are most successful in these experiments in arboriculture, as well as gather information to guide them in the future. Instructions are given to the local authorities to deal severely with any person who steals or cuts down the trees of others. The Viceroy says that his intentions in issuing this proclamation are to afford another source of livelihood to the peasants, to help in preventing droughts and checking floods, to regulate the rainfall, and to beautify the country.

The eight directions and the ten benefits are worth recording. The directions are as follow:—(1) To fortify the roots against injury from cold, which, on account of the loose nature of the soil near the surface, readily injures the roots, a fertilizer, made by burning a mixture of dung and grass, should be used when planting trees, and when the fertilizer is put in, the roots should be carefully covered. (2) When a tree has been securely planted, a small cumulus of earth should be placed around it, 6 or 7 inches high, and should be renewed before winter sets in every year till the close of the third year. By this means the wind and cold cannot reach the roots, nor will the necessary natural nourishment in the earth escape. (3) In places exposed to high winds the trees should be planted to a depth of at least 3½ feet; at this depth the rich part of the soil is reached. In case of willows and other such trees, the outspreading and dependent branches are to be carefully pruned. (4) Rich earth, with a suitable fertilizer, is to be added to poorer soils. (5) To prepare the ground for the reception of the seeds of such trees as the oak, elm, poplar, cypress, &c., which are shed every year, a trough is to be dug round each tree and filled with water to keep the soil moist. (6) Willow and mulberry trees should be planted in the spring, when there is rain. Before planting the young shoots, the soil should be well loosened and fertilized, and grafting should always take place after the rain, and the graft-trees should be well watered every alternate day. (7) In transplanting trees, the greatest care should be taken to preserve the three vertically-projecting roots, which every tree has, from the wind and sun. When there is rain, a small hole is to be dug by the side of the tree, cutting away one of these roots; this operation is to be repeated in a fortnight if there is rain; if not, a month must elapse before the second root is cut, and similarly in the case of the third root. When the roots are cut away, innumerable little roots will be thrown out. If there is no rain, the ground must be well watered before any transplanting is attempted. (8) In raising trees from the seeds of the oak, mulberry, &c., some fertile spot should be prepared just as it would be for a crop of grain, and the seeds are planted in the same way as grain is planted. Spring-time is the best, and while there is rain. When the young trees spring up and grow to the height of one or two feet, they can easily be transplanted as directed above.

The ten benefits of planting trees are thus enumerated by His Excellency:—(1) By planting trees at the river-banks the loose and sandy soil is strengthened by the roots, and the banks increase in height. (2) A large and profitable industry will spring up if pine, elm, willow, &c., are planted in the mountains on the borders. (3) The planting of trees around fields and farms will do away with the superfluous moisture and preserve a fair equilibrium of wind and fluid influences. (4) Where trees are in abundance, droughts will be unknown. (5) Abundance of trees also help to ward off epidemics, and in thickly-populated districts trees should be specially planted for this purpose. (6) Where there is abundance of trees, travellers and families can find rest and shelter in the summer. (7) The operations of highwaymen and banditti are hindered where trees and forests are plentiful. (8) The snows on the mountains of the border will be absorbed by forests. (9) The poorer peasants will have sufficient fuel from the branches, which are pruned every year. (10) Many of these trees, as the *Quercus mongolica*, afford food to the silk-worm, which, in the mountainous regions, weaves a cocoon which makes much cheaper and more durable silk than that of the mulberry silk-worm.

SUPERSTITION AND SORCERY IN NEW GUINEA.

IN the Report to the Colonial Office of the Special Commissioner for British New Guinea during the past year, there is a long and very interesting account of some of the superstitions of the natives of that country, written by Mr. H. H. Romilly. One of the most sacred obligations, he says, on the relatives of a deceased man is to place in his grave, and in his accustomed haunts, food and water for the spirit of the departed. It is thought that this spirit is all that remains of the deceased, and the human appetites take possession of it, or, rather, remain in existence, just as if the body had not died. If, however, he is killed in battle, there is not the same necessity of constantly feeding his spirit; the head of one of the tribe or race who killed him is sufficient. If the slayer is a white man, the angry spirit can be laid by a large payment of goods to the relatives of the deceased, and this constantly happens. Dreams are, to them, voices from the land of spirits, telling them what to do, for whom to work, from whom to steal, and what to plunder. White men are always attended by a familiar spirit, which is blamed for any mischief that befalls the natives in a locality where a white man happens to be. If the white man is a friend of theirs, they merely demand compensation, which he will pay, says Mr. Romilly, if he is a wise man; if he is unfriendly to them, the unfortunate white man may prepare for the worst. His attendant spirit will not help him, for it flies at the sound of a gun. On the death of a relative, there is a great drumming and burning of torches to send the spirit safely and pleasantly on its travels. In some parts of the country, certain trees have spirits, and on feast-days a portion of the food is set apart for these spirits. It is worthy of remark that all their spirits are malignant, and these have to be overcome by force of arms, by blessings, or by cursings. They cannot grasp the idea of a beneficent spirit, but regard them all as resembling Papuans generally—that is, vindictive, cruel, and revengeful. Consequently, these spirits are much feared; though they cannot be seen, yet they constantly use arrows and spears when they are vexed. The great opposer of spirits is fire, and hence, on every possible occasion, bonfires and torches are employed. Strange to say, though fire is thus all-powerful with them, they have no god or spirit of the fire. In this they are at least true to their belief, for no spirit can be, with them, beneficent. Sorcerers are implicitly believed in, and they generally do a good trade in the sale of charms, which are made, not on any fixed principle, but according to the freaks of fancy of the sorcerer or the purchaser. Sometimes it is a bit of bark, sometimes a crab's claw worked in the most fantastic way. These are protectors against all injuries or accidents that may happen to a

man. A sailor will wear one as a protection against shipwreck, another charm saves its wearer from wounds in battle, another from disease, and so on. Besides being a sorcerer, that personage is also a physician and surgeon, and usually the astrologer and weather prophet of his district. It can hardly be said that he is skilled in these professions. An unvarying mode of treatment of a patient who is suffering pain from any cause whatever is to make a long, and sometimes a deep, incision over the abdomen. As may be imagined, this is not a very safe remedy. In one instance Mr. Romilly mentions, a woman, who was suffering severely from several spear-wounds, was thus treated by the native sorcerer, who, in pursuit of his profession of surgeon, inflicted by far the most severe wound the poor woman received, thus destroying the chance of life which she had before he attended her. Many of the tribes are, through the influence of the missionaries, shaking off these superstitions. "But even these people," says Mr. Romilly, "the most civilized in New Guinea, and many of them professed Christians, in times of great excitement revert to their old habits. This was shown during the autumn of 1886. At that time a severe epidemic raged along the south coast. The people were dying, by hundreds, of pneumonia, and were beside themselves with fear. The usual remedies for driving away spirits at night were tried, remedies which had been in disuse for years; torches were burnt, horns were blown, and the hereditary sorcerers sat up all night cursing; but still the people died. Then it was decided that the land spirits were working this harm, and the whole population moved their canoes out in the bay and slept in them at night; but still the people died. Then they returned to their village, and fired arrows at every moving object they saw. . . In course of time the epidemic wore itself out; but while it lasted the civilized Motuans were as superstitious as any of their neighbours could have been."

THE MUSEUM OF COMPARATIVE ZOOLOGY, HARVARD COLLEGE.

THE Annual Report of Prof. A. Agassiz for 1887–88 has been issued. It gives the usual interesting account of the various courses of instruction which have been provided at the Museum during the academic year, and of the reports from the several officers about the collections under their care. Excellent progress has been made with the extensive addition to the Museum building, in which there will be ample accommodation for the geological and geographical departments. While numerous specimens have been sent to specialists, a number of applications have from necessity been refused, as the Museum staff is very far from being large enough to meet the demand on its time which attention to all such applications would require. For the future, the very reasonable rule has been laid down that only single specimens for special study can be sent out from the Museum, so that the larger collections must be studied at the Museum, where, we may add, they may be examined with every advantage. In an appendix, a list of the publications of the Museum during the past year will be found, and there is also a most important list of all its publications from the commencement: the Annual Report from 1859, the Bulletin from 1863, the Memoirs from 1864. In a footnote comment is made on some remarks appearing in the preface to the *Zoologischer Jahresbcricht* for 1886, on the irregular way in which the publications of the Museum appear. We only allude to this to express our hope that no criticisms will alter the present arrangement, which is one that allows of the prompt publication of the various new facts brought to light by the band of workers at Harvard. We can conceive that by a librarian, simply as such, the publication of a volume in parts is held in abhorrence, and the publication of parts of two or three volumes of a series, at the one time, fills him with dismay; but to the working student it is very different, and such owe a great deal of gratitude to the Curator of the Museum at Harvard, for the speedy publication of the Museum Memoirs as well as for the great liberality with which these are immediately posted to Europe on their issue from the press. The following paragraph we read with mingled feelings of regret and pleasure:—"In the past fifteen years I have been in the habit of supplying deficiencies for such expenditures as seemed to me essential for the rapid development of such an establishment. But it has now become evident that, while such a policy may have been useful in the early stages of the Museum, it has of late been rather a detriment to it than otherwise, as it was fast coming to be regarded as my personal establishment. The demands upon my time for the administration of the affairs have become so great, that I must retire from active duty to devote myself to scientific work, which I have too long neglected for the sake of bringing the Museum to the point it has reached. It is high time that I should withdraw, and that a younger man, more in sympathy with the prevailing tendency of science in this country, should endeavour to develop the Museum by increasing the interest of the friends of the University in its behalf." We fail to comprehend how any man living could be more in sympathy with modern science than Alexander Agassiz, but we recognize as a fact that he has original work to finish, while it is yet day, and it is universally acknowledged that he has established such a museum at Harvard as may employ the energies of many workers for years to come.

RESULTS OF EXPERIMENTS UPON THE GROWTH OF POTATOES AT ROTHAMSTED.

DR. GILBERT has, in the form of a lecture recently delivered at the Royal Agricultural College, given a *résumé* of twelve years of experimental work in connection with the growth of potatoes. The subject is in itself highly interesting, including, as it does, a large number of important questions relating to the propagation of new varieties, the proper cultivation of the ground, the potato-blight, as well as the best fertilizers for the crop. Dr. Gilbert at once disclaims all idea of entering upon the larger questions involved in potato-cultivation, and confines himself entirely to that of fertilizers, and in regard to this point he is not able to throw much fresh light upon the usual practices of growers. The old story of the value of a due apportionment of nitrogenous and mineral substances is clearly shown to be required for the growth of potatoes, as for all crops. The value of farmyard manure is also well indicated in a manner which, on the whole, supports the present practice of all good farmers. The meagre results obtained from mere mineral manures, unassisted by nitrogenous manures, are also well brought out. The practice of employing liberal dressings of dung, superphosphate, and potash salts, or of substituting nitrate of soda or sulphate of ammonia for farmyard dung, is simply indorsed by Dr. Gilbert's results, and, beyond this, no new light is shed upon the subject of fertilizers for potatoes.

The effect of liberal applications of nitrogenous and mineral manures in increasing the proportion of diseased tubers, in years in which the blight is prevalent, is too familiar to need further proof; and as a matter of fact, the wisest course appears to be to balance the advantages of a heavy crop against an increased liability to disease.

A point is made by proving very conclusively that the continuous growth of potatoes upon the same land does not render the crop more liable to disease, but rather the reverse. For example, the percentage of diseased tubers during the first four years of potato-growing ranged in the various plots from 5·14 to 12·82, the largest amount of disease occurring upon the land manured heavily with dung and nitrogenous dressings. In the second four years, the average amount of diseased potatoes ranged from 1·63 to 4·95 per cent., while in the third series of four years it was reduced to from 1·43 to 1·73 per cent. No fluctuations of season can overturn these figures. They have an important bearing upon the question of the propagation of the disease, and appear to detract from the value of suggestions that the blight continues to exist in the form of resting spores in the ground. If such was the case, the disease, when once established, would surely tend to greater virulence in the case of constantly repeated growths of diseased crops. Practical agriculturists would scarcely be induced, from these results, to take special measures for destroying diseased tubers, for carefully preventing their introduction into manure-heaps, or for gathering diseased haulm off the land—all of which precautions students of potato-disease have advised agriculturists to take.

The composition of the tubers, after manuring with the various fertilizers employed, is strikingly similar, with the exception that the heavier crops are rather more watery in character—a result which may always be looked for in luxuriant vegetation. The general result of these experiments is encouraging, in so far as they show that the methods in general use for manuring the potato crop are the best that can be devised for the growth of potatoes.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 28.—"On certain Ternary Alloys. I. Alloys of Lead, Tin, and Zinc." By C. R. Alder Wright, D.Sc., B.Sc., F.R.S., Lecturer on Chemistry and Physics, and C. Thompson, F.C.S., F.I.C., Demonstrator of Chemistry in St. Mary's Hospital Medical School.

It is well known, that quite apart from a tendency to separate more or less completely into different mixtures during solidification, certain mixtures of molten metals show a tendency to separate into two alloys of different densities on standing fused for some time. Lead and zinc and bismuth and zinc have been shown by Matthieson and V. Bose to form two such mixtures; the authors find that aluminium and zinc or aluminium and bismuth also behave in the same way; in each case two different alloys are formed, one consisting of the heavier metal with a little of the lighter one dissolved therein, the other of the lighter metal containing a small quantity of the heavier one.

On the other hand, *tin* will alloy indefinitely in all proportions with any of the four metals, lead, bismuth, zinc, or aluminium, the mixtures exhibiting no particular tendency to separate into two different alloys on simply remaining at rest in a fused condition, although in certain cases more or less separation is apt to occur *during solidification*, owing to partial formation of eutectic alloy. Various other metals, *e.g.* cadmium, antimony, silver, &c., appear to behave like tin in this respect.

It seemed to be of interest to examine the behaviour under similar conditions of ternary mixtures where two of the ingredients are not miscible together in all proportions (like aluminium and lead), whilst the third is miscible indefinitely with either of the other two (like tin). It might be expected that with certain proportions a single stable alloy would result, whilst with others the mass would divide into two different ternary mixtures. In point of fact this is precisely what occurs.

For a variety of reasons the authors selected the alloys of lead, tin, and zinc for their first experiments.

These led to the conclusion that the greater the proportion of tin present (provided it does not exceed the limiting amount beyond which no separation takes place) the more zinc is contained in the heavier alloy, and the more lead in the lighter one; but that the distribution of the tin throughout the entire mass is by no means uniform, the lighter alloy containing the greater percentage when the proportion of tin in the total mass is low, and *vice versâ* when it approaches towards the limiting amount; so that with a particular proportion of tin in the total mass uniform distribution as regards weight percentage occurs, but with no other proportion.

The authors next attempted to find out whether a moderately large variation in the temperature at which the mass kept molten had any great influence on the end result; for if not, obviously much laborious work would be saved. Two series of compound ingots (forty in all) were accordingly prepared, one at a temperature close to 565° C., the other at near to 689° C. From the analytical results obtained, three noteworthy curves are deducible—

(*a*) When the tin percentages in the heavier alloy are plotted as abscissæ and the zinc percentages as ordinates.

(*b*) When the tin percentages tin the lighter alloy are plotted as abscissæ and the lead percentages as ordinates.

(*c*) When the tin percentages in the heavier alloy are plotted as abscissæ and excesses of the percentage (+ or −) in the lighter alloy over those in the heavier one as ordinates.

These three curves respectively represent approximately the solubility of zinc in lead containing tin, that of lead in zinc containing tin, and the relative distribution of tin in the two alloys formed simultaneously. The three curves obtained from one series are practically identical with the corresponding curves from the other series, so that it may be fairly concluded that the effect of variation in temperature from 565° to 689° is negligible as compared with the experimental errors, more especially those due to imperfect separation by gravitation of the two alloys from one another.

The curves representing the tin distribution are remarkable. As long as the tin percentage in the total mass is less than about sixteen the lighter alloy contains more tin than the heavier one; at about this point (representing some 14 per cent. in the heavier and 18 per cent. in the lighter alloy) the difference becomes a maximum, after which the difference diminishes, until at about 28 per cent. the same percentage of tin is contained in both alloys. After this the heavier alloy contains more tin than the lighter, the difference continually increasing.

Certain irregularities were observed due to the existence of some cause interfering with the proper separation by gravitation of the heavier from the lighter alloy: this was ultimately traced to convection currents set up through unequal heating of the walls of the containing vessel at different levels, and it was found that the imperfect separation could be almost completely obviated by so heating the mass as to avoid this inequality of temperature. This was finally effected by employing crucibles very long in proportion to their diameter (large test-tubes moulded on a core from a plastic mixture of fireclay and syrupy silicate of soda, diluted with about three times its weight of water), heated by immersion in a bath of molten lead some 6 or 7 inches deep, contained in an iron cylindrical vessel (the lower two-thirds of a mercury bottle), surrounded by a concentric clay jacket and heated by a number of bunsen burners playing into the annular interspace. Several series of compound ingots were thus prepared, containing lead and zinc in ratios different for each series (2 to 1, 1 to 1, 1 to 2), some at a temperature near to 650°, others at about 750°. From the results of the analysis of upwards of 130 different alloys thus obtained, the following conclusions are drawn:—

When a mixture of lead, tin, and zinc in the molten condition is well stirred up by mechanical means and then left to itself for some hours at as nearly as possible a uniform temperature, a single homogeneous alloy results if the proportion of tin present is not less than three-eighths of the whole; but if materially less tin than this is present, the mass divides itself into two different ternary alloys, lead predominating in the heavier one and zinc in the lighter one. This phenomenon is entirely distinct from the segregation of alloys during solidification, in consequence of formation of eutectic or other differently fusible alloys.

If there is little or no inequality of temperature at different parts of the mass, separation by gravitation only is complete in a few hours, at any rate when tolerably pure metals are employed; but if the mode of heating is such that convection currents are set up, the separation is greatly interfered with, and in extreme cases almost entirely prevented.

The heavier alloy is a saturated solution of zinc in lead containing tin, and the lighter one a similar solution of lead in zinc containing tin. No matter what the relative proportions between lead and zinc in the original mass, the two alloys always correspond to two conjugate points on the solubility curves of zinc in lead-tin and of lead in zinc-tin.

But little, if any, difference in the way in which a given mass divides itself is noticeable, whether the temperature which the molten mass maintained is below 600° C. or above 700° C.

The tin contained in the mass does not distribute itself equally in the two alloys except when present in one particular proportion, which varies with the ratio of the zinc to the lead in the entire mass. With less tin than this the lighter alloy, and with more the heavier one, takes up the higher percentage of tin.

Curves drawn representing the tin present in the heavier alloy as abscissæ, and the (+ or −) excess of tin in the lighter alloy over that in the heavier one as ordinates, are found to differ with the ratio of zinc to lead in the entire mass. They always possess the same general features, viz. rising from the origin to a maximum elevation, then sinking down again to the base line, and crossing it so as to become negative; but the position and height of the maximum, the crossing point, and the general dimensions of the curve, vary with the ratio of zinc to lead in the mass.

As a result of this, whilst an indefinite number of different mixtures may be prepared, each one of which will give the same heavier alloy, the lighter alloy simultaneously formed will be different in each case; and conversely.

When no tin is present, lead dissolves zinc to such an extent as to form an alloy containing 1·24 per cent. of zinc, and zinc dissolves lead forming an alloy containing 1·14 per cent. of lead; the higher values found by previous observers being slightly incorrect through imperfect separation.

Nothing abnormal appears to characterize the solubility curves of zinc in lead-tin and of lead in zinc-tin; in each case the amount of one metal dissolved by the other increases as the quantity of tin present increases, in such a way that the curves are somewhat concave upwards.

Royal Society, April 4.—"On the Magnetic Inclination, Force, and Declination in the Caribee Islands, West Indies." By T. E. Thorpe, Ph.D., F.R.S.

The following determinations of the magnetic elements among the Caribees or Windward Islands were made in

August 1886, on the occasion of the Eclipse Expedition of that year to Grenada.

The instruments employed were magnetometer Elliott No. 61, and Dip Circle Dover 83, belonging to the Science and Art Department.

The method of observation was similar to that adopted in the Magnetic Survey of the British Isles for epoch January 1, 1886, for which these instruments were also employed.

The results may be thus summarized:—

Station: August 1886	Inclination	Force		Declination
		Horizontal	Total	
St. George, Grenada ...	40° 54'·7	3·1093	4·1144	0° 41'·5 E.
Hog Island, Grenada ...	41 14·1	3·1000	4·1223	0 51·5 E.
Island of Carriacou ...	—	3·0771	—	0 16·3 E.

Linnean Society, April 4.—Mr. Carruthers, F.R.S., President, in the chair.—Mr. D. Morris exhibited a specimen of the hymenopterous insect, *Eulema cayennensis*, concerned in the fertilization of *Coryanthes macrantha* (see Crüger, Journ. Linn. Soc., viii. 129), and obtained from Mr. Hart of Trinidad. Referring to the illustrations of the structure of the flowers, given in the *Gardener's Chronicle* (xvii., 1882, 593; and xxiii., 1885, 145), Mr. Morris explained the process carried out by the insects, chiefly bees, in removing the pollinia and subsequently attaching them on the stigma. The observations of Crüger had been verified by Mr. Hart in the Botanic Gardens, Trinidad.—Sir Edward Fry exhibited and made some instructive remarks on a copy of Grisley's "Viridarium Lusitanicum," 1661, presented by Linnæus to his pupil Loefling, the author of the "Iter Hispanicum."—Prof. R. J. Anderson exhibited some photographs of educational museum cases in Queen's College, Galway.—A paper was read by Mr. Lister on the Myxomycetes, or Mycetozoa, a group of organisms on the borderland between the animal and vegetable kingdoms, and formerly classed with Fungi. His remarks were illustrated by numerous coloured drawings of representative species, and the author also exhibited under the microscope the swarm cells from the spores of *Amaurochæte* and the streaming plasmodium of *Badhamia*. Attention was especially directed to the mode of feeding of the swarm cells and observations made on those of *Stemonitis*, where large bacilli were seen to be caught by pseudopodia projected from the posterior end of the organism, and drawn into its substance and digested. An interesting discussion followed, in which the President, Prof. Marshall Ward, Prof. Howes, and Mr. Breese took part.—A paper was then read by Mr. E. W. Hoyle, on the deep-water fauna of the Firth of Clyde, embodying the results of recent investigations. The explored area, which is shut off from the Irish Sea by a submarine plateau extending from the Mull of Cantyre to the Ayrshire coast, contains seven distinct deep-water basins, in which the depth exceeds 20 fathoms, and in some cases reaches 80 or 100 fathoms. An account was given of the dredging which had been carried on, with lists of the species obtained at various depths. A discussion followed in which Messrs. John Murray, W. P. Sladen, and G. B. Howes took part.

Chemical Society, March 21.—Mr. W. Crookes, F.R.S., in the chair.—The following papers were read:—The molecular weights of metals (preliminary notice), by Prof. W. Ramsay, F.R.S. The molecular weights of a number of metals have been determined by Raoult's vapour-pressure method, viz. by ascertaining the depression of the vapour-pressure of the solvent produced by a known weight of dissolved substance, the relation between molecular weight and depression being expressed by the equation, $W = \frac{W' \times P \times p}{100 \times d}$, where W is the molecular weight to be found; W' the molecular weight of the solvent; P/100 the percentage weight of the dissolved substance in solution; p the vapour-pressure of the solution; and d the depression in the vapour-pressure of the solvent produced by adding the substance dissolved. The solvent employed was liquid mercury; the temperatures 260° and 270° for a few substances, and the boiling-point of mercury for most. The results obtained are as follows:—

Element.	Atomic weight.	Molecular weight.		Molecular formula.
		Found.	Calculated	
Lithium . . .	7·02	7·00	7·02	Li_1.
Sodium . . .	23·04	12·1	11·52	$Na_{\frac{1}{2}}$.
Potassium . .	39·14	28·57	?	K_1 (?).
Silver	107·93	109·0	107·93	Ag_1.
Gold	197·22	204·3	197·22	Au_1.
Barium . . .	137·0	74·45	68·5	$Ba_{\frac{1}{2}}$.
Magnesium . .	24·3	20·33	24·3	Mg_1.
Zinc	65·34	60·85	65·43	Zn_1.
Cadmium . .	112·1	100·0	112·1	Cd_1.
Gallium . . .	69·9	68·1	69·9	Ga_1.
Thallium . . .	204·2	183·5	204·2	Tl_1 (?).
Tin	119·1	114·9	119·1	Sn_1.
Lead	206·93	204·1	206·9	Pb_1.
Antimony . .	120·2	134·2	120·3	Sb_1.
Bismuth . . .	208·1	209·2	208·1	Bi_1.

These numbers represent some of the actual results. Nevertheless, they must not be taken as absolute; although in many cases they are conclusive as to the molecular weight of the metal, still further experiments are needed. As an instance of what occurs, the metals thallium and antimony may be chosen. With thallium, for example, the following results were obtained:—

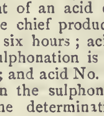
Percentage of thallium in amalgam.	Molecular weight.	
	Found.	Calculated.
0·8191	157·4	204·2
1·666	183·5	204·2
2·894	174·3	204·2
3·290	183·9	204·2

No appreciable change is produced on concentration. But with antimony, the molecular weight increases proportionately to the amount present, thus—

Percentage of antimony in amalgam.	Molecular weight.	
	Found.	Calculated.
1·117	134·2	120·3
1·526	155·4	120·3 to 240·6
2·257	193·4	120·3 to 240·6
3·289	294·6	240·6 to 481·2?

Here an association of atoms is evidently in progress. The results are based on the assumption that the molecular formula of mercury is Hg_1, in favour of which strong reasons can be adduced.—The application of Raoult's depression of melting-point method to alloys, by Messrs. C. T. Heycock and E. H. Neville. As a result of some preliminary experiments on the change in the solidifying point of tin caused by the addition of small quantities of other metals, the authors conclude that the dissolution of a metal in tin follows the same laws as that of compounds in other solvents, *i.e.* (1) that the fall in temperature of the solidifying point is directly proportional to the weight of metal added; and (2) that the fall of temperature is inversely as the atomic (molecular?) weight of the metal added. With tin, copper, silver, cadmium, lead, and mercury, the dissolution of one atomic proportion in 100 atomic proportions of tin caused a fall in temperature of the solidifying point varying from 2°·16 to 2°·67, with aluminium a fall of 1°·34, and with antimony a rise of 2°·0. In the discussion which followed the reading of these papers, Prof. Armstrong said that notwithstanding the apparent regularity and simplicity of the results, he was not prepared to accept them as in the least degree final. There was not sufficient evidence in his opinion that the effect observed was not in part at least the outcome of a change in the molecular composition of the solvent. The results obtained by Raoult's methods were, he thought, comparable with those obtained by determining the specific heats of the elements; in the latter case the observations were undoubtedly made with masses of molecules, which probably were of varying degrees of atomic complexity, and yet the results were found to be such as to justify conclusions being drawn as to the relative magnitudes of

their fundamental constituents—the atoms. In the same way it was possible that the results obtained by Raoult's method by means of observations on the behaviour of molecular complexes might afford the means of deducing the relative magnitudes of the fundamental molecules comprising the complexes, but not of the actual complexes operated with. Mr. Crompton drew attention to Beckmann's recent experiments on the lowering of the freezing-point; these show that the true molecular weight was only obtained when solutions were used the concentration of which was allowed to vary only within certain narrow limits; and that if the solutions were too dilute the molecular weight obtained from the lowering of the freezing-point was too low, while if the solutions were too concentrated, it was too high. In some cases the variation of the number obtained with the concentration was enormous. Prof. Carey Foster remarked that much depended on the definition given of a molecule, whether it is defined as that smallest quantity capable of existence *per se*, or as that quantity which produces a given effect in depressing vapour-pressure, or freezing-point, &c. The two magnitudes were not necessarily the same. The relation observed could hardly be accidental; yet he thought that the value obtained might be a quantity connected with the molecular weight but not necessarily identical with it. Prof. Ramsay, in replying, said that substances in dilute solutions must be regarded as in the gaseous state, their molecules being so far distant from each other as not to exert appreciable attraction on each other; and as occupying but a small portion of the space they inhabit. It has long been argued that the molecular complexity of the gases, hydrogen, oxygen, and nitrogen, must be the same, inasmuch as these elements have equal coefficients of expansion within the widest limits of temperature. A similar argument applies to substances in dilute solutions; it is much more probable that they have a simple and similar molecular structure than that the molecules, if complex, dissociate to an equal extent on equal rise of temperature, or on equal alteration of concentration. As regards the empirical nature of Raoult's laws, it is paralleled by the empirical nature of Boyle's and Gay-Lussac's laws—that is, such laws are merely approximations to truth, and depend on the fact that the molecules are sensibly beyond the sphere of each other's attraction, and themselves occupy no appreciable space. Hence their inapplicability at high concentrations.—Some compounds of tribenzylphosphine oxide, by Dr. Collie.—Contributions to our knowledge of the isothiocyanates, by Dr. A. E. Dixon.—The constitution of primuline and allied sulphur-compounds, by Mr. A. G. Green.—The determination of the constitution of the heteronucleal $\alpha\beta$- and $\beta\beta$-di-derivatives of naphthalene (second notice), by Prof. H. E. Armstrong and Mr. W. P. Wynne. Three heteronucleal α-chloro-β-naphthylaminesulphonic acids can be obtained when 1 : 2-α-chloro-β-naphthylamine hydrochloride is sulphonated with four times its weight of an acid containing 2 per cent. of SO_3. Acid No. I. is the chief product when the sulphonation is effected at 70° during six hours; acid No. II. is almost the sole product when the sulphonation is allowed to continue for a further six hours at 100°; and acid No. III. is obtained, together with acid No. II., when the sulphonation is effected at 160° during six hours. The determination of the constitution of the heteronucleal $\alpha\beta$- and $\beta\beta$-di-derivatives of naphthalene is arrived at from a study of these acids in the following way. Adopting the conventional symbol for naphthalene, with the α- and β-positions indicated, and numbering the positions 1, 2, 3, 4, 1′, 2′, 3′, 4′, as shown—



it is obviously possible to determine the relative positions of the three radicles, Cl, NH_2, and SO_3H, in a heteronucleal chloronaphthylaminesulphonic acid by determining the relative positions of the three pairs of radicles, Cl and NH_2, Cl and SO_3H, and NH_2 and SO_3H, and on this result to base the absolute orientation of the radicles, provided that it can be shown how the radicles are situated in any one of the two pairs of hetero-di-derivatives obtainable from the tri-derivative. No absolute method, free from reproach, has yet been devised for determining the constitution of any known hetero-di-derivative of naphthalene, but in the case of the hetero-$\alpha\alpha$-di-derivatives arguments may be advanced which are of such weight as to leave but little room for doubt that the $\alpha\alpha$-di-derivatives corresponding in constitution with ζ-dichloronaphthalene (m.p. = 83°) have the constitution 1 : 1′; the $\alpha\alpha$-di-derivatives corresponding in constitution with γ-dichloronaphthalene (m.p. = 107°) having then, by exclusion, the alternative formula 1 : 4′. The constitution of α-chloro-β-naphthylamine, and consequently the relative positions of the radicles Cl and NH_2 in the three sulphonic acids derived from it, was determined by the authors to be 1 : 2 (cf. NATURE, December 13, 1888, p. 166); the relative positions of the radicles Cl and SO_3H in the three acids were determined by replacing the NH_2 radicle by H by von Baeyer's hydrazine method, and converting the resulting heteronucleal chloronaphthalenesulphonic acids into the corresponding dichloronaphthalenes by treatment with phosphorus pentachloride, and the relative positions of the radicles NH_2 and SO_3H were ascertained by replacing the Cl by H by reduction with sodium amalgam, and converting the resulting heteronucleal naphthylaminesulphonic acids, first into the corresponding chloronaphthalenesulphonic acids by Sandmeyer's method, and finally into the corresponding dichloronaphthalenes. Acid No. I. yields, by displacing NH_2 by H, a chloronaphthalenesulphonic acid corresponding in constitution with γ-dichloronaphthalene, and therefore contains the radicles Cl and SO_3H in the positions 1 : 4′; it follows then, since the radicles Cl and NH_2 are in the positions 1 : 2, that the radicles NH_2 and SO_3H must be in the positions 2 : 4′. The naphthylaminesulphonic acid obtained from No. I. acid by reduction was found to be identical with Dahl's modification of β-naphthylamine-α-sulphonic acid, and to yield a dichloronaphthalene identical with so-called η-dichloronaphthalene (m.p. = 48°), so that these and all corresponding heteronucleal $\alpha\beta$-di-derivatives are proved to have the constitution 2 : 4′. Acid No. III., on displacing NH_2 by H, yields a chloronaphthalenesulphonic acid corresponding in constitution with the Badische modification of β-naphthylamine-α-sulphonic acid and with the heteronucleal $\alpha\beta$-dichloronaphthalene melting at 63°·5, and this must, by exclusion, be the 1 : 2′-compound, since the only alternative formula for a heteronucleal $\alpha\beta$-di-derivative, viz. 1 : 3′ or 2 : 4′, has been proved above to belong to $\alpha\beta$-di-derivatives corresponding in constitution with η-dichloronaphthalene (m.p. = 48°). Inasmuch, then, as acid No. III. contains the radicles Cl and SO_3H in the positions 1 : 2′, and the radicles Cl : NH_2 in the positions 1 : 2, it follows that the radicles NH_2 and SO_3H must be in the positions 2 : 2′. The naphthylaminesulphonic acid obtained from No. III. acid by reduction was found to be identical with Bayer and Duisberg's modification of β-naphthylamine-β-sulphonic acid, and to yield a dichloronaphthalene identical with δ-dichloronaphthalene (m.p. = 114°), so that these and all corresponding heteronucleal $\beta\beta$-di-derivatives are proved to have the constitution 2 : 2′. Acid No. II., on displacing NH_2 by H, yields a chloronaphthalenesulphonic acid convertible into η-dichloronaphthalene; it follows, then, that it contains the radicles Cl and SO_3H in the positions 1 : 3′, and since the radicles Cl and NH_2 are in the positions 1 : 2, the radicles NH_2 and SO_3H must be in the positions 2 : 3′. The authors could not, however, succeed in isolating this naphthylaminesulphonic acid owing to the peculiar behaviour of acid No. II. on reduction with sodium amalgam, but they have been able by other methods to place it beyond doubt that the acid when isolated would be found identical with Brönner's β-naphthylamine-β-sulphonic acid, and would yield a dichloronaphthalene identical with ϵ-dichloronaphthalene (m.p. = 135°), hence these and all corresponding heteronucleal $\beta\beta$-di-derivatives have the constitution 2 : 3′. These results not only render it possible to determine the constitution of the heteronucleal $\alpha\beta$- and $\beta\beta$-di-derivatives of naphthalene, but also afford a method of ascertaining the constitution of the two heteronucleal sulphonic acids obtained on sulphonating 1 : 2 dichloronaphthalene, and of the three trichloronaphthalenes which have been obtained from the three chloronaphthylaminesulphonic acids; the method is being extended by the authors to all the known chloronaphthylamines for the purpose of determining the constitution of the sulphonic acids obtained by them in characterizing the corresponding dichloronaphthalenes. The results, moreover, establish the correctness of the opinion, long held and frequently expressed by the authors, based on the higher melting-points of the "uniform" ϵ-di-derivatives (*i.e.* di-derivatives containing two similar radicles) in comparison with the isomeric δ-di-derivatives, that the ϵ-di-derivatives are symmetrically constituted; this conclusion, in

fact, is probably the most important outcome of the experiments, since it affords conclusive proof of the influence of symmetry as the determining cause of high melting-point, slight solubility, &c., in the case of naphthalene derivatives.—Contributions to the knowledge of citric and aconitic acids, by Mr. S. Skinner and Dr. S. Ruhemann.

Entomological Society, April 3.—Mr. F. Du Cane-Godman, F.R.S., Vice-President, in the chair.—Mr. Osbert Salvin, F.R.S., exhibited specimens of *Ornithoptera trojana*, Staud., and *O. plateni*, Staud., received from Dr. Staudinger, and obtained in Palawan, an island between Borneo and the Philippines. He remarked that *Ornithoptera trojana* was allied to *O. brookiana*, Wall.—Mr. R. McLachlan, F.R.S., exhibited, and made remarks on, seven examples of *Æschna borealis*, Zett., a little-known species of European Dragon-flies. He said that some of the specimens were captured by himself at Rannoch, in June 1865. The others were taken in Luleå, North Sweden, and the Upper Engadine (5000–6000 feet), in Switzerland.—Mr. W. H. B. Fletcher exhibited specimens of *Agrotis pyrophila* from various localities, including two from Portland, three from Forres of a smaller and darker form, and a melanic specimen from Stornoway at first supposed to belong to *A. lucernea*, but which, on closer examination, was seen to be referable to this species. He also exhibited series of *Triphæna orbona* from Stornoway and Forres, and *T. subsequa* from Forres and the New Forest. The specimens of *T. subsequa* from Forres were more distinctly and richly marked than those from the New Forest, and were also rather more variable in colour.—Dr. Sharp exhibited specimens of *Proculus goryi*, Kaup, found by Mr. Champion in Guatemala, prepared to show the rudimentary wings under the soldered elytra. Dr. Sharp called attention to the existence of a peculiar articulated papilla at the base of one of the mandibles; and he also showed sections of the head of *Neleus interruptus* displaying this papilla, as well as the articulated teeth on the mandibles.—The Rev. Canon Fowler exhibited specimens of *Agapanthia lineatocollis*, Don, and remarked that they were able to produce a distinct stridulation by the movement of the head against the prothorax, and of the hinder part of the prothorax against the mesothorax. He further remarked that Dr. Chapman had lately informed him that *Erirrhinus maculatus*, F., had the power of stridulating strongly developed.—Mr. Edward Saunders exhibited, on behalf of Mr. G. A. J. Rothney, in illustration of his paper on Indian Ants, specimens of the following:—*Camponotus compressus* and fragments of *Solenopsis geminatus* destroyed by it; *Camponotus* sp. (?), with a mimicking spider (*Salticus* sp.); *Pseudomyrma bicolor*, with its mimicking *Salticus*, and a new species of *Rhinopsis*, viz. *ruficornis*, Cameron, also found with it, and closely resembling its host; *Diacamma vagans; Holcomyrmex indicus*, with specimens of the grain which it stores and the chaff which it rejects; and a species of *Aphænogaster*, with the pieces of *Mimosa* with which it covers its nest.—Mr. G. A. J. Rothney communicated a paper entitled "Notes on Indian Ants."—Mr. Lionel de Nicéville communicated a paper entitled "Notes regarding *Delias sanaca*, Moore, a Western Himalayan Butterfly."—Captain H. J. Elwes communicated a note in support of the views expressed by Mr. de Nicéville in his paper.

Geological Society, April 3.—Mr. W. T. Blanford, F.R.S., President, in the chair.—The following communications were read:—The elvans and volcanic rocks of Dartmoor, by Mr. R. N. Worth.—The basals of Eugeniacrinidæ, by Mr. F. A. Bather. Although Profs. Beyrich and von Zittel had alluded to certain specimens of *Eugeniacrinus* as proving, by the course of the axial canals, that in this genus the basals had passed up into the radials, yet the two chief authorities who subsequently discussed the subject practically ignored this argument. M. de Loriol contented himself with denying any trace of basals, while Dr. P. H. Carpenter maintained that the top stem-joint represented a fused basal ring. In a previous paper the author had argued in favour of Prof. von Zittel's view without convincing Dr. Carpenter of its correctness. Such scepticism was, no doubt, warranted by the lack of detailed description and of figures. The object of the present note was to set the matter at rest by describing and figuring certain dorsal cups of *Eugeniacrinus caryophyllatus* kindly lent to the author by Prof. von Zittel. Owing to the mode of fossilization the canal system is plainly seen. The axial canal passes up into the radial circlet and gradually widens; at a short distance below the floor of the calycal cavity it gives off five interradial branches; these soon bifurcate, and the adjacent radial branches converge. Before they meet, each radial branch gives off a very short branch; this connects the radial branch with the ring-canal that contained the interradial and intraradial commissures. The evidence of all other crinoids that have these canals shows that the basals always contain the interradial branches. And in *Eugeniacrinus*, since the interradial branches have their origin in the middle of the radials, the basals must have passed up in between the radials. The President, Mr. P. Sladen, and Dr. Hinde took part in the discussion which followed the reading of this paper.—On some Polyzoa from the Inferior Oolite of Shipton Gorge, Dorset, by Mr. E. A. Walford.

Mathematical Society, April 11.—Mr. J. J. Walker, F.R.S., President, in the chair.—The Secretary read the following papers:—On the free vibrations of an infinite plate of homogeneous isotropic elastic matter, by Lord Rayleigh, F.R.S.—On the constant factors of the theta series in the general case $p = 3$, by Prof. F. Klein.—On the generalized equations of elasticity and their application to the theory of light, by Prof. K. Pearson.—On the reduction of a complex quadratic surd to a periodic continued fraction, by Prof. G. B. Mathews.—Construction du centre de courbure de la développée de contour apparent d'une surface que l'on projette orthogonalement sur un plan, by Prof. Mannheim.—Mr. Kempe and the President made short communications.

BERLIN.

Physical Society, March 22.—Prof. du Bois-Reymond, President, in the chair.—Dr. Assmann gave an account of the results he had obtained by a microscopic examination of the structure of rime, hoar-frost, and snow. In opposition to the view most usually held, that the solid condensations of aqueous vapour from the air are crystalline, he had observed some years ago, during a sojourn in winter on the Brocken, that hoar-frost consists of amorphous frozen drops, which, by their juxtaposition in rows, build up the long needles of which it is composed. He observed the same structure in some rime which he had collected from very various objects in December last during a cold which was not at all intense; in this case also the spicules of ice were composed of amorphous drops of ice frozen together in lines. In one case the little masses of ice which composed the rime were frozen together into a leaf-like structure. At the same time some small, scattered, and glittering ice-formations which had been formed in large numbers on the ground were crystalline in structure, consisting of thicker or thinner six-sided tablets or somewhat elongated prisms. On other occasions he found that the rime was itself composed of unequally developed crystalline structures, which branched at angles of 60°, and thus gave rise to a dendritic formation; at the same time the hoar-frost was also composed of crystalline structures. He had also succeeded in forming ice-flowers artificially on a pane of glass, and had satisfied himself by a microscopic examination of the same that they are always crystalline in structure. The structure of snow was investigated on the snow-garlands which had been described at a meeting of the Meteorological Society, and consisted of amorphous granules, such as compose the upper surface of a glacier. Dr. Assmann attributes the formation of rime and of hoar-frost to the existence of over-cooled drops of water, which suddenly solidify when driven by the wind against the solid substructure on which they are found. On the other hand, solid transparent ice is formed when water at 0°, or some temperature above zero, comes in contact with any solid object whose temperature is very low.—Prof. Liebreich exhibited a series of experiments intended to explain the occurrence of the inert layer in chemical reactions. Two years ago he had demonstrated to the Society the chief phenomena of its occurrence, as seen when a solution of sodium carbonate is mixed with chloralhydrate. When this is done the larger part of the mixed fluids very soon becomes milky, owing to the formation of innumerable small drops of chloroform, while at the same time a thin layer on the surface of the fluid remains clear: this clear portion is the inert layer, and is bounded above by the general meniscus of the mixture and below by a curved surface, whose convexity is turned upwards towards this meniscus. The speaker had, by means of a series of experiments, disposed of the view which had been put forward that the inert layer is only a portion of the mixed fluids from which the chloroform had evaporated. Of these experiments it may suffice to mention only one, in which the fluid was poured into a flat, open basin until it projected with a convex surface above the edges of the basin. Notwithstanding the larger

fluid-surface thus exposed no inert layer was to be seen. Similarly he had been able to show, by observations under the microscpe, that the phenomenon cannot be explained by any vortex movements in the fluid. Further, the assumption that it is due to a solution of alkali from the glass, which then prevents the precipitation of the chloroform, had been excluded by using a vessel made of quartz crystal. Prof. Liebreich inclined to the view, on the basis of his past experiments, which, however, must be further followed and extended, that the suppression or slowing of the chemical reaction at the surface of the fluid, which gives rise to the inert layer, is determined by the greater solidity and resistance of this part of the liquid.

Meteorological Society, April 2.—Prof. von Bezold, President, in the chair.—Prof. Börnstein spoke on the ebb and flow of the tide. After explaining the nature of the moon's action on the fluid part of the earth's surface, and showing that the flood is essentially due to a diminution of gravity and the ebb to its increase, he passed on to the consideration of the moon's attraction as it affects the atmosphere. Many experiments have been made with a view to proving the influence of the moon on the atmosphere, and at various places observers have succeeded in establishing a daily variation in the pressure of the air dependent upon the moon, and showing two maxima and two minima; these places are Singapore, St. Helena, Melbourne, and Batavia. The amplitude of the variation amounted to from 0·079 to 0·2 mm. But opposed to these are the observations of Laplace on the variations of the barometer in Paris, as also of Kreil in Prague, and further, Bessel's observations on atmospheric refraction. All these last-named observers found that the action of the moon on the earth's atmospheric envelope was either *nil* or else the reverse of that described above. Prof. Börnstein then discussed the question whether any ebb and flow of the atmosphere could possibly be detected with the means now at our disposal, and showed that the mercurial barometer can never be able to give indications of any such action, since it is itself affected by the alterations of gravity which are due to the varying position of the moon. He explained the phenomena observed at the four stations mentioned above as due to the fact that they are situated either on the sea-coast or on islands, at places on the earth's surface at which the ebb and flow of the sea is very considerable. The ebb and flow of the sea acts secondarily on atmospheric pressure, especially by means of the alteration of surface, and give rise to corresponding increases and diminutions in that pressure. Paris, Prague, and Königsberg are, on the other hand, inland stations, at which the barometer cannot be affected by any variations in the level of the sea's surface.

STOCKHOLM.

Royal Academy of Sciences, March 14.—On the essential results of the mathematical paper for which M. Poincaré received the mathematical prize of the King of Sweden, by Prof. Mittag-Leffler.—Derivation of some independent expressions of the Bernouillian numbers, by Dr. A. Berger.—On the plane curves which may be rectified through Abel's integrals of the first kind, by Dr. J. Brodén.—On the conform delineation of a paraboloid on a plane, by Herr H. von Koch.—On some remarkable minerals formed at a later period in the primordial strata of Sweden, by Baron Nordenskiöld.—Sur la chaleur latente de vaporisation de l'eau et la chaleur spécifique de l'eau liquide, par Dr. N. Ekholm.—New observations on the variation of the shape of the first abdominal appendices of the female crawfish, by Dr. Bergendahl.—Contributions to the anatomy of the Trematode genus *Apoblema Dujardin*, by Herr H. Juel.—Ascomycetæ from the Isle of Öland and from Östergötland, by Herr C. Starbäck.—On some triazol derivatives, by Dr. J. A. Bladin.—On bisphenyl-methyl-triazol, by the same author.—On the molecular weight of maltose and some inulinoid carbohydrates, by Dr. Ekstrand and Herr R. Manzelius.—Annotations on some European Orthotricha, i., by Lector Grönvall.—Déterminations des éléments magnétiques dans la Suède méridionale, by Herr W. Carlheim-Gyllenskiöld.—Formulas and tables for calculation of the absolute perturbations of the planets, by Herr Masal.

AMSTERDAM.

Royal Academy of Sciences, March 30.—Dr. Van den Sanden in the chair.—M. Forster stated the results of some experiments made in his laboratory, by Mr. Hunder Stuart and Mr. Fraser Ewman, on the presence of bacteria in the intestines. Mr. Stuart found that ordinary, and Mr. Ewman that typhoid, bacteria, introduced into the stomach along with the food, are discovered ter only in the lowest part of the smaller intestine and further in the large intestine. Ordinary bacteria have, therefore, no influence on the digestive process.—By means of known properties of polar systems and of elementary reasoning about reality, M. Schoute proved geometrically that the co-variant of Hesse, belonging to a binary equation with real co-efficients, is negative for the values of the variable that correspond to the real roots of the equation, independently of the number of its real roots; this is an extension of Dr. F. Gerbaldi's theorem (compare *Rendiconti di Palermo*, tome iii. p. 22).—M. J. A. C. Oudemans read a paper on the present state of the methods for determining the parallaxes of fixed stars.

VIENNA.

Imperial Academy of Sciences, February 21.—The following papers were read:—On the specific brightness of colours, a contribution to the physiology of visual sensations, by F. Hillebrand.—On the law of the decreasing of the power of absorption at increasing thickness of absorbent layers, by W. Müller-Erzbach.

CONTENTS.

THURSDAY, APRIL 25, 1889.

THE SURFACE OF THE EARTH.

Das Antlitz der Erde. Von Eduard Suess. Mit Abbildungen und Kartenskizzen. Erste Abtheilung, 1883: Zweite Abtheilung (Schluss des I. Bandes), 1885. (Prag: F. Tempsky. Leipzig: G. Freytag.) Zweiter Band. Mit 42 Text-Abbildungen, 1 Tafel, und 2 Karten in Farbendruck. (Prag: Wien. Leipzig: F. Tempsky, 1888.)

THE varied attainments of geographers have enabled them to express emphatic views on the scope of their subject. Each in turn has augmented knowledge of the earth's surface till it has become difficult to distinguish the contributions of mathematician and astronomer, physicist and physical observer, geologist and naturalist. Many geologists have been eminent as geographers, and Lyell and Humboldt gave the subject an enduring scientific importance by teaching the effects of geological causation in shaping the earth's surface. Every geologist is aware how the light of geological structure illuminates the problems of mountain form, position, and relation to surrounding land; but never till now has an author attempted to narrate the geographical story and history of the earth's surface from a geological point of view. Prof. Suess has brought to the subject the qualifications of a great teacher, who realizes that science has a duty to make itself available to the unlearned, no less than to aid the researches which are yet to be made; and he has conceived of the earth's surface in a new, forcible way, which stimulates alike imagination and thought, and lays before the reader a wide knowledge of fact. This work, which we know has occupied the author for the past twelve years or more, can scarcely be judged of as a whole, because the third volume, whose subject gives a title to the treatise, is unpublished; but we may say that a more luminous and profound endeavour to place the elements of scientific geography before the general reader has not been made. We may perhaps think the subjects discussed need the aid of more figures to enable the reader to think as the author thinks, and attain a similar command of his facts. The aim of the work is to lead the reader through a consideration of the movements in the outer layers of the earth's crust which are manifested at the present day, and in the first half of the first volume the more striking phenomena are narrated, which are associated with volcanic disturbance and earth movements. The second part of the volume examines the structure and construction of mountain chains. The author naturally takes the Alpine system first, as nearest to the Austrian people, and then treats of the depressions, like the Adriatic and Mediterranean, associated with the prolongations of the Alpine system. Successive chapters tell the story of the mountain structure of Southern Africa and the Sahara, of Central Asia and the Malay Islands, and of the mountain systems of America and the West Indies. Thus, by raising the mountain chains, the author leads up, in the final chapter of the first volume, to a discussion of the nature and origin of continents, no less than of their relations to the seas from which they emerge.

The introduction is an introductory lecture, not written like a syllabus, for that is given in the table of contents, but designed to introduce the reader to conceptions of a large kind on which the scientific aspects of geography are based. The distribution and forms of land masses and depths of the oceans are shown to be effects of movements of the earth-rind which have varied through successive geological ages and so changed the distribution of life.

The work begins with an exposition of the Flood and ancient Babylonian cosmogonies, and the author states that the Deluge was connected with the lower Euphrates and flooding of the low land of Mesopotamia, owing probably to an earthquake combined with a cyclone from the south. The interest of the unlearned reader is thus insured. An excellent account is given of earthquake phenomena, followed by a chapter on "Dislocations," which are defined as resulting from decrease in the volume of the earth, and as comprising horizontal and vertical movements. The crumpling, contortion, and folding of the rocks of mountain masses is classified as consequent on tangential thrust, sinking, and the combined effects of these actions. Volcanic phenomena occupy the next chapter, and are regarded as dependent on the formation of radial fissures. These general studies completed, we turn in the second part of the first volume to the mountains of the earth. The Russian table-land is described as consisting of granite in Finland, on which rest Silurian and Devonian, and successively newer rocks stretching under the Carpathians; but it is uncertain whether the newer rocks of this plain extend under the Bug. The Sudetic Alps are described as closely linked in origin with the Russian table-land and the Carpathians. The Franconian-Suabian basin follows, and leads to a discussion of the system of the Alps, which is regarded as beginning with the Carpathians, as curving south with the Jura, being prolonged south-east with the Apennines, and then continued west through North Africa to the pillars of Hercules. The plain of Hungary is compared to the eastern half of the Mediterranean. The Adriatic basin is closely connected with the Plain of Lombardy, both being defined by the Apennines, which, though at one time independent of the Alps, have now become connected with them. These mountains rise in an unbroken, steep curve facing those depressions, and looking like an outer border of the Alps thrust up above the level of the deep-lying basins. The history of the Mediterranean Sea is illustrated by the newer Tertiary deposits and the life which they contain. At first the sea reached the central plateau of France, the valley of the Rhone, Styria, Switzerland, Hungary, and Transylvania, stretching east to the source of the Euphrates and Northern Persia. The second phase of the Mediterranean was excluded from Switzerland and the valley of the Danube, and extended over the Russian plateau to Kherson and into Asia Minor. Later still it filled the valley of the Rhone, and approximated to its present outline, being excluded from Asia Minor; but the Ægean Sea was a fresh-water lake. The distribution of these deposits in North Africa is shown by means of a map in the chapter on the Sahara and Egyptian deserts; and evidence of the antiquity of the fauna of the Nile is found in the distribution of its life in Syria and Arabia. The

author now passes to South Africa, the Indian peninsula, and Madagascar, which have the characters of a table-land which was once continuous, and from their geological history the sediments are derived which constitute the Cretaceous and Tertiary rocks of the Sahara and Arabia. The high land to the north of India is fully described, chain by chain, in the details of geological structure which govern their forms and continuity, leading to the volcanic regions of Java and Sumatra. There appear to be four great curves southward, seen in the Iranian chain, Hindu Kush, Himalayas, and the Malayan chain. The connection between the mountains of Central Asia and Europe is traced on the basis of the distribution of Tertiary strata : all the European mountains are regarded as continuations of chains which extend from the Thian Shan group. The continuity here sought to be established would appear to depend not less on the evidence of denudation than upon stratigraphical proofs of contemporary folding. The author, for example, carries the line of Cyprus through Crete into the Dinaric Alps, while the chain of the Caucasus passes through the Crimea and Balkans by Ovsova into the Carpathians ; but these curved lines seem to us rather the results of denudation of folded rocks than an indication of the directions in which the lines of folding were prolonged.

Three chapters are devoted to North and South America and the West Indies, treating of the rock-structure and folding of the earth-rind in the same way as in other parts of the globe. The rind appears to the author as more plastic or more symmetrically bent than we have been accustomed to regard it, insomuch that he everywhere finds the chains curved, whereas we often find them extending at angles to each other. The volcanoes of the West Indies are found to have the same relation to the main chain as have those of the Apennines and Carpathians, being on the inner side of the arch. And the Caribbean Sea is further compared with the western part of the Mediterranean.

The second volume is devoted to the oceans, and commences with an historical account of views held by successive investigators on the displacement of the shore-line. Three lines of investigation suggest themselves : first, the changing distribution of the seas in successive periods of time, which may be furnished by evidence of shore-lines and sea-margins ; secondly, by comparing the areas of deposition of sediments in past time, some idea is obtained of the ancient oceans ; and thirdly, by studying existing shores, evidence is found of oscillations in level. Beginning with the great waters of the present time, a detailed history is given of the Atlantic. Its shores are described, especially in the northern regions, and the mountains which extend towards the European coast are traced, and said to be paralleled by chains on the other side of the Atlantic, so that the old rocks of Ireland, Cornwall, and Brittany, appear to extend beneath the ocean. The west coast of Africa, and shores of Central and South America, are similarly described and compared in the light of their geological structure. The Serro do Mar in South America is regarded as comparable with the Appalachian chain, and hence it follows that the entire American continent is the consequence of a tangential thrust towards the Pacific Ocean. The history of the Pacific Ocean begins with the shores of New Zealand and Australia, but the author avails himself of the fossil floras and other evidences to indicate ancient relations of the strata with the corresponding rocks of Europe, India, and other localities. The line is followed on through New Ireland, New Caledonia, Borneo, Cochin China, Tonquin, the Philippines, and Japan, and so by the Kurile and Aleutian Islands to the west coast of America, everywhere dwelling on the light thrown by the geological structure of those countries upon the variations in extension of the sea. The Atlantic and Pacific are compared with each other, and found to have many points of structure in common. The foregoing evidences of change in ancient oceans furnished by the rocks seen on their borders, necessitate a history of geological changes in the Palæozoic, Mesozoic, and Tertiary periods of time. In a chapter on Palæozoic oceans, it is stated that they make us aware of two continents which now only remain in fragments. The first occupied the North Atlantic Ocean, furnished the ancient sediments of Europe and America, and its remains persist as Greenland. The second continent is first recognizable at the end of the Carboniferous period. Its relics persist in Africa, India, and Australia. As the former is known as Atlantis, so the latter is named Gondwanaland. No seas of the Mesozoic period have left sediments which indicate great depth of water. The chalk alone may be evidence of a deep ocean, which stretched from Europe towards the West Indies in a yet earlier time. Towards the close of the Cretaceous period the seas became smaller. In North America the prairie lands from Canada to Texas and Alabama emerged from the water, and similar up-heaval is seen in Europe, and especially evidenced in the freshwater strata of the Pyrenees and Southern France, which make a transition from the Cretaceous to the Tertiary, like that shown by the Purbeck beds in early strata.

These earliest shallow conditions in Tertiary Europe were succeeded by a central sea which reached far to the east, and is estimated to have spread from London to Khartoum, and from Kiew to the Indian Ocean. And the author sketches with a bold hand the succession of physical conditions changing the breadths of water which have resulted in the contours of existing shore-lines in America and the Old World.

Evidences of the changes which have occurred in the contour of existing shores are found in detailed study of the coasts of Norway, and the inland terraces, which mark earlier extent of the sea and glacial action. Other evidences of instability of the shore-line are recorded with similar detail on the coasts of Italy. And the history of the Baltic and North Sea emphasize the mutability of shores. The historical records of the Mediterranean shores supply, especially in its eastern parts, striking proofs of oscillation in Greece, Syria, Egypt, and Asia Minor. The northern shores of the world supply many proofs that at the close of the Glacial period the shore-line was more elevated than it is now. An examination of the shores of the equatorial and southern seas demonstrates the former wide spread of deposits in which the life is substantially the same as in the nearest oceans, though there is sometimes, as in South America, a larger number of European species.

Finally, a summary is given of the characteristics and geological history of the oceans which have been de-

scribed. The southward direction of peninsulas is attributed to folding of the earth's crust, and to depression of the ocean floor, which has caused the water to predominate towards the south, so that they are always in relation to areas of depression. It will thus be seen that, in simplicity of conception, largeness and continuity of the ideas dealt with, amplitude and detail of the knowledge and inductions brought together and correlated, this work promises to be one of the most valuable contributions to the history of the earth which we possess. From the time when Godwin-Austen planned his work on the ancient physical history of Europe which geology supplies, data have been accumulating with a rapidity which has made the task almost hopeless, of writing a history of the earth's surface which should be at once exact in details and large in ideas. But Prof. Suess does not so much trench on geological history, which can only be told intelligibly when supported by masses of technical facts; for his aim is to impart vitality to learning and teaching of those phenomena with which the geographer is concerned. It may be too much to say that he attempts to do for the surface of the earth what Darwin did for the distribution and classification of life, because so much had been previously contributed with which his own work is in perfect harmony; but we may say that henceforth no geographical teacher can neglect to place before his pupils the methods and results which the author's work brings to his hand. And we may anticipate that much as Lyell's treatise, the "Principles of Geology," has laid the firm foundations of geological thought and of scientific observation in geographical science, so this treatise appears likely to mark a similar epoch in the history of geography, becoming a guide to its principles for students and readers.

It is significant that it is the outcome of long experience, first as Professor of Palæontology, then as Professor of Geology, on the part of one who has given many of the best years of his life to the endeavour to make practical application of geological knowledge in improving water-supply and navigation of the earth's surface which surrounds Vienna. The same thoroughness and devotedness with which these earliest of his public works were done are seen in this latest contribution to education; and we cannot but see that geography, as Prof. Suess teaches it, is a science based upon the sciences which he has himself professed, though expanding in its ultimate developments to include that knowledge which the naturalist and the observer of Nature record. Every chapter is followed by a long bibliography, in which the reader finds the more important original sources of information with which the writer has refreshed his memory; and the beautiful drawings and engravings scattered through the volumes will be not less welcome to the earnest student as presenting typical examples of the geological foundations of geographical truths seen on the earth's surface.

H. G. SEELEY.

NATURAL INHERITANCE.

Natural Inheritance. By Francis Galton, F.R.S. (London: Macmillan and Co., 1889.)

IT is related that, when some boastful patriot was once describing the trees in his country as so high that a man could hardly see their tops, a stranger retorted: "That is nothing to the trees in my country, which are so high that two men are required to see the top of them; one man looks as far as he can, and the other begins where the first stops." A similar division of labour would be required in order to survey adequately the imposing scientific edifice which Mr. Galton has constructed; based as it is on a foundation of geometrical reasoning, and culminating in the clouds of biological hypothesis. The parts which are nearest to *terra firma* are most within our ken. The mathematical foundation and the structure which rests immediately thereupon appear to us solid and elegant. The author has re-stated the law of error in a form adapted to sociological investigations. He says truly and happily:—

"This part of the inquiry may be said to run along a road on a high level, that affords wide views in unexpected directions, and from which easy descents may be made to totally different goals to those we have now to reach."

Mr. Galton reads a useful lesson to statistical practitioners, when he complains that they limit their inquiries to averages, without taking account of those deviations from the average which are the subject of the theory of errors.

"Their souls seem as dull to the charm of variety as that of the native of one of our flat English counties, whose retrospect of Switzerland was that, if its mountains could be thrown into its lakes, two nuisances would be got rid of at once."

Mr. Galton is not dead to the charms of "normal variability." Statistical theory illustrated by him becomes in a high degree fascinating:

"Not harsh and crabbed as dull fools suppose."

He may well say:

"Some people hate the very name of statistics, but I find them full of beauty and interest."

Some of his riders on the law of error may be interesting even to physicists. The following problem is not so familiar to astronomers, but that Mr. Galton's solution of it may deserve attention. Given three or four observations relative to an unknown quantity; and again another small group of observations made on some other quantity by the same instrument or method of observation; and so on, each of the different little groups not in general comprising the same number of observations: find from the residuals, or apparent errors, presented by the respective groups, the true "probable error" incident to the method of observation. Mr. Galton gives four solutions of this problem, of which two involve data which are special to his subject; two may be described as general. Neither of the latter coincides with the theoretically best possible method; but the consilience of their results with each other and with the other two methods is interesting.

We have worded the problems in terms of *errors.* The form in which it presents itself to Mr. Galton relates rather to the deviations of individuals from their common type. He is determining the "probable error" or dispersion of the heights of brothers compared with their mean. It proves to be much less than the corresponding constant for the adult population generally. The question arises in the course of an inquiry whether the mean height of brothers and sisters deviates from the general average of adults less than the height of their parents. There is a little difficulty in stating the question

owing to the difference in the mean stature of the sexes. Mr. Galton gets over this difficulty by multiplying all his female data by a proper constant—pushing them up, so to speak, to the male standard. Upon this understanding, suppose that the mean height of the father and the "transmuted" mother—the stature of the "mid-parent" in Mr. Galton's phraseology—differs from the mean height of the general population by say three inches. Then the mean height of the sons and "transmuted," or pushed up, daughters, is most likely to be not three inches, but two inches. The constant of "regression" is determined with equal precision for other relationships. A general idea is obtained of the extent to which the peculiarities of an individual are likely to be shared by his kith and kin.

It is not easy in a few words, or perhaps in any number of words unaccompanied by symbols, to do justice to the cogency and precision of this anthropometrical reasoning. The manipulation to which Mr. Galton's materials have been subjected by one of his mathematical coadjutors, Mr. Hamilton Dickson, fully attests their consistency and strength. Some additional corroboration may be afforded by the following considerations. The probable error or dispersion for the statures of adult men, which Mr. Galton has extracted from the family records submitted to him, is identical with, or differs only by a fraction of an inch from, the constant furnished by many other sets of measurements. The value here obtained for this constant is 1·7 inch. The same value is obtainable from the measurements made by Mr. Galton for the British Association. The same value has been obtained by Signor Perozzo for the whole of Italy, and for each of its provinces. The agreement of observations made under such different circumstances is calculated to give us confidence in the higher theory of anthropometry. The result which has been thus verified may be used to confirm Mr. Galton's reasoning at several points. Any scruples which he may suggest as to the discrepancy in the values of mean stature determined from his different records are removed by a consideration of the error or diversity to be expected among these results. Again, consider those tables in which Mr. Galton compares the heights of a number of persons with the mean height of their children or brothers, in which it is shown, for instance, that men of the height 71·5 inches have brothers averaging 70·2. That all the entries point in the same direction—namely, that of "regression"—is in itself adequate evidence of that fact. But not only are the faggots strong in their union, but also each individually is possessed of considerable strength. Thus, the discrepancy which we have just noticed between the height of a man and the mean height of his brethren, namely, 1·3 inch, is founded on eighty-eight instances. The chances against this degree of divergence occurring by accident are some hundreds to one. The odds that the appearance of law which the tables present is not accidental are immensely increased by this consideration. We should be curious to know whether Mr. Galton's experiments on the "regression" of sweet peas would admit of this sort of corroboration.

The human stature is a subject particularly well adapted to Mr. Galton's exact methods of measurement. Length admits of more exact gradation than the so-called secondary qualities. To arrange in a regular scale the colours of eyes which are variously described as dark blue, blue-green, hazel, and so forth, is a delicate task. How far Mr. Galton has triumphed over this imperfection of his data, it must be for specialists to decide. The student of probabilities cannot doubt that the correspondences between his observations and his calculations are indicative of a real law. The coherence of the table in which he compares fact and theory as to the number of light-eye-coloured children born to parents of various eye-colours cannot possibly be accidental. Ill-adapted as eye-colour may be to exact measurement, it is a more satisfactory quality to deal with than "the artistic faculty." Can we suppose that the compilers of the different family records which Mr. Galton has analyzed have employed at all similar standards, when they applied the epithets "artistic" and "non-artistic" to their relations? Our misgivings increase when we go on to apply the calculus to the returns as to disease which are obtained from the family records. To arrange parents and children in a graduated scale of "consumptivity," upon the testimony of unprofessional relatives, seems precarious. The author himself abandons the use of the more delicate methods when he goes on to consider "good and bad temper." He has not, however, shrunk from dividing into five degrees or classes some sixty shades of temper ranging from "amiable" and "buoyant" to "surly," "uncertain," "vicious," and "vindictive."

We ascend into a region of hypothesis when we speculate on the causes of the phenomena which have been evidenced. The attention of biologists should be called to Mr. Galton's views on "particulate inheritance," "latent characteristics," and the stability of organic forms. The conceptions which he has formed as to the processes of heredity are placed by him in a variety of lights, and illustrated by many happy analogies. "Appropriate and clear conceptions," it has been well said, are essential conditions of science. Mr. Galton has done much to make his abstract ideas clear, but are they also appropriate? This is a question upon which, perhaps, only a few specialists are competent to advance an important opinion; and their authority is liable to be impaired by the prejudices incident to an exclusive line of research. We shall be slow to accept adverse criticism from any whose studies may not have qualified them to appreciate the support which Mr. Galton's theories receive from his masterly use of the calculus of probabilities.

F. Y. E.

NATURE'S HYGIENE.

Nature's Hygiene: A Systematic Manual of Natural Hygiene, containing a Detailed Account of the Chemistry and Hygiene of Eucalyptus, Pine, and Camphor Forests, and Industries connected therewith. By C. T. Kingsett, F.I.C., F.C.S. Third Edition. (London: Baillière, Tindall, and Cox, 1888.)

THIS book aims at being a systematic manual of natura[l] hygiene. The introductory chapters deal in a popular manner with chemical principles and chemical changes, leading up eventually to questions affecting the chemistry and hygiene of the atmosphere, of water, of sewage, and of

numerous other subjects supposed to be included within the domain of natural hygiene. The second part of the book is devoted to what are called the sanitary properties of Eucalyptus-trees, of pine-trees, and of camphor forests. At first sight the general character of the work impresses the reader favourably. He is disposed to read it for the sake of acquiring information on subjects which force themselves on public notice in every large town. These are: the purification of water; the relations existing between micro-organic life and the so-called infectious or contagious diseases; the measures to be adopted for the disposal and treatment of sewage, and the relative value of certain antiseptics and disinfectants. The author devotes to these subjects numerous pages of information more or less relevant to them. At p. 217, however, the author arrives at the matured conclusion that "the only disinfectant which, while possessing all these characters, also acts upon anaërobic and aërobic forms of life alike, of which I have knowledge, is that known as ——, for the existence of which I am proud to take credit." Besides this disinfectant, there is an equally good "fluid," an equally good "oil," and an equally good "powder," for all of which, no doubt, the writer has also pride in taking credit. There are in all some thirty references to these specifics.

The concluding chapters, in which *Eucalyptus globulus* and other species of Australian gum-trees are credited with wonderful powers as "fever-destroying trees" on account of "the aromatic vapours which emanate from the trees, and the preservative powers of the branches and leaves which fall on the ground," repeat a well-known but scarcely established doctrine of hygienists. It is probable that any fast-growing tree, suited for swampy districts, would produce exactly the same or similar results. But, granted for the moment that the essential oil given off in a vaporous condition from Eucalyptus or pine-trees is disinfectant in character and conducive to health, we fail entirely to see how this can apply also to camphor-trees. Yet we are told that "the natural history of camphor forests affords us another and remarkable feature of Nature's hygiene; . . . that atmospheric oxygen is constantly being absorbed by the essential oils that are continuously evolved into the air, and this simple process gives rise to the production of a number of active chemical substances, including peroxide of hydrogen and soluble camphor, all of which purify the air and enhance the healthful influences of the climate." Those who are at all acquainted with camphor-trees will admit that this is a very fanciful picture indeed. In common with most members of the *Laurineæ*, the emanations from camphor-trees are neither agreeable nor balsamic. The author brings no evidence whatever to establish his position, and we beg leave to doubt the healthful influences of camphor-trees on the grounds stated until we have something more tangible than the mere assertion of the author of this work.

OUR BOOK SHELF.

Elementary Inorganic Chemistry. By A. Humboldt Sexton, F.R.S.E., F.I.C., F.C.S. (London: Blackie and Son, 1889.)

THE chief part of this manual of 320 pages is specially prepared for students who are guided by the elementary division of the Syllabus of the Department of Science and Art. In addition there are twenty-five pages about the metals and their compounds, a chapter of nine pages on what is called "Organic Chemistry," twenty-three pages of "Experimental Illustrations," a chapter on "Chemical Arithmetic," a series of questions, an "Elementary Course of Qualitative Analysis" occupying thirty pages, and a few less important matters.

The main part of the book is pretty much what one is accustomed to in elementary treatises: it is clear and calculated to be useful; but the chapters on the metals and on organic chemistry are obviously meagre to a degree. The organic part deals with those substances mentioned in the alternative course of the above-mentioned Syllabus, but it would have been much better for the book and the students who use it if these few pages had been omitted. The analytical course refers to eight metals and four acids. It is not stated why these substances are specially favoured.

It is a pity that those who write on a subject like elementary inorganic chemistry, which has been so prolific of text-books that practically speaking no exertion or thought is needed in the selection of topics or the manner of their treatment, should not more often concentrate a little attention upon the exactness of their expressions. The statement, for example, that "If hydrogen and oxygen or air be mixed, and a light be applied, they will combine with a violent explosion," is open to much censure. Do hydrogen and air ever combine? Will a mixture of hydrogen and oxygen as a matter of course explode under the circumstances described? Again, the statement that "Potassium and sodium only expel one-half of the H from water" may be legitimately described as untrue. The equation "$Na + H_2SO_4 = NaHSO_4 + H$" is more likely to deceive than instruct the student. These are not isolated examples.

A Class-book of Geography. By C. B. Clarke, F.R.S. (London: Macmillan and Co., 1889.)

THIS is a new and revised edition of Mr. Clarke's well-known class-book of geography, which was first published in 1878. The populations of towns have been brought up to date, as also the political geography of Egypt, Turkey, &c. The names of places which have lately become of importance in consequence of commercial enterprises, such as Baku, have also been added. Perhaps the most important addition, however, is a chapter on astronomic geography, which is very clear, though necessarily not very detailed. An excellent outline of chartography has also been added. The particulars given relating to each country are of the usual character. They include an historical sketch of each country, manufactures, minerals, animals and plants, languages, religions, and forms of government. At the end of each section is a condensed statement of the principal features of each country. A short description of the different races of animals might have been given with advantage, as at present the student can only gatner the meanings of such terms as "Pachyderms" and "Chiroptera" from the examples quoted. The omission of the word "species" in such a sentence as: "England possesses one *dormouse* and one *squirrel*," is rather apt to make one inquire as to the location of those favoured animals.

There are eighteen excellent double-page maps, but of course they are not so full of detail as is necessary for a complete study of the subject. This, however, is no great drawback in these days of cheap atlases.

Travel-Tide. By W. St. Clair Baddeley. (London: Sampson Low, 1889.)

THE writer of this volume has visited many different parts of the world, and here he sums up the impressions produced upon him by the most remarkable of the scenes with which he has made himself familiar. There is

nothing of strictly scientific interest in the book; but we may say that Mr. Baddeley has the great merit of always trying to see things with his own eyes, that in his judgments of men and places there is no trace of any kind of British prejudice, and that his style is fresh and interesting. Among the subjects of which he has something to say are Bulgaria, Buenos Ayres, Constantinople, and Tunis.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Large Fireball.

ON the night of Monday, April 15 last, at 12h. 26m., a meteor of very exceptional proportions was observed from many parts of the country. The full moon was shining at the time, and near its meridian passage, but the brilliancy of the fireball was such that it vividly illuminated the sky and landscape with a flash which many people mistook for sheet lightning. Several observers describe the meteor as larger and considerably more brilliant than the moon, and at Swindon and Ramsbury a detonation was heard. At the former place the meteor "appeared so close that people thought it descending upon the town; it startled the rooks out of the trees, and suddenly illuminated the country round like the electric light."

At Worthing the meteor is described as falling almost perpendicularly from west-north-west to due north. At Clapham it seemed to take a slanting course from the south towards the west. At Bath the meteor was seen in the east moving horizontally, at a considerable altitude, from right to left. Probably therefore the body was situated over the region of Berks, but the data are altogether too imperfect to admit of trustworthy inferences either as to its position or height above the earth's surface.

It will be important if other observers can furnish accounts in which the position and direction of this fireball are more definitely given. The phenomenon was clearly one of uncommon character, but its apparition occurred at such a late hour that comparatively few persons must have witnessed it.

Bishopston, Bristol, April 20. W. F. DENNING.

Variable Stars and the Constitution of the Sun.

IN NATURE of March 21 (p. 492), Mr. A. Fowler has given an excellent account of my theory of the constitution of the sun, but he has not succeeded so well in describing my theory of the variable stars. I may here draw attention to some of the cardinal points not sufficiently noticed by Mr. Fowler:—

(1) The proof that the chemical combination at the external layers of the stars must be intermittent with regular intervals. This proof, pp. 8, 9, and 10, is mentioned as the very basis of my theory of the sun and stars.

(2) The fact that the intermittent eruptions of heat, if produced in this manner, cannot become visible through some perceptible increase of the heat of the star.

(3) The high probability that in the case of some red stars the vapours, noticed by the spectroscope in their external layers, are cooled to their dew-point, and so, with the smallest radiation of heat, are made ready to change into clouds, which suddenly withdraw the invariable inner light from our view.

(4) The high probability, too, that only those stars will be variable in which the external layers are cooled down to their dew-point, and that the intermittent eruptions of heat become visible because at intervals they cause the evaporation of the clouds, which surround the invariable inner light of the star during the minimum.

Therefore only those stars of Class III. will be variable, whose external vapours are cooled to their dew-point. The others also have their periodical eruptions of heat, but these are inperceptible to our eye.

The changes of the variable stars, therefore, are never associated with important changes of temperature. It would be possible for them to take place without the least change of temperature if the calories produced by an eruption of heat were entirely used for the evaporation of the clouds. And so even an increase of temperature of 1° would be sufficient to make a seemingly extinguished orb glitter again as a new star, whilst a similar decrease of temperature would suffice to restore the veil, which, steadily growing thicker, would make it invisible again, perhaps for centuries together.

Mr. Fowler is mistaken in saying that I do not seem to be aware that Algol is one of the hottest stars in the heavens, and that its spectrum is the same at maximum as at minimum. On the contrary, on p. 15, I have stated the exceptional case of Algol, and, seeing the impossibility of making it agree with my theory as in the case of those Algol-stars which are red at minimum, I ascribed the variability of Algol to the periodicity of its spots. Moreover, I added that this seeming contradiction to my theory was only a physical peculiarity of little importance. For the spots, too, are caused by periodical eruptions of heat in clouds. The only difference is that the clouds—I mean on the sun and Algol—are photospheric, and by vaporization cause dark spots which diminish the light, whilst in the cooler red stars, the clouds form a dark veil round the star, and therefore by vaporization increase its interior light.

In this defence of my theory, gradually passing from the variable stars by means of Algol to the sun, I must observe that my theory by no means suggests, as Mr. Fowler thinks, that the sun should have more spots in the Polar regions than near the equator. I only say that the spots must be found in parallel zones; of the breadth of those zones I say nothing. The spots can only be produced in places where the temperature and the chemical compositions work together to produce eruptions of heat. As the places of equal chemical composition and of equal temperature are only possible in the photosphere in two parallel zones of equal latitudes on opposites sides of the equator, it is plain that the spots must be produced there.

I conclude with an expression of gratitude to the Editor of NATURE and to Mr. Fowler for the trouble they have taken in noticing my theory. A. BRESTER, Jz.

Delft, April 1.

IN reply to Dr. Brester I have to remark, in the first place, that I made no attempt to give all the details of the theory, limitations of space not permitting. One of my principal arguments against the theory was that, if it were true, *all* cool stars should be variable, and I still see no reason to alter my views. The observations of the red stars by Dunér show that the spectra of some of the stars which are not variable are identical with some of those which are. For example, the spectra of 120 Schj., and D.M. + 47°·2291, which are not variable, are exactly like those of χ Cygni and R Leonis. The *compositions and temperatures* of the gaseous surroundings of these bodies are therefore similar, and there is no reason, from Dr. Brester's point of view, why one should be variable more than another, since, if they are cooling, they all start cooling under exactly equal conditions. (It may fairly be assumed that the spectra of the variables have been generally taken at maximum.) The cooling to dew-point is therefore not in question in the variable any more than in the apparently invariable stars.

The high probability that by far the greater number of variables are uncondensed meteor-swarms which are increasing in temperature, as demonstrated by Mr. Lockyer, is also obviously against any theory of variability which assumes a state of cooling.

The same objections which apply to the red stars apply also to the "unimportant" case of Algol; there are many other stars with identical spectra, and therefore temperatures, which exhibit no variability at all.

With regard to the sun, I remarked that the theory would suggest that spots should be most numerous at the poles, for the reason that it would be there where the atmosphere in the neighbourhood of the sun would be coolest, and where, therefore, chemical combinations would be most likely to take place. To this Dr. Brester replies that his theory only requires that spots should be formed in equal zones on opposite sides of the equator, and says nothing about the breadth of the zones. Of course, if it be assumed that the substances present in Polar regions are not such as to form combinations competent to produce spots, the difficulty is overcome, but an explanation depending upon such an assumption is far from satisfactory.

London, April 5. A. FOWLER.

Tertiary Chalk in Barbados.

IN a previous communication (NATURE, February 14, p. 367) we called attention to the series of oceanic deposits in Barbados, of which the well-known Radiolarian earth (or Polycistina marl) forms a part. We stated that these deposits had a wide extension, and were of variable composition, some being much more calcareous than others; and further that they formed an independent series, resting unconformably on the older clays and sandstones which are supposed to be of early Tertiary age.

Since the date of our former note, we have examined many sections along the outcrop of the deposits, and find that the varieties which we had noticed fall into a natural succession, the calcareous earths lying principally at the base, though in the northern part of the island there is a development of similar beds at the summit. The total maximum thickness is about 200 feet, and the series contains many interesting varieties of rock. We hope to describe these at length, and to lay our results before the Geological Society, but as some time must elapse before this can be done, we write at once to place on record the fact that some of the beds have all the essential characteristics of typical (Cretaceous) chalk.

We have samples which consist of from 80 to 90 per cent. of calcium carbonate, which give the usual white streak of chalk, which contain Foraminifera in abundance, and have a minute structure which can hardly be distinguished from that of certain portions of the English chalk. A thin slice examined under a 1-inch objective shows many Foraminifera distributed through a matrix which under this power appears to be amorphous; the Foraminifera are chiefly Globigerinæ of the thick-shelled type similar to that figured in Carpenter's "The Microscope and its Revelations," sixth edition. Examined under a higher power the matrix can be resolved into definite particles, among which can be distinguished many forms identical with the so-called crystalloids of the chalk. Our friend Mr. W. Hill, to whom we sent a specimen of this Barbadian chalk, says it presents a very close analogy to our English chalk. Other samples combine the characters of chalk and Radiolarian earth having a calcareo-siliceous matrix containing a mixture of Radiolaria and Foraminifera.

We believe that the Barbadian deposits were formed on the floor of the Atlantic previous to the upheaval of the Caribbean Islands, and this conclusion is strengthened by the fact that similar Radiolarian earths occur in Trinidad and Hayti. We find too that the late Dr. Carpenter remarked that if the modern oceanic oozes were uplifted they would form deposits similar to the Barbados earths ("The Microscope and its Revelations," sixth edition, p. 602).

We wish to correct one paragraph in our former letter, in which we tacitly assumed that the Caribbean Islands were originally part of the American continent, and were therefore continental islands; we are now disposed to regard Barbados at any rate as an oceanic island, and believe that it has never been connected with South America since its upheaval as an island. Colonel Feilden has collected some evidence on this point which we hope he will shortly publish. We may state that the nearest island to Barbados (St. Vincent) is one hundred miles to the west, and that the intervening sea is more than 1000 fathoms deep.

But whether classed as an oceanic or a continental island, the rocks of Barbados are equally interesting to the physical geologist, since they give proof of a complete interchange of continental and oceanic conditions in Tertiary times; for the underlying sandstones and shales imply the close proximity of a continent during their formation, while the chalky series proves the subsequent conversion of this shallow sea into an oceanic area. Moreover, the existence of both sets of rocks now at the surface is entirely antagonistic to the prevalent theories respecting both continental and oceanic islands.

J. B. HARRISON.

A New Mountain of the Bell.

I HAVE just returned from a journey of four weeks in the desert of Mount Sinai, made with the especial object of studying the *Jebel Nagous* in connection with the joint researches of Dr. Alexis A. Julien and myself on "musical sand." The "Mountain of the Bell" is situated on the Gulf of Suez, about four and a half hours from Tor by the roundabout camel route. It was first described by Seetzen in 1808, since which time it has been visited by Ehrenberg, Gray, Wellstedt, Rüppell, Ward, Newbold, and the late Prof. Palmer, as well as by large numbers of pilgrims. My observations confirm in the main their accounts of the acoustic phenomena heard, but my measurements differ widely from those of all the travellers save Prof. Palmer.

The name Jebel Nagous is given by the Bedouins to a mountain nearly three miles long and about 1200 feet high, composed of white sandstone bearing quartz, pebbles, and veins. On the western and northern sides are several large banks of blown sand, inclined at high angles. The sand on one of these slopes, at the north-west end of the mountain, has the property of yielding a deep resonance when it slides down the incline either from the force of the wind, or by the action of man. This bank of sand I distinguish from the others by calling it the *Bell Slope*. It is triangular in shape, and measures 260 feet across the base, 5 to 8 feet across the top, and is 391 feet high. It has the high inclination of 31° quite uniformly. It is bounded by vertical cliffs of sandstone, and is broken towards the base by projecting rocks of the same material. The sand is yellowish in colour, very fine, and possesses at this inclination a curious mobility which causes it to flow when disturbed, like treacle or soft pitch, the depression formed being filled in from above and advancing upward at the same time. The sand has none of the characteristics of sonorous sand found on beaches. When pulled downwards by the hands or pushed by the feet a strong vibration is felt, and a low note is plainly heard resembling the deep bass of an organ-pipe. The loudness and continuity of the note are related to the mass of sand moved, but I think that those who compare it to distant thunder exaggerate. The bordering rocky walls give a marked echo, which may have the effect of magnifying and prolonging the sounds, but which, as I afterwards demonstrated, is not essential. There are no cavities for the sand to fall into, as erroneously reported. The peak of Jebel Nagous rises above the Bell Slope to the height of 955 feet above the sea-level, as determined by a sensitive aneroid.

After studying the locality and phenomenon for several days, I formed the opinion that it could not be unique as hitherto supposed, and accordingly I tested every steep slope of blown sand met with on the caravan route northward to Suez. On April 6 I examined a steep sandbank on a hillock only 45 feet high, and was rewarded by the discovery of a second Nagous. This new Nagous is in the Wadi Werdan, only five minutes off the regular caravan route, and one and a half days, by camels, from Suez. The hillock is called by the Bedouins *Ramadan*, and forms the eastern end of a range of low hills about one quarter of a mile long; being the only hills in the Wadi, the locality can easily be found by travellers. The hills consist of conglomerate and sandstone, and to the west of gypsum; they slope up gradually from the north and end in bold cliffs on the south side. Sand blown by the north wind is carried over the cliffs, and rests on the steep face at two inclinations, 31° above, and 21°, or less, below. By applying the usual tests with the hands to the fine-grained sand, I found that wherever it lies at the requisite angle to produce mobility (31°), it yielded the bass note, though not so loud as on the Bell Slope of Jebel Nagous. In one instance, my friend and fellow traveller, Mr. Henry A. Sim, of the Madras Civil Service, who kindly aided me in my investigations, heard the sound while standing 100 feet distant. The Nagous sand occurs at intervals throughout the 500 yards of low cliffs; the main bank at the east end being 150 feet wide and 60 feet high measured on the incline. I stirred up the mobile sand pretty thoroughly on this slope, and the next day it failed to give the sounds, not having recovered its properties. The intervening night was very cold (53°). I feel confident that this phenomenon is not very rare in the desert, though the spontaneous production of sounds by sliding of the sand without man's agency, as at Jebel Nagous, may be. Whether the *Rig-i-Rawan*, north of Cabul, is caused by similar conditions remains to be determined, but I fear that the peculiar relations existing between England and Russia will prevent my visiting Northern Afghanistan. The Bedouins who accompanied us were greatly astounded at my discovery of a new Nagous, and I fear that their faith in a monastery hidden in the heart of Jabel Nagous has received a severe shock. It is interesting to note that the Nagous or modern gong is in daily use in the Monastery of St. Catherine, Mount Sinai.

I made photographs of Jebel Nagous and vicinity, as well as of the new Nagous, and collected specimens of the rocks, sand, &c. This communication must be regarded as a preliminary notice, full details being reserved for the work on "Musical Sand" in preparation by Dr. Julien and myself.

I shall be obliged if those who have opportunities of examining banks of dry and fine sand inclined at 31° will report through your columns whether they yield deep sounds when disturbed.

Cairo, April 10. H. CARRINGTON BOLTON.

AIR-TIGHT SUBDIVISIONS IN SHIPS.

THE last two months have been unfortunate ones for shipping generally, and more particularly for the navies of at least four of the great powers. France has lost two torpedo boats under such circumstances as to involve the condemnation of a whole class of vessels. Germany and the United States of America have each lost a small fleet in a hurricane of unusual violence. Besides the material loss of ships these three nations have to bemoan the loss of a considerable number of men. Only little more than a month ago one of the largest ships of the British Navy stranded in waters rightly assumed to be perfectly safe, and has become a total wreck. Fortunately in this case there was no loss of life. Another of her H.M. ships only just escaped the disaster which overwhelmed the German and American fleets at Samoa, and the circumstances attending her escape are worthy of a moment's attention.

The storm approached not without warning, and it is evident that the captains of all the ships set about making preparations for meeting it as best they might. They appear all to have got up steam, so as to ease their cables by steaming to their anchors, in case it should be impossible to get out. The only ship that did get out was H.M.S. *Calliope*, and without in any way detracting from the merits of her captain and those under his orders, it is evident, from the brief accounts to hand, that all would probably have been unavailing had she not been provided with very powerful machinery. In the Navy List her tonnage is given as 2770, and her horse power as 4020, or one and a half indicated horse power per ton of displacement. The most powerful of the other ships was the German corvette *Olga*, which apparently had considerably less than one horse power per ton of displacement.

The other ships, especially the American ones, were so deficient in power that they were unable to make any front to the storm at all. Even with her great power the *Calliope* was only able to attain an effective speed of half a knot per hour in the teeth of the storm. All praise is due to the men who were able to make such good use of this very meagre margin as to have saved a costly ship and many valuable lives for the further service of their country.

The Samoan disaster has thus, in a dramatic and even tragic way, shown the uses of steam power in saving a vessel by propelling her against a storm. Reflections on the loss of the *Sultan* lead us to ask if steam power cannot be made more useful in succouring and saving a ship after she has struck a rock, or in any other way received such damage to her hull as to render her loss by foundering imminent.

According to convention an engine is working at the rate of one horse power when it is lifting a weight of one ton against gravity at a velocity of 14·74 feet per minute. If, then, a ship is fitted with engines indicating one horse power per ton of displacement, these engines would, if their whole power could be usefully applied and directed against gravity, be able to keep the ship afloat so long as she did not sink at a greater rate than 14·74 feet per minute. The *Vanguard* took seventy-two minutes to sink. The practical question comes to be, How can the ship's power, of engines or men, be best applied so that the greatest proportion of it may be made available for keeping her from sinking?

Hitherto it has been usual to fit all ships with suction pumps, capable of being worked, some by steam and some by hand power. To use such pumps with effect it is necessary that they should be worked at such a rate as to throw overboard more water than can enter the ship in a given interval of time. The lower they bring the water in the hold of the damaged ship, the greater is the facility offered for the water to enter, and the harder becomes the work of lifting it. If the damage to the ship's hull is in any way serious, dealing in this way with its effect is almost always hopeless, unless it is possible to get at the leak and reduce its dimensions or close it altogether. The bottom of a ship at sea is very inaccessible. If she remains fast on the rock it is usually impossible to get at the leak either from the outside or from the inside. If she is afloat, and will keep afloat long enough, the leak can often be efficiently dealt with by passing a tarpaulin or sail under her bottom. But this is by no means a simple or easy operation, even when performed as a matter of drill with plenty of time, and in the absence of excitement or danger.

When a ship is sinking, she does so because water has got into her either from above or below, and has displaced the air with which she was charged. In order to stop her sinking and to raise her to her original level, it is necessary to reverse the operation and replace the water again by air. If the water has come in from above, by shipping seas, this can be effected by suction pumps, which throw it overboard again. If it has entered and is entering through a hole in the bottom of the vessel, it is necessary not only to remove the water which has entered, but to stop any further entry, and this is achieved by any means which enables us to thrust the water out again by the same way as that by which it entered.

If we consider a ship's hold, and assume that the deck covering it above, and the bulkheads shutting it off fore and aft, are all sufficiently strong and air-tight, then, if the whole bottom were allowed to drop out, her stability being otherwise assured, she would be very little the worse; the water would rise in her hold only until it had so far compressed the air that its tension exactly balanced the pressure of the column of water outside, and matters might safely remain in this condition of equilibrium almost indefinitely. Thus, by making the main deck of a modern ship, to which the water-tight bulkheads are carried up, air-tight, she would be practically proof against all risk of sinking from damage to her bottom.

I do not think that there would be any difficulty in making the compartments of a ship perfectly air-tight, or more properly, in fitting them so that the rise of tension quickly produced by the entry of water through a serious leak, would at once close any joints or small openings, in the same way as the door of the air lock giving entrance to a submarine caisson is kept closed and air-tight by the pressure of the air within. But inasmuch as the smallest leak of air, whether through the deck or through the bulkheads, would represent an equivalent of water entered and of buoyancy lost, it is necessary to be able to make good the loss by mechanical means. The more carefully the decks and bulkheads have been fitted in the first instance, the less will be the amount of air which will be required to be supplied by engine or man power in order to keep the water out in the event of serious damage to the ship's bottom.

Dealing with leaks in this way is equivalent to transferring the leak from the ship's bottom to her deck, and dealing with it there in the shape of an escape of air in place of an entrance of water.

In order to make successful use of this method it is necessary that the ship's deck and bulkheads should be not only air-tight, but also sufficiently strong to resist a pressure which, in the case of even the largest ships, would not exceed one atmosphere, or 15 pounds per square inch. Each compartment would have to be about as strong as an old low-pressure marine boiler.

Modern men-of-war are built in such a way that they require nothing but the air-tight hatches, and air-forcing

pumps to make them quite secure against the most extensive damage to their bottoms. Indeed, as regards the stoke-holds, they are already fitted with the air-tight hatches in order to be able to used forced draught for the furnaces. Modern merchant ships are built with an iron deck, so that there is no difficulty about providing the strength. Their hatchways are, however, always very large; but, on the other hand, there is little traffic through them, so that they could be treated in a more substantial way than the smaller hatchways of a man-of-war with her large complement of men. The bulkheads which subdivide the hold into compartments always profess to be water-tight, and to be able to resist the pressure exercised by the water filling the compartment. There should therefore be no difficulty about them. Indeed, if ships were built to withstand air pressure, a very simple method would be provided for testing the efficiency of the bulkheads without the disagreeable process of filling the compartment with water. It would be only necessary to close the legitimate openings and get the air in it up to a pressure equal to that of the ship's draught of water, and the result would be unequivocal. It is proper to observe that the construction of an air-tight bulkhead would differ slightly from that of a water-tight bulkhead, inasmuch as it will be exposed to the maximum pressure over its whole surface, whereas the water-tight bulkhead is exposed to a graduated pressure, being greatest at the keelson, and least under the deck.

A further advantage of fitting a ship with air-tight subdivisions is, that it not only gives her greater security against foundering, but it affords a means of largely insuring her against risks of fire. This has more especial reference to merchant ships. If the contents of a ship's hold catch fire, the easiest way of putting it out is to stop the supply of air, and this can be done if the hold is air-tight.

So far the damage to the ship is supposed to be a rent in the bottom. If it is not in the bottom, but somewhere above it, then the air can only expel the water down to the level of the breach, when the air will begin to escape through its uppermost part. It will now depend on the supply of forced air available, how large a hole can be kept continuously filled by a stream of air rushing out. The area so occupied is necessarily closed to the entrance of water, and if the machinery can supply air at a sufficient rate, the whole rent can be filled by a current of air, which, so long as it is kept up, is as efficient a leak stopper as a plate of iron would be, and meantime the bottom of the hold can be cleared by the ordinary bilge pumps.

Rents in a ship's side, such as are produced when she is run down, or rammed by another, are usually so extensive and serious that, unless the ship is protected by an inner skin, immediate destruction ensues before there is time to take any measures for rescuing her. But with an inner skin the damage may be so far reduced as to make it possible to deal with it as above indicated. The higher up on the ship's side is the damage the less suitable is the pneumatic method for dealing with it, if it is of a really extensive character; but, on the other hand, the more easy is it (given the time) to get at it, and deal with it from the outside. In all cases where the ship has been damaged by touching the ground, or by torpedo explosion under the bottom, and not involving the destruction of the ship, the pneumatic method affords the readiest means of combating the results.

It must be remembered that a ship's hold when filled with compressed air will be *habitable;* that is, if an air lock is provided, men can descend into it and repair the damage, just as they can descend into a caisson and dig out the foundations for the pier of a bridge.

The pneumatic method is however not only adapted for keeping damaged vessels afloat, it is also useful for raising sunken or stranded ships. For this purpose the salvage steamer must be provided with air-forcing pumps as well as the suction pumps which she usually carries. Having closed, and if necessary strengthened the deck, by means of divers if below water, she then pumps air into the holds of the ship, and at once restores a large proportion of her original buoyancy to her. If she does not rise, the other methods of salvage can be applied in addition, and with much increased chance of success.

The principle of this method is not new. A very old device in endeavouring to float, or to keep afloat, ships, is to fill as much of their damaged hold as possible with empty casks. A later modification of this method is to use inflatable india-rubber bags. It may be remembered that after the *Vanguard* sank Admiral Popoff of the Russian Navy sent a large apparatus of this kind in order to render assistance in trying to float her. Both these appliances are cumbersome. A ship's hold is seldom quite empty when she sinks, and even if it were, it is not easy to fill it under water with casks full of air, or even with inflatable air bags; and in any case it is difficult in this way to fill more than a fraction of the hold with air. The simple and efficient way of dealing with the matter is to treat the ship's hold itself as the vessel to be filled with air.

Compressed air is every day occupying a wider field as a means of transmitting power. It is already used as a substitute for gunpowder in the guns for firing shells with high explosives. It seems to me that if it can be used for largely increasing the safety of life and property at sea it is right that the fact should be brought as prominently forward as possible, in the hope that it may receive practical application in the hands of the shipbuilder and the engineer. J. Y. BUCHANAN.

NOTES ON STANLEY'S JOURNEY.

I HAVE watched every footstep of Stanley for the past twenty years, had constant intercourse with him during his short visits to this country, and have unbounded confidence in him as a pioneer, for I cannot but admire the noble efforts he has made to open up Africa to civilization. Wherever he has travelled he has left his mark behind him; others may follow his example without fear of being molested, and he has given us such vivid descriptions of the regions mapped by him that, for all practical purposes, no traveller need supervise his work. Some say he has been too high-handed with the natives, but I may be allowed to think that his power of influencing those over whom he holds command has proved him to be the most trusted and successful traveller of the age. If his explorations be quickly and judiciously followed up, the native inhabitants will feel security against all oppression, and the traders in slaves will be expelled from the country.

Brilliant is scarcely the name to give the exploit of Mr. Stanley, as given in his recently published letters. What instance in travel can excel such devotion? Is there a schoolboy who does not admire a man with his indomitable pluck and dogged perseverance? His latest journey to relieve Emin Pasha has outstripped, if possible, all his previous explorations in the "Dark Continent." Those 160 days of toil, from June 28 to December 12, 1888, through starvation, desertion, mutiny, savage dwarfs and cannibals, thorny thickets, darkness, and swamps, were enough to try the patience of any human being; but, thank God, his British pluck never failed him; on and on he pressed, while his native followers were in utter despair, and broke out into mutiny. He used every persuasion with them: all failed. What was he to do? He felt that his duty was to relieve Emin Pasha—his countrymen expected this—and, with his accustomed sense of what was just and right, the two ringleaders of the mutinous band

were hung in the presence of his camp followers. This wholesome example proved to be the saving of his expedition. He emerged from the poisoned atmosphere of the forest, and says that he was amply rewarded when his remaining native followers kissed his hands in grateful acknowledgment of being delivered from death.

The party proceeded on, moving with great glee across the grassy slope amidst villages and cultivation, soon standing upon the brink of the crags which overhang the western shores of the Albert Nyanza of Baker. Here fresh difficulties arose; the suspicious natives would give them no canoes, would hold no intercourse with him. Emin Pasha's steamer was not in sight, and, after consulting his officers, Stanley retired to an entrenched position, sent Stairs, R.E., for his English-built boat, and, terrible though this journey has been in every form, the heroic Stanley won his point, and shook hands with Emin Pasha on April 29, 1888, 465 days after leaving Charing Cross to his relief.

It is quite possible that he may return to England by the end of May, but there are several reasons which may delay him. The difficulty of providing for so large a party as ten thousand followers belonging to Emin Pasha—this is a most anxious charge. Again, Stanley's thirst to solve the problem of the unexplored country south of the Albert Lake may lead him there, and I really feel more anxious about him since the arrival of his letters than I felt before we heard of his safety, for he is so fearless, he never sees a difficulty.

The marvellous growth of vegetation upon Stanley's route is not to be wondered at, as we know that in similar latitudes, such as Uganda, Borneo, and the Amazon, the same density of undergrowth and forest exists. A band of moisture encompasses the world at the equator, extending three to four degrees of latitude on either side; the vertical rays of the sun beat down with great intensity, and vegetation is almost seen to grow. In Uganda I have seen the banana trees, after being felled, shoot up from their centres immediately after their stems had been cut across; the roots of the trees are surrounded by spongy soil laden with moisture from the daily fall of misty rain, and the powerful sun completes the formation of the great forests of banana trees, without the aid of cultivation, beyond the help of the decayed leaves. We see the same process in the great belt of forest called in India the "Terai," which extends along the bases of the southern spurs of the Himalayas. Here the rains which fall upon these spurs, ooze out over the lands of the "Terai" and feed the roots of the magnificent forest trees, forming food and shelter for the wild elephant, boar, and swamp-loving creatures; but the atmosphere is almost certain death to all human beings except the inhabitants. We cannot, therefore, feel any surprise that Stanley and all his party suffered from sickness, and wonder how any of them escaped alive.

"Ugarrowa or Ulede Balyuz, a tent-boy of Speke's," an "Arab slave-dealer," is constantly mentioned in Stanley's interesting narrative. I am able to give some information about this person if he be the same "Ulede," one of "Speke's faithfuls," represented in the *Illustrated London News* of July 4, 1863, as "Ulede Senior," in a photograph taken by Royer in Cairo. He told me that he was a native of Uhiao, was captured by the Watuta in infancy, and sold as a slave to a Zanzibar trader. He was engaged by Speke as a load carrier, and became my valet, which he continued to be till our arrival in Cairo. He was thoroughly trustworthy, as many of his race are, and more intelligent than most of our men. He could name accurately every march in our journey, most of the trees and plants, and could tell a capital story. His career has been deservedly successful, and though from circumstances he has become a well-known dealer in slaves, I might ask what career is open to any young man of African origin who has never received the slightest education. Ulede Balyuz (*i.e.* the Consul's boy) has done good service in sheltering Stanley's sick, and in transmitting the graphic despatches which we have all read with profound interest, therefore he ought not to be condemned too hastily, but rather be utilized by the Congo Free State Government as the head of a district.

The dwarfs mentioned by Stanley must be very numerous, as he came upon one hundred and fifty villages of them. One specimen alone was seen by Speke and myself in Unyoro, and at least one perfect skeleton has been received from Emin Pasha by Prof. Flower. They seem very proficient in hunting, and used every conceivable device to poison the men of Stanley's party by placing staked pitfalls on the path, in the manner they would trap an elephant or antelope, and it appears they were only too successful.

We must wait for Stanley's return to hear more of the race of Manyema. I believe this race to be the Nyam-Nyam described thirty years ago by Mr. Petherick, but without knowing their tribal marks and arms, this cannot be decided. Meantime, these daring cruel savages have shot down poor Major Barttelot, and are engaged by the slave-dealers of Zanzibar to plunder, capture, and kill the inhabitants, and reduce the country to a wilderness; so that, through Stanley's brave deeds, we have our work of civilization before us.

J. A. GRANT.

FURTHER NOTES ON THE GEOLOGY OF THE EASTERN COAST OF CHINA AND THE ADJACENT ISLANDS.

TWO years ago some notes were published in NATURE (vol. xxxvi. p. 163) on the geology of a portion of the coast of China, compiled from a report forwarded by Surgeon P. W. Bassett-Smith, R.N., of H.M.S. *Rambler*, to the Hydrographical Department of the Admiralty. Since then Mr. Bassett-Smith has extended the area of his investigations both to the north and south of the coast-line dealt with in this report, so as to embrace the whole eastern coast from Shanghai and Hong Kong; and has embodied his observations in two further reports to the Hydrographical Department. These documents, with the specimens referred to in them, having been submitted by the Hydrographer to the Director-General of the Geological Survey, Dr. Hatch, of the Petrographical Department of the Survey, has drawn up the following abstract of the reports and notes regarding the specimens:—

Speaking generally, the whole coast between Shanghai and Hong Kong consists of granite; the high mountain-ranges, especially in the south, present chiefly this rock. Flanking the granite on various parts of the coast are vast masses of crystalline schists (gneiss, mica-schist, &c.), parts of which are rich in metallic ores, even auriferous quartz occurring, as at Chinsan, and more plentifully in the Shangtung province, where it is profitably worked by the Chinese. A curious conglomerate, found at Sharp Point Islands, River Min, at Davis Island, Yangtse-kiang, and also in the Shangtung province, is overlain by slates, probably of Cambrian age, but for the most part unfossiliferous, although some fish-remains and Algæ have been found in the Shangtung province.

In the northern part of the coast (Chusan to Shanghai) there are many traces of ancient volcanic activity. The older volcanic rocks consist of porphyritic felsites (Chinsan Island, Davis Island, Elliot Island, Bonham Island, and Side Saddle Island) and basalts (Changtau), both of which are intrusive in the granite and crystalline schists. More recent volcanic tuffs and breccias were obtained in a quarry near Ningpo.

The Chusan Archipelago.—Of this group of islands, situated at the mouth of Hang-chow Bay, south of Shanghai, the northern members have a marked vol-

canic character, the rocks composing them being volcanic conglomerates, breccias and tuffs, together with felsitic, trachytic and basaltic lavas, the more acid types of which show well-marked flow-structures. The vents from which these lavas were erupted are situated chiefly in the large island of Chusan; another focus of emission is probably represented by Changtau Island.

One of the most noticeable features of the group is presented by the vast stretches of land that have been rescued from the sea. Many islands formerly isolated have been united; and broad plains of rich alluvial ground have been reclaimed, are now highly cultivated, and support a dense population. This has been chiefly brought about by the construction of strong embankments and sea-walls from point to point across the bays, after the latter had been allowed to become partly silted up by the mud brought down from the Yangtsze River and Hang-chow Bay. This difficult work testifies to the marvellous energy and industry of the Chinese.

Details are given of the geology of the following islands of the Archipelago:—

Video Island, the outermost of a long chain of islands, extending in a west-south-west direction, has a conical shape, with steep cliffs, and consists of a pinkish quartz-trachyte, penetrated by numerous dykes of basalt.

Tripod Island, an elongated island, about 600 feet high, sloping moderately to the west, but descending on the east almo t perpendicularly into the sea, is composed of a volcanic breccia, frequently penetrated by dykes of basalt.

Keusan Island, a high island of irregular elongated shape, separated from Changtan Island by a narrow channel of 5-7 fathoms, with a good anchorage, presents, at its north-eastern end (Radstock Point), a coarse volcanic breccia ("trachyte-conglomerate"), with which are associated well-banded acid lavas (trachyte). In other parts of the island a greenish tuff occurs, which is abundantly penetrated by an interlacing system of basaltic dykes.

Changtau Island, a rugged island with a double-peaked summit, shows, along its west coast, cliffs consisting of a stratified green tuff and trachyte-breccia, with dykes of basalt and flows of a well-banded trachytic lava.

Taeshan Island, a series of high hills attaining to a height of 700 feet, connected by broad alluvial plains, consists on its north-east coast of a grey quartz-porphyry, weathering blood-red, and salmon-coloured felsites, penetrated by numerous dykes of basalt.

Show Island is formed entirely of a coarse trachyte-breccia, containing large angular fragments. This rock is much quarried, the stone being conveyed away in junks.

Volcano Island, the most westerly of the chain, is composed of the same volcanic breccia, associated here with felsitic lavas.

North-East Islet, off Chusan Island, and Nine-Pin Rocks are composed of a compact dark-coloured felsite, with a marked bedded character. In places the rock shows distinct flow-structure.

Poo too Island consists of a high peak, separated from a number of smaller ones by deep gullies, filled with blown sand. The summit of the hill is formed of a compact white trachyte, which has been erupted through the granite forming the base of the hill.

Chusan Island, the largest of the group, being twenty-two miles long and ten miles wide, consists of a long range of mountains, many peaks of which are over 1000 feet high. Between the numerous spurs given off from these mountains lie tracts of highly fertile land, the lower parts of which have been recently reclaimed, and are protected by a series of embankments. Outside the outermost of these the mud-flats are used for the collection of salt, to obtain which the mud is scraped up, filtered, and the brine evaporated in wooden trays. The old cliff-line now stands far back from the present coast; and former islands appear now as isolated hills. This island is less bleak than the smaller ones of the group, owing to the protective influence of the small fir-trees that are encouraged to grow on the hill-sides. Other trees here met with are the camphor, tallow, maple, and numerous evergreens in the neighbourhood of the villages. The rocks are quartz-porphyries and felsites.

Lateo Island consists of a coarse volcanic breccia, containing large angular fragments of quartz-felsite. This stone is extensively quarried.

Ketsu Island.—A small rugged double island off Chusan, consisting of dark-banded felsite with small porphyritic crystals of red felspar.

Blackwall Island.—A large well-cultivated island, with hills of dark-coloured felspar-porphyry and felsite. Volcanic breccia also occurs, penetrated here and there by basalt dykes.

Kintang Island.—A large island near the mainland, presenting a fine, pointed summit of red felspar-porphyry. Along its cliffs are highly contorted volcanic breccias and felsites.

Taoutse Island.—A small narrow island of red felspar-porphyry (red felsitic ground-mass embedding small bright red crystals of felspar).

Changpih Island.—A large island with much reclaimed land; red felspar-porphyry.

Chinhai Island.—A small rock in the mouth of the Ningpo River, composed of the same red porphyry.

Rambler Island, Hang-chow Bay.—A rounded mass with steep smooth sides, composed of volcanic breccia and brown felspar-porphyry.

Mr. Bassett-Smith adds that no traces now remain on the China coast of the volcanic activity that gave rise to the enormous accumulations of lava and tuff referred to in the above notes, with the exception of a few scattered hot springs. He is of opinion that after the eruptions ceased, a subsidence must have taken place, but that the ground is now probably rising.

WHICH ARE THE HIGHEST BUTTERFLIES?

THE following extracts from a letter received a few weeks back from Mr. W. H. Edwards, of Coalburgh, touch on this question, and may be of interest to lepidopterists. Having now for many years ceased to give attention to this subject, I cannot express any opinion, but I think Mr. Edwards's facts are very curious, and the conclusion expressed in his last paragraph not far from the truth.

ALFRED R. WALLACE.

"In a recent part of my vol. iii. I have figured one of the high Alpine Colorado Erebias, *E. Magdalena*, found on the extreme summits, among nothing but rocks. I have also succeeded in breeding another of the Alpine Erebias, *E. epipsodea*, from egg to imago, and have a full set of drawings for plate. Have also had *Chionobas chryxus* (also Colorado) and imago, and have all the drawings there. Connected with these Alpine species is a matter I talked over with you, and of which I now write. There must be many genera of Satyridæ in which the larvæ are thick-bodied, inert creatures, very much like many of the Noctuidæ. I have twice raised *Arge Galatea* from egg to imago. This larva is remarkably like a Noctuid in shape, inertness, in the manner it lies on the ground—curled up so that head touches tail, in a ring, or like a *d*. The pupa is so like a Eudamus, that when I sent one to Mr. Scudder to ask what it was, he replied, 'Some Hesperid probably, very near to *E. tityrus*.' It is made loose on the ground or

in the sod, there being no outer case, and no attachment. The usual hooks of the cremaster are not bent, but straight out and few. Now the *Erebia epipsodea*, and the three Chionobas which have been bred in this country, *C. chryxus*, *semidea*, and *jutta*, are like the *A. Galàtea* in larval habits and appearance, and the pupa is unattached, and has actually no hooks at all. I read in Buckler, that *Satyrus Semele* actually makes a case underground (like some of the Sphingidæ), and is inside that like a Hesperid. It is to be supposed that many genera of the Satyridæ pupate unattached, or in cocoons. Mr. Scudder says the eggs of Satyridæ are very like the Hesperidæ, and has to admit the resemblances I have spoken of in the other two stages. But he passes over all this as a mere trifle, and insists that 'in the prime features,' as he calls it, of the imago, the Satyridæ 'out-rank all others.' Now what are the 'prime features' he tells about? They are two: one is that the pupa hangs by the tail, and that there is a regular progression from the Hesperid style of attachment through the Papilionidæ, the Lycænidæ and the Satyridæ; and that the flat ventral side of pupæ in what he calls the higher families, the Suspensi, is an evidence that once they or their ancestors were attached by a girdle, like the Papilionidæ. The other is the atrophied condition of the fore-legs, which is more extreme in the Satyridæ than in any other family, and reaches the last degree in Chionobas. He, in his 'Butterflies of New England,' now issuing, puts *Chionobas semidea* at the head of the North American butterflies, the top rung of the ladder, beyond which we can go no farther! This is what I call your attention to.

"When we used to study 'Euclid,' we sometimes proceeded by an apparently correct mode of demonstration, till we came to 'which is absurd,' and I hold that this conclusion of Mr. Scudder is absurd on its face. Here is a butterfly on the top of the White Mountains of New England. Its species is found nowhere else than in Labrador and in Colorado, in the latter on the loftiest summits. There is no difference between the three butterflies from the three regions, and yet they cannot have had any communication for untold ages. It is considered as a relic of pre-glacial times in the White Mountains. This butterfly lives in a semi-torpid condition through its short season, lies about on the rocks, has but a trifling power of flight, and dodges the high winds in crevices of rocks. To say that an insect which for perhaps 50,000 years has lived this sort of life, and has not changed in all that time, is the most advanced in the scale of North American butterflies, and so of all the world, is absurd and ridiculous! The wonder is that it has not lost the use of its wings. Therefore the argument is wrong somewhere that leads to such a conclusion. If the premisses are allowed to be correct, then the reasoning has a flaw.

"I do not believe there ever was any derivative progression from one family of butterflies to another. And we cannot say that the Papilionidæ are derived from the Hesperidæ (either because of six legs, or the epiphysis, or any other reason), or the Papilionidæ from the Lycænidæ, or the four-legged families from the six-legged. There is not in the rocks a particle of evidence of such a progression, and the whole thing is the merest fancy. Any differences between families are not owing to derivation, but to the development of each independently, like the rays of a fan. "W. H. EDWARDS."

NOTES.

WE regret to have to record the death of Mr. Warren De la Rue, F.R.S. He was born in 1815, and died on Good Friday, after a short illness, from pneumonia. Mr. De la Rue was a most devoted observer and munificent patron of astronomy, and in him and Balfour Stewart solar physics has lost its chief founders.

THE death is announced of Dr. Paul du Bois-Reymond, Professor of Mathematics at the Technical High School of Berlin, and formerly at the Universities of Freiburg and Tübingen. He was the author of two well-known mathematical works, and brother of the eminent physiologist of the same name. He was born on December 2, 1831, and died at Freiburg in Baden, on April 7.

THE Rev. J. H. Thomson, Vicar of Cradley, whose death is announced, had made what is described as an extensive and valuable collection of European plants, and it is understood that he has bequeathed them to the Worcestershire Naturalists' Museum.

THE National Union of Elementary Teachers has been holding its twentieth annual conference this week at Birmingham. The conference was opened in the Town Hall on Monday afternoon, when an address was delivered by Mr. R. Wild, the President-elect, on the report of the Education Commission, and on the latest edition of the Code. The defects of the existing system of national education were discussed at a crowded meeting on Tuesday evening. Mr. Chamberlain, in addressing this meeting, spoke of payment by results, in the sense in which the expression is now used, as a method which everyone condemns. "We want you," he said, "to show us a better way, and it is through such conferences as those which are now being held that Parliament and the Government may hope to find, tested by your practical experience, a substitute for a system which we desire to alter."

THE picture of Sir William Bowman, by Mr. Ouless, R.A., has, by special permission, been exhibited to subscribers in the Marsden Library of King's College, and has now been sent to the Royal Academy. The list of subscribers numbers 420, and will be closed on June 1.

SIR ROBERT BALL, the Royal Astronomer of Ireland, has just been elected an Honorary Fellow of the Royal Society of Edinburgh.

PROF. CORFIELD, M.D., has been elected a Corresponding Member of the Italian Association "Dei Benemeriti," and awarded a gold medal for his contributions to hygiene.

DR. SCHWEINFURTH arrived at Aden on March 23, on his return from a three months' stay in Central South Arabia. He has started for Europe, bringing a very interesting botanical collection with him.

THE *Japan Weekly Mail* says that Mr. W. Gowland, who has occupied a prominent place in the Imperial Mint at Osaka, has retired from the Japanese service. In 1872, Mr. Gowland was selected by Dr. Percy, of the Royal School of Mines, London, as Chemist and Metallurgist to the Japanese Government. His first task in that country was the organization of the metallurgical department of the Copper Mint and the establishment of chemical and metallurgical laboratories. He subsequently filled the posts of Technical Adviser and Assayer, and as such was directly responsible for the accuracy of the coinage. Amongst other reforms at the Imperial Mint he introduced a novel process by which crude copper could be converted into bronze coinage bars at one operation, and also elaborated processes for the coinage conversion. His investigations into the effect of bismuth on the ductility of silver are well known. He made many interesting discoveries amongst the tumuli and shell-heaps in the interior. The Emperor conferred several distinctions on him before his departure.

THE Berlin Academy of Sciences has lately been presenting various sums of money to promote scientific research. Dr. Franz-Stuhlmann, assistant at the Würzburg Zoological Institution, has received £50 (Mk. 1000) to enable him to proceed with his

investigation of the fauna of Zanzibar, where he has been since last spring. A sum of £60 (Mk. 1200) has been sent to Dr. Gustav Weigand to help him in his linguistic and ethnographical researches in the Balkan peninsula; and Dr. Pomtow has received £25 (Mk. 500) towards the publication of his work on Delphi.

A CORRESPONDENT in Paris writes to us that the British Section of the Paris Exhibition is nearly ready, and is much in advance of most other parts of the Exhibition.

THE following are the dates of some of the Exhibition Congresses which are to be held in Paris:—Technical Education, July 8 to 12; Bibliography of the Exact Sciences, July 16 to 26; Chemistry, July 29 to August 3; Ballooning, July 31 to August 3; Pigeons, July 31 to August 3; Hygiene, August 4 to 11; Higher Education, August 5 to 10; Physiological Psychology, August 5 to 10; Geography, August 6 to 11; Photography, August 10 to 17; Criminal Anthropology, August 10 to 17; Primary Education, August 11 to 19; Horticulture, August 16 to 21; Prehistoric Man and Remains, August 19 to 26; Electricity, August 24 to 31; Chronometry, September 2 to 9; Mines and Metallurgy, September 2 to 11; Applied Mechanics, September 16 to 21; Meteorology, September 19 to 25; River Utilization, September 22 to 27; Commerce and Industry, September 22 to 28; and Hydrology and Climatology, September 30 to October 15.

LECTURES will be delivered in Gresham College, on April 30, and May 1, 2, and 3, by Dr. E. Symes Thompson, on the medical aspects of life assurance.

AT a recent meeting, the Liverpool Geological Society appointed a Committee to report on the boulders occurring in the glacial deposits of Liverpool and district. This Committee, after full discussion, has reported that the investigations would be better carried out if extended over the whole of Lancashire and Cheshire, and by a larger Committee, consisting of representatives from all parts of the two counties. The objects of the enlarged Committee would be to examine and record the occurrence, nature, and facts bearing on the mode of transport, of erratics in the glacial deposits of Lancashire and Cheshire. If this suggestion meets with general approval, a meeting of all interested in the question will be held at some convenient centre at an early date.

IN a paper reprinted in NATURE (vol. xxxiv. pp. 220, 239), M. A. Blytt gave his views on variations of climate in the course of time. Believing that periodical variations of climate are to be attributed to changes in the strength of ocean-currents, he finally traced back their origin to the precession of the equinoxes and the eccentricity of the earth's orbit. He has now issued a paper, with two supplementary notes, in which he seeks to explain the displacement or alteration of beach-lines, by changes in the tidal-wave, caused by variations in the eccentricity of the earth's orbit. Referring to his former conclusions, that dry periods should be marked by chemical deposits, and rainy periods by mechanically-formed sediment, he passes on to consider the character of the Tertiary strata in the Paris and Hampshire Basins. In the author's opinion, the alternation of sediments of different nature indicates periodical variations in climate; and he endeavours to correlate these variations with particular phases in the eccentricity of the earth's orbit, the period or duration of which has been calculated in years. The author also believes that the lengthening of the sidereal day has had much influence on the form of the globe. This lengthening has been caused mainly by the tidal wave, and as the centrifugal force diminishes under such circumstances, strain accumulates in the solid earth, until the limit of resistance is reached. Hence, in the author's opinion, arose vertical displacements of beach-lines.

A REPORT from Sumatra states that the volcanic crater on the west coast of the island, which has been quiet for several centuries, was active during the middle of February.

SEVERE shocks of earthquake, lasting for eight seconds, were noticed at Zvornik in Bosnia, on April 2. The direction was from south to east.

WE have received from the Deutsche Seewarte, the second part of the *Deutsche Ueberseeische Meteorologische Beobachtungen* (see NATURE, vol. xxxvii. p. 444) containing complete observations made at six stations in Labrador during the year 1885, and at one station in Walfisch Bay (south-west coast of Africa) during the year 1887. Both sets of observations are carried on under considerable difficulties; in Labrador the rain-gauges are frequently inaccessible on account of drifting snow-storms, and the ordinary hygrometers are unmanageable during very low temperatures. In Walfisch Bay the thermometers are often choked by sand, or are liable to be affected by the intense radiation from the ground. Nevertheless the work supplies very valuable materials from remote regions where little is yet known about the peculiarities of the climate.

A CARBOHYDRATE of the empirical composition $C_6H_{10}O_5$, and possessing properties very closely resembling those of the arabin of "gum arabic," has been artificially prepared by Prof. Ballo, of Buda-Pesth. This achievement is the outcome of an attempt to reproduce the conditions under which the acids of the vegetable world are reduced by chlorophyll. It was assumed that the iron of chlorophyll is present in the ferrous state, and tartaric was the acid upon which operations were commenced. About equal quantities of tartaric acid and ferrous sulphate were dissolved in a minimum bulk of water, and the solution was warmed upon a water-bath. In a short time a greyish-yellow precipitate began to separate. The whole was then evaporated until it completely solidified on cooling. The cold mass was next extracted with alcohol and the extract again evaporated. The residue thus left by volatilization of the alcohol was neutralized with milk of lime, and the filtered solution again placed on the water-bath. It was now noticed that as the water was gradually expelled the contents of the evaporating dish became more and more viscid, until, finally, a sticky mass was left, reminding one most forcibly of gum arabic. Knowing that this familiar article of commerce chiefly consisted of the calcium and potassium compounds of arabin, the likeness was felt to be somewhat indicative of the formation of an arabin-like substance. On allowing the concentrated syrup to cool, a calcium salt readily crystallized out, yielding on analysis numbers pointing to the formula $(C_6H_9O_5)_2Ca + 9H_2O$. From this the free carbohydrate was obtained in two ways, either by precipitation of the solution in water with lead acetate and subsequent decomposition of the lead salt with sulphuretted hydrogen, or by addition of the calculated quantity of oxalic acid. The syrup of "iso-arabin," as it is provisionally termed, was further purified by repeated treatment with alcohol and ether and subsequent re-evaporation. It was then allowed to stand over sulphuric acid, some specimens for a month and others so long as a whole year. Each of these specimens, on combustion, yielded numbers indicating the empirical formula $C_6H_{10}O_5$. Iso-arabin is an almost colourless syrup, readily mixing with water. It does not reduce Fehling's solution, but rotates the plane of polarization to the right. It behaves, in short, exactly like the carbohydrates of the $(C_6H_{10}O_5)_n$ group. The potassium salt, obtained by decomposing the calcium salt with potassium carbonate, also crystallizes well in large anhydrous crystals. In addition to iso-arabin itself, a small quantity of its hydrate, $C_6H_{10}O_5 + H_2O$, is also formed by the action of ferrous sulphate upon tartaric acid, and separates out in crystals from the alcoholic washings of the crude iso-arabin.

Natural arabin itself forms a similar hydrate, the precipitate formed by addition of hydrochloric acid and alcohol to a solution of gum-arabic, when dried at 100° C., possessing this composition.

MR. FLETCHER, of Warrington, has recently put in the market a new and very cheap sensitive flame. It consists of a special arrangement of the small Argand bunsen, and differs from other sensitive flames inasmuch as any considerable sound completely extinguishes it. An interesting point in connection with it is that its sensitiveness is not constant, but apparently varies with the atmospheric conditions. The circular issued with the burner particularly states that the transparency of the flame renders it unsuitable for lecture experiments.

MR. W. A. HOLLIS writes to us from Brighton, describing a dream in which rooms and things in his house seemed to be in their relative positions, but transposed. The displacement extended itself to a servant, who appeared to be dusting some furniture; the cloth she was using she held in her left hand. This experience suggests to Mr. Hollis the question, "Is it possible that in dream-land we see things as in a looking-glass, like our little friend Alice?"

PISCICULTURISTS will read with interest M. Albert Le Play's pamphlet on the rearing of carps. It is entitled "La Carpe," and contains many new facts and suggestions concerning this branch of pisciculture.

AMONG foreign works which have been translated into French during the last two years, and the translations of which have been considered worthy of a reward, we notice two English books. The one is Mr. Green's "Short History of the English People"; the other Darwin's "Life and Correspondence," translated by M. H. de Varigny. The two other works to which, with the preceding, the Prix Langlois has been awarded, are Janssen's "Germany under the Reformation," and Nordenskiöld's "Travels." It is interesting that a book on Darwin should have been rewarded by the French Academy. M. Renan and M. Taine were on the jury, and did much to bring about the result.

WE have received the first three numbers (January to March 1889) of the *Bulletin international de l'Académie des Sciences de Cracovie*. The ordinary transactions of the Cracow Academy, being published in Polish, are not accessible to scientific students unfamiliar with the Slavonic languages. To remedy this inconvenience the Academy will henceforth issue a monthly *Bulletin* containing extracts in French and German of its regular proceedings, as well as summaries of all important memoirs in one or other of these languages at the option of the authors. Besides several historical, philological, and antiquarian papers, the present numbers contain contributions by Prof. Kreutz on the granites of Volhynia containing tourmaline and garnets; by M. Olszewsky, on an improved method for liquefying and solidifying the permanent gases and for studying their spectra; by M. Krzyzanowski, on the liquefaction and solidification of hydrogen in M. Pictet's experiments; by M. Olearski, on the elasticity of zinc and copper alloys; and by M. Sawicki, on the influence exercised by the physical and chemical agents on the electric properties of the nerves.

THE removal of tattoo-marks is a matter of no little difficulty, and many different methods have been tried (blistering, suction, thermo-cautery, counter-tattooing with white powder or milk, &c.). Criminals sometimes pour vitriol on their arms or hands, and letting it act for a few seconds, plunge the limb in water. The following method is recommended by M. Variot (in the *Revue Scientifique*):—The skin is first covered with a concentrated solution of tannin, and re-tattooed with this in the parts to be cleared. Then an ordinary nitrate of silver crayon is rubbed over these parts, which become black by formation of tannate of silver in the superficial layer of the dermis. Tannin powder is sprinkled on the surface several times a day for some days to dry it. A dark crust forms, which loses colour in three or four days, and, in a fortnight or so, comes away, leaving a reddish scar, free of tattoo-marks, and, in a few months, little noticeable. It is well to do the work in patches about the size of a five-franc piece at a time. The person can then go on with his usual occupation.

FROM a report of the Belgian Consul-General in the Congo State, it appears that the efforts made to introduce European vegetables and fruits in that district have been rewarded with very great success. The Government has imported tobacco-seed from Havana and Sumatra, which is cultivated in conjunction with native tobacco. The natives cultivate tobacco badly, but efforts are being made by the Government to teach them better methods. The inhabitants of the Lower Congo have been very successful in cultivating not only the usual African products, such as manioc, sweet potato, &c., but also sorghum, maize, and the "wandu" haricot, called "Boma" by the natives. The cotton-plant grows in its wild state, and the natives manufacture from it hats, wallets, &c. No effort has yet been made to cultivate it for trade purposes.

THE American Commercial Agent at Limoges, in a report on the result of the sanitary investigation as to the effect of plastered wines—that is, wines to which sulphate of lime has been added—says that the practice is very ancient, and one about the evil effects of which the highest hygienic authorities have differed. The Academy of Medicine has held special meetings and discussed the subject at great length. The advantages claimed for the practice are that fermentation is increased very much; that it is more rapid and complete; that the wine keeps longer when it has been plastered, and that the colour is richer and more lasting. It is now settled, however, that plastered wines have occasioned functional troubles, as, for instance, in the Department of Aveyron, where, the doctors report, those who consumed plastered wines suffered from an unquenchable thirst, an insupportable dryness of the throat, and various other troublesome symptoms. The action of sulphate of lime on the bitartrate of potash in ordinary wine produces an acid sulphate of potash; and in wine treated with lime, sulphuric acid in a free state is formed, and sulphate of magnesia; and these combined act as a purgative and sometimes as a caustic. M. Marty, who was appointed by the Academy of Medicine to report on the practice of plastering, examines all the arguments adduced in favour of the process, and, on his recommendation, the Academy condemns the custom as being detrimental to health.

THE British Consul-General in Algeria, in his report to the Foreign Office, says that hitherto the Government have been in the dark as to the habits and natural history of the locusts which now and then work such ravages in Algeria. Last year, however, a distinguished naturalist, M. J. Künckel d'Herculais, President of the Entomological Society of France, was sent to study the question on the spot, and he has published two reports on the subject. The species of locust which has ravaged the country since 1885 is not the same as that which invaded the same district in 1876–77. The former is *Stauronitis maroccanus*, the latter *Acridium peregrinum*. The former is found in most of the countries bordering on the Mediterranean, especially in Asia Minor and Cyprus. Morocco is, however, its original home, where it was observed in 1845, and again in 1867. Specimens of it collected in both those years still exist. Hitherto the accepted theory has been that they are brought from the desert by a strong southerly wind, but M. Künckel says that none have ever been observed in the Sahara, and he believes

them to have their origin in the mountainous regions of Hodna. Fortunately the exact moment of their appearance may be predicted, and steps can be taken to destroy them. With this object M. Künckel has made charts of the localities where they laid their eggs last autumn, and has arranged a methodical system of campaign. The destruction of eggs is an uncertain and expensive process, he thinks, whereas one man can destroy a million young insects in a day.

A CHINESE native paper published recently a collection of some zoological myths of that country, a few of which are worth noting. In Shan-si there is a bird, which can divest itself of its feathers and become a woman. At Twan-sin-chow dwells the Wan-mu Niao (mother of mosquitoes), a fish-eating bird, from whose mouth issue swarms of mosquitoes when it cries. Yung-chow has its stone-swallow, which flies during wind and rain, and in fine weather turns to stone again. Another bird when killed gives much oil to the hunter, and when the skin is thrown into the water it becomes a living bird again. With regard to animals, few are so useful as the "Jih-kih" ox, found in Kansuh, from which large pieces of flesh are cut for meat and grow again in a single day. The merman of the Southern Seas can weave a kind of silky fabric which keeps a house cool in summer if hung up in one of the rooms. The tears of this merman are pearls. A large hermit-crab is attended by a little shrimp which lives in the stomach of its master; if the shrimp is successful in its depredations the crab flourishes, but the latter dies if the shrimp does not return from his daily excursions. The "Ho-lo" is a fish having one head and ten bodies. The myths about snakes are the strangest of all. Thus the square snake of Kwangsi has the power of throwing an inky fluid when attacked, which kills its assailants at once. Another snake can divide itself up into twelve pieces, and each piece if touched by a man will instantly generate a head and fangs at each end. The calling snake asks a traveller "Where are you from, and whither are you bound?" If he answers, the snake follows him for miles, and entering the hotel where he is sleeping, raises a fearful stench. The hotel-proprietor, however, guards against this by putting a centipede in a box under the pillow, and when the snake gives forth the evil odour, the centipede is let out, and, flying at the snake, instantly kills him with a bite. The fat of this snake, which grows to a great size, makes oil for lamps and produces a flame which cannot be blown out. In Burmah and Cochin-China is a snake which has, in the female sex, a face like a pretty girl, with two feet growing under the neck, each with five fingers, exactly like the fingers of a human hand. The male is green in colour, and has a long beard; it will kill a tiger, but a fox is more than a match for it.

A SERIES of regulations with regard to patents and designs has just been issued in Japan. All inventors, whose discoveries are beneficial or are calculated to improve existing processes of manufacture, may apply for letters patent. No patents, however, will be granted in the case of articles of food or drink, or in case of medicines. Inventors who do not receive letters patent are powerless to sue in respect of piracy of their inventions. In order to register an invention, application must be made to the Patents Bureau, and if the officials are satisfied as to the genuineness of the invention, it is registered, on certain forms being complied with and certain fees paid. A curious omission occurs in the regulations, but it is not plain whether it is intentional or not. Nothing whatever is said as to the rights of a foreigner to patent an invention, but it is presumed that he will not be able to do so. Nor has any provision been made for advertising applications for letters patent. The Patents Bureau is to be the sole judge of all cases submitted to it, and from its decision there is no appeal; but, in certain cases, two judges sit with the Bureau and assist in deciding whether a patent should be granted or not. The duration of a patent is to be five, ten, or fifteen years, according to the amount paid in fees. The patent, of course, passes by assignment *inter vivos*, or to the patentee's heir, but nothing is provided for the cases of bankruptcy or marriage.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Miss Caroline Newton; a Leopard (*Felis pardus* ♂), a Lesser Koodoo (*Strepsiceros imberbis* ♂) Malindi, East Africa, two White-crested Touracous (*Corythaix albocristata*) from South Africa, presented by Mr. G. S. Mackenzie; a Common Squirrel (*Sciurus vulgaris*) British, presented by Mrs. Arthur Faulkner; an Indian Wolf (*Canis pallidus*) from Afghanistan, five Chaplain Crows (*Corvus capellanus*), an Indian Python (*Python molurus*) from Fao, Persian Gulf, presented by Mr. B. T. Ffinch, C.M.Z.S.; two Slender-billed Cockatoos (*Cacatua tenuirostris*) from Australia, presented respectively by Mr. Walter Bird and Mrs. Hunt; an Eagle (*Aquila* sp. inc.) from Foochow, China, presented by Messrs. J. de la Touche and George Siemosen; two Alligators (*Alligator mississippiensis*) from Florida, deposited; a Wanderoo Monkey *Macacus silenus* ♀) from the Malabar Coast of India, an Indian White Crane (*Grus leucogeranos*), six Rose-coloured Pastors (*Pastor roseus*) from India, three Elliot's Pheasants (*Phasianus ellioti* ♂ ♀ ♀), thre Amherst's Pheasants (*Thaumalea amherstiæ* ♂ ♀ ♀) from China, two Swinhoe's Pheasants (*Euplocamus swinhoii* ♂ ♀) from Formosa, two Vulturine Guinea Fowls (*Numida vulturina* ♂ ♀) from East Africa, two Crested Screamers (*Chauna chavaria*) from Buenos Ayres, two Pochards (*Fuligula ferina* ♂ ♂), European, purchased; two Viscachas (*Lagostomus trichodactylus*), a Vulpine Phalanger (*Phalangista vulpina* ♂), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE CONSTITUTION OF CELESTIAL SPACE.—M. G. A. Hirn has recently published an able and interesting work, entitled "Constitution de l'Espace Céleste," in which he inquires into the nature of the medium or agent which establishes and carries on the relationships of the celestial bodies. For all of these, from the most enormous sun to the most infinitesimal meteorite, are in constant relationship to each other, continually attracting each other, continually radiating and receiving light and heat. Newton long ago regarded it as the greatest of absurdities to imagine "that one body might act upon another at a distance, through a vacuum, without the mediation of anything else, by and through which their action and force may be conveyed from one to another. Gravity," he added, "must be caused by an agent acting constantly according to certain laws; but whether this agent be material or immaterial, I have left to the consideration of my readers."

This question, left unsolved by Newton, Hirn answers as follows:—"The thorough analysis of the most diverse facts revealed to us by science to-day allows us to reply to the first question by the most absolute negation. That which fills space and which establishes relations between the celestial bodies is not diffuse matter."

That "ponderable matter in the state of a diffuse gas" does not fill interplanetary and interstellar space M. Hirn seeks to prove by inquiring what effect such a medium would have on the various members of the solar system, and particularly upon their movements. Many of his conclusions are exceedingly striking, and if accepted certainly prove his main proposition given above. Perhaps the most remarkable is that relating to the secular acceleration of the moon. To explain a secular acceleration of $0''\cdot5$ in the mean motion of the moon it would be sufficient if 1 kilogramme of gas were distributed over 975,000 cubic kilometres of space; a rarefaction one million times greater than that of a Crookes vacuum of the millionth of an atmosphere. But the effect of the shock of the particles of this rarefied gas against a body like the moon as it moved forward in its orbit would be to raise the gas to a temperature of

38,000° C., and inconceivably attenuated as this interplanetary atmosphere would be, the moon would yet come into contact with 600 kilogrammes of it in each minute of time. On a body like the earth, surrounded by an atmosphere, the inevitable result of this unceasing collision with the interplanetary atmosphere would be the stripping away of the terrestrial atmosphere layer by layer. Arriving at results of a similar unacceptable character from the consideration of the action of a diffuse interplanetary gas on the other members of the solar system, M. Hirn decides that matter exists only in a sporadic state in space; only in the state of distinct bodies—stars, satellites, meteorites, and the like. It exists in a state of extreme diffusion only in nebulæ, but elsewhere space is perfectly empty, or, at least, whatever remains cannot suffice to explain the relations of stars to stars.

COMETS 1888 *e* AND *f* (BARNARD, SEPTEMBER 2 AND OCTOBER 30).—The following ephemerides for these objects are in continuation of those given in NATURE of April 4, p. 546, and are for Berlin midnight:—

	Comet 1888 *e*. R.A.	Decl.	Comet 1888 *f*. R.A.	Decl.
	h. m. s.	° ′	h. m. s.	° ′
April 30	23 25 51	1 28·1 N.	9 31 10	37 39·4 N.
May 4	23 23 34	1 41·6	9 33 48	37 35·8
8	23 20 54	1 54·1	9 36 36	37 30·4
12	23 17 50	2 5·5	9 39 38	37 23·7
16	23 14 18	2 15·7	9 42 50	37 15·8
20	23 10 15	2 24·5	9 46 12	37 6·7
24	23 5 37	2 31·6 N.	9 49 43	36 56·8 N.

α URSÆ MAJORIS.—Mr. Burnham reports from the Lick Observatory that he has discovered this star to be a close double. He gives the following measures of the companion:—

			Mag.
1889·142	P = 327°·0	D = 0″·96	11
1889·151	= 325·9	= 0·83	11

Mr. Burnham was not able to see the companion with the 12-inch telescope, and concludes that it is too difficult for such an aperture, the difference in magnitude between the two components being so great.

THE WHITE SPOT ON SATURN'S RING.—M. Terby, writing to the *Astronomische Nachrichten*, reports that he has not been able to see the white spot again which he observed on March 6 and 12 (NATURE, vol. xxxix. p. 497). MM. Knorre, Knopf, Lamp, Struve, and Schiaparelli have likewise failed to detect it. On the other hand, Prof. McLeod, of Montreal, and Mr. Brooks, of Smith Observatory, Geneva, U.S.A., both state that they have seen it; and the latter reports it variable. If it be a real spot, and not a mere effect of contrast with the shadow of the planet, it evidently would only occasionally be seen in the place where it was first discovered, but would be observed from time to time in other parts of the ring, for it would be carried round with it in its rotation.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 APRIL 28—MAY 4.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on April 28

Sun rises, 4h. 39m.; souths, 11h. 57m. 20·7s.; sets, 19h. 16m.: right asc. on meridian, 2h. 23·9m.; decl. 14° 18′ N. Sidereal Time at Sunset, 9h. 44m.

Moon (New on April 30, 2h.) rises, 4h. 36m.; souths, 10h. 54m.; sets, 17h. 25m.: right asc. on meridian, 1h. 20·3m.; decl. 3° 3′ N.

Planet.	Rises.	Souths.	Sets.	Right asc. and declination on meridian.	
	h. m.	h. m.	h. m.	h. m.	° ′
Mercury..	4 46	12 12	19 38	2 38·6	15 42 N.

THE CORROSION AND FOULING OF STEEL AND IRON SHIPS.[1]

THE difficulty of obtaining adequate experimental data, and the fact that nearly everyone who has worked at the subject has had a composition of his own to bring before the public, has so hampered and restrained the free discussion and interchange of ideas on this most important question, that at the present time we have made but scant progress beyond the point reached twenty years ago, and my object in bringing this paper before you is more to excite you to discussion, and to show you the known facts of the case, than to tell you of any very new or startling discoveries.

Corrosion generally precedes fouling on exposed metal surfaces, and it is therefore this portion of the subject that will be considered first, together with the means which have been taken to prevent it and to protect the plates of our vessels from decay.

In a paper which I had the honour to bring before you two years ago, I pointed out that in all processes of rusting carbonic acid gas and moisture played an important part, the iron uniting with the carbonic acid and oxygen of the water to form ferrous carbonate whilst the hydrogen was set free, and that the ferrous carbonate then took up oxygen dissolved in the water, or present in the atmosphere as the case may be, and was decomposed into ferric oxide (rust) and carbonic acid, which being liberated in actual contact with the moist surface of the iron carried on the process of "rusting."

This view of the case was confirmed by a paper read by Prof. Crum Brown before the Iron and Steel Institute, at Edinburgh, last autumn, and is generally accepted as the true explanation of the corrosion taking place on iron or steel surfaces exposed to moist air or fresh water; but the rusting of the metal in sea water has by many chemists been ascribed to a more complex action, in which the salt present plays an important part by first forming oxychloride of iron.

This preliminary stage of corrosion in sea water is, I am inclined to think, a myth. When iron filings or turnings are exposed to the action of sea water, hydrogen gas is evolved, and ferrous oxide and carbonate are formed, and this changes, as in air or fresh water, into ferric oxide, by taking up dissolved oxygen present in the water. At no time have I been able to

[1] A Paper read at the thirtieth session of the Institution of Naval Architects, by Prof. V. B. Lewes, F.C.S., F.I.C., Royal Naval College Associate, on April 12, 1889.

detect the presence of oxychloride, and from the fact that a few drops of alkali added to the sea water stop the corrosion, I am of opinion that the simple rusting of iron in sea water is due to the same cause as in fresh—*i.e.*, the decomposition of the water by the iron in presence of carbonic acid.

The saline constituents of sea water, however, do undoubtedly play an important part in a more active form of corrosion, by helping to excite galvanic action between the iron in the plates and any foreign metal or impurities present, an action which is also materially aided by want of homogeneity in the metal, by particles of rust, by mill scale, by wrought and cast iron or steel in contact with each other; or even by the different amount of work, such as hammering or bending, undergone by different parts of the same plate; and in all of these cases the galvanic action set up causes rapid oxidation of the iron at the expense of the oxygen of the water, hydrogen being evolved.

We may therefore consider that on the skin of a ship two processes of rusting are going on, the simple corrosion on exposed surfaces of the metal, due to the presence of moisture, carbonic acid and free oxygen, which forms a fairly uniform coating of rust on the metal, and the more local corrosion due to galvanic action, which results in pitting and uneven eating away of the plates.

As I pointed out in a previous paper, rust cones are due to the most local form of galvanic action, caused by the presence of a spec of deposited copper, lead, or other foreign metal, or even a small particle of rust, or mill scale, left on the surface of the iron, and covered by the compositions used as protectives and antifoulers; as soon as the sea water penetrates to these, galvanic action is set up, water is decomposed, rust formed, and the escaping hydrogen pushes up the composition, forming a blister, the hydrogen leaks out, the water leaks in, the action becoming more and more rapid, and the blister gradually filling with the result of the action—rust. The blister bursts, but the cone of rust has by this time set fairly hard, and continues to grow from the base, the layers of rust being perfectly visible in a well-formed cone, and when the rust cone is detached, the pitting of the metal at the base of the cone is, as a rule, found to be of considerable depth.

The speck of foreign matter which has caused this destructive action generally clings to the surface of the iron, and, being at the bottom of the pitting, escapes detection and removal, and when the vessel, newly coated with fresh compositions, again goes to sea, the corrosion will again probably be set up in the same spot.

The corrosion of the plates in the interior of a vessel is a subject quite equal in importance to the external action of sea water and dissolved gases on the metal; and from the fact that certain portions of the interior plates, from their position, escape the frequent examination and attention bestowed upon the exterior, it becomes a still greater source of danger.

Corrosion, like all other forms of chemical action, is much accelerated by increase of temperature; and in the bottom of a ship, near the furnace-room and boilers, this has a considerable effect in increasing the rapidity of rusting. Also in the coal bunkers, the mere contact of moist coal with the iron plates sets up galvanic action, carbon being electro-negative to iron, and the coal dust which sifts down into the double bottom lends its aid to the destruction of the plates; whilst, if the coal contains any "pyrites," which is nearly always the case, these double sulphides of iron and copper are gradually oxidised into soluble sulphates of the metals, and these, washing down into the bilge water, would at once cause most serious corrosion, should they come in contact with any bare portion of the plates. Repairs to any portion of the inside plates will loosen rust and mill scale, which, finding its way into the bottom, tends to set up galvanic action: whilst the scale of oxide of copper from copper and brass fittings and pipes is another great cause of danger, as the bilge water would gradually convert it into soluble salts, which will deposit their copper upon the iron wherever a crack or abrasion enables them to come in contact with it; and finally, leakages from stores and cargo are in many cases of a character highly injurious to iron.

In addition to all these sources of danger, we must remember that the interior of the vessel is the part most liable to abrasion from shifting and moving of cargo, coals, &c.

The protection of the outsides of the bottoms of our ships from the destructive agencies of sea water and dissolved gases may be said to have been attempted in two ways, by metallic and by non-metallic coatings.

So far, all attempts at metallic coatings have proved failures, and, as far as it is possible to judge, there is but small likelihood of their ever being made to succeed, because if zinc is used in order to protect the iron of the ship there must be galvanic action, and this action must take place evenly all over the surface of the iron plates, which means that the sheathing must be in uniform metallic contact with the iron, in which case the wasting of the sheathing would be so rapid that it would have to be renewed frequently, which, even leaving out the question of cost, is in many cases impossible.

Zinc is practically the only metal which could be used for this purpose, in order to place the plates of the ship in an electro-negative condition, and it is, therefore, to zinc that inventors have turned from time to to time, the chief novelties introduced being the method of attachment. As far back as the year 1835, I believe Mr. Peacock tried zinc plates on the bottom of H.M.S. *Medea*, and in 1867 Mr. T. B. Daft again brought the subject forward; Sir Nathaniel Barnaby, Mr. McIntyre, and others, also suggesting various plans of attachment, whilst as late as last year Mr. C. F. Henwood read a paper at the United Service Institute strongly advocating zinc sheathing as attached by his system.

Where the galvanic contact has been but small there the sheathing has had a certain life, but has afforded but little protection to the iron, and has gradually decayed away in a very uneven fashion; whilst in those cases where galvanic contact has been successfully made the ship has on several occasions returned from her voyage minus a considerable portion of the sheathing.

Another drawback to the use of zinc sheathing is one which was found when it was used to coat wooden ships, and that is that zinc when in sheets, like every other metal, is by no means homogeneous, and that for this reason the action of sea water upon it, leaving out of consideration galvanic action, is very unevenly carried on, the sheathing showing a strong tendency to be eaten away in patches, whilst the metal itself undergoes some physical change, and rapidly becomes brittle.

Attempts have been made to galvanize the iron before the building of a ship; but Mr. Mallet showed as early as 1843 that this coating was useless when exposed to sea water, as in from two to three months the whole of the zinc was converted into chloride and oxide, and that, when, therefore, galvanising is used, care must be taken to protect the thin coating of zinc. This does not, of course, apply to fresh water, in which galvanised iron would answer very well, the rapid action being due to the salts in the sea water; but even in this case the galvanising would have to be done after the plates had been riveted together, as any breaking of the surface would set up rapid wasting of the zinc, and it could, therefore, only be used on small craft.

Copper, tin and lead have been proposed for coating ships, but these metals are electro-negative to iron, and would rapidly destroy the hull, should any abrasion of the coating or damage to the insulating material take place.

The non-metallic coatings which are intended to do away with corrosion have been almost endless. At the present moment there are upwards of thirty in the market; whilst the patent list of the last fifty years contains an enormous number which were practically still-born.

They may be divided for convenience into—

(*a*) Oil paints.

(*b*) Pitch, asphalt, tar, or waxes.

(*c*) Varnishes, consisting of resins and gums dissolved in volatile solvents.

(*d*) Varnishes, containing substances to give them body.

(*e*) Coatings of cement.

And, before going into these in detail, it is necessary to consider the condition of the surfaces to which they will have to be applied, and the effect this will have upon them.

Air has the power of holding water vapour in suspension, the amount so held being regulated by the temperature; the higher the temperature the more can the air hold as vapour, whilst any cooling of the air saturated at the particular temperature causes a deposition of the surplus moisture. When a ship is scraped down to the bare iron in the dry dock, we have a huge surface of metal which varies in temperature much more rapidly than the surrounding air, and cools much more rapidly than the stone walls of the dock; as it cools, so it chills the layer of air in immediate contact with it, and causes a deposition of the surplus moisture on its surface—a phenomenon known as the "sweating

of iron"—and on to this moist surface the protective composition has to be painted. If now a rapidly-drying varnish is put on, the rapid evaporation of the volatile solvent causes again another sudden fall of temperature—evaporation being always accompanied by loss of heat—and this fall of temperature again causes a deposition of moisture, this time on the surface of the protective, so that the coating is sandwiched between two layers of moisture, both of them probably acting deleteriously upon the resin or gum in the varnish, whilst the moisture on the iron also prevents adherence of the varnish to the metal. If, instead of a quick-drying varnish, the old-fashioned red lead and linseed oil protector had been used, the second deposition would not have taken place, but the sweating of the iron would have prevented cohesion, and, when dry, any rubbing of the coating would bring it off in strips.

The condition of the outer skin of a ship, when she is being coated with her protective composition, is one of the prime factors in the discrepancies found in the way in which compositions act. It being a very usual thing for a composition to give most satisfactory results on several occasions, and then, apparently under exactly similar circumstances, to utterly break down, and to refuse even to keep on. Too much stress cannot be laid upon the condition of the plates at the time of coating, and it is absolutely essential either to have a perfectly dry ship or else a composition which is not affected by water.

When an old ship is broken up, you will often see on the backs of the plates the numbers which had been painted on them with white lead and linseed oil before the ship was built, and, under the paint, the iron in a perfect state of preservation, the secret being that the paint was put on while the plates were hot and dry.

Boiled linseed oil, mixed with red or white lead, is amongst the oldest of the protective compositions in use, but of late years has been but little employed, since it was proved by M. Jouvin, of the French Navy, and also in this country, that compounds of lead, when exposed by the wasting of the vehicle to the action of sea water, are converted into chloride of lead, and this is rapidly acted on by the iron, depositing metallic lead and forming chloride of iron, the deposited lead carrying on the corrosion of the iron by rapid galvanic action. The drying of boiled linseed oil is due to the fact that it has in it a certain quantity of an organic compound of lead, and the drying properties are given to it by boiling it with litharge (oxide of lead), so that, even when red or white lead is not mixed with it, still lead compounds are present, and this action will go on to a lesser extent. When the boiled oil drys, it does so by absorbing oxygen from the air, and becomes converted into a sort of resin, the acid properties of which also have a bad effect upon iron, so that protectives containing boiled oil are open to objection. Within the last two months a good example of the action of sea water on the bottom of an iron ship, coated with red lead, has been afforded by H.M.S. *Nile*, which, after being painted over with coats of red lead, was allowed to remain for some months in Milford Haven, with the result that her bottom is very seriously corroded, and, on examination of specimens of rust taken from her, the crystals of metallic lead are in many cases easily identified.

If red lead is used, it can only form a ground-work for an anti-fouling composition which has to protect the red lead as well as the iron of the ship from the action of sea water, and when the anti-fouling composition and the vehicle perish, then serious corrosion must ensue.

The second class of protectives, consisting of tar and tar products, such as pitch, black varnish, and also asphalt and mineral waxes, are amongst the best protectives, the waxes especially not being affected by the sweating of the plates, and forming admirable coatings for the plates. Certain precautions, however, must be taken in the case of tar and tar products, both of which are liable to contain small quantities of acid and of ammonia salts; but if care be taken to eliminate these, and if it could be managed to apply this class of protectives hot to warm plates, the question of protection would be practically solved, bituminous and asphaltic substances forming an enamel on the surface of the iron which is free from the objections to be raised against all other protectives, that is, that being microscopically porous they are pervious to sea water.

The third class of protectives consists of varnishes formed by dissolving gums or resins in volatile solvents, such as spirit, turpentine, naphtha, fusel oil, &c., and such varnishes are open to several objections—in the first place, they are acted upon by moisture, which causes a deposition of the resins or gums as a non-coherent powder and destroys tenacity of the varnish. The amount of action which moisture has on such a spirit-varnish depends to a considerable extent upon the proportion of resin or gum to spirit, when the solvent is present in large quantities, and the resin in comparatively small; then the moisture has apparently little action; but it must be remembered that the drying of such protectives means the rapid evaporation of the solvent and concentration of the resin or gum, whilst the rapid volatilization which is going on cools the hull of the ship, and causes deposition of moisture on the drying varnish with most disastrous results.

Another point which must be borne in mind is that no such varnish is impervious to gases and liquids. We are apt to think of a coating of varnish as being perfectly homogeneous; but, on examining it through a microscope, it is seen to be full of minute capillary tubes, which become gradually enlarged by the action of water, and finally result in the destruction of the varnish, whilst moisture and dissolved gases find their way to the metal, and carry on corrosion. The application of several coats of varnish tends to diminish this evil, as in many cases the holes in the first coat will not correspond with the holes in the second, and so each succeeding coat will tend to make the protective more and more impervious. In using such varnishes, they must only be applied in favourable weather, and must be allowed to thoroughly harden before being brought in contact with the water.

In the fourth class we have varnishes of this kind to which body has been given by the addition of foreign constituents, generally mineral oxides; and this class is far preferable to the last, if the solvent used is not too rapid in its evaporation, and if care has been taken to select substances which do not themselves act injuriously upon iron or upon the gums or resins which are to bind them together, and are also free from any impurities which could do so.

At present the favourite substance used to give colour and body to such varnishes is the red oxide of iron, the colour of which effectually cloaks any rusting which may be going on under it. In using the red oxide for this purpose, care should be taken that it contains no free sulphuric acid or soluble sulphates, as these are common impurities, and are extremely injurious, tending to greatly increase the rate of corrosion. The finest coloured oxides are, as a rule, the worst offenders in this respect, as they are made by heating green vitriol (sulphate of iron), and in most cases the whole of the sulphuric acid is not driven off as the heat necessary impairs the colour; this acid is often neutralized by washing the oxide with dilute soda solution, but very little trouble, as a rule, is taken to wash it free from the resulting sulphate of soda, which is left in the oxide.

A sample of exceptionally good colour intended for using in protective compositions was sent me a few weeks ago for analysis, and proved to contain no less than 15·3 per cent. of sulphate of soda.

The best form of oxide of iron to use for this purpose is obtained by calcining a good specimen of hæmatite iron ore at a high temperature. When prepared in this way, it contains no sulphates, but from 8 to 40 per cent. of clay; if the percentage does not, however, exceed 12 to 18 per cent. it is perfectly harmless.

Composition manufacturers can easily test their red oxides for themselves, to see if it contains soluble sulphates, by warming a little of it with pure water, filtering through blotting paper, and adding to the clear solution a few drops of hydrochloric acid, and a little solution of chloride of barium (easily obtained at any druggist's). If a white sediment forms in the solution, the sample should be rejected.

In a previous paper[1] on the corrosion and protection of iron and steel ships, I pointed out that when such a varnish perished, the oxide of iron being left in contact with the iron plates, increased the corrosion going on at the surface of the metal, all oxides being electro-negative to the metals from which they are produced, and on that occasion I advocated the use of finely divided metallic zinc, which can be obtained as an impalpable powder, in place of the oxide of iron, pointing out that such a composition would last as long as any varnish of this class, and that, when the varnish perished, as it must do after long exposure to sea water, then the metallic zinc would, on coming in contact with the iron, set up galvanic action; but that, instead of being electro-negative, as in the case of oxide of iron, and causing corrosion of the plates, it would be electro-positive, and in consequence would protect them, being itself slowly oxidized, and so would give a fresh period of protection.

[1] Transactions of the Institution of Naval Architects, vol. xxviii.

I hoped at the time that I had made it perfectly clear that the zinc would in no way act until both the anti-fouling and protective varnish had perished, and had become spongy and porous, and that the idea was a prolongation of the period of protection, the great point which has now to be aimed at; but the remarks made afterwards in several journals which were kind enough to notice my paper showed me that they had mistaken my intention, and supposed that the zinc was put in to at once create galvanic action, and predicted that if by any chance it did act, the hydrogen generated would blow the composition into blisters, and defeat its own purpose. I need hardly point out that nothing was farther from my intention, as zinc in fine powder will be acted on more rapidly than the dense metal in plates, and I have already pointed out that this is destroyed too rapidly by galvanic action to render it of practical use as a protective *per se*.

As to the hydrogen blowing off the composition, no gas could be generated until both the anti-fouling and the protective coatings had been perished and rendered perfectly porous by the action of the sea water, a condition which would have permitted the free escape of the generated hydrogen, which, it must be remembered, will permeate through openings which other gases cannot pass through.

One of the largest firms of composition manufacturers had enough curiosity to try the effect of zinc *versus* oxide of iron, and painted a patch of it upon a ship coated with his compositions, and after a long voyage she returned with her protectives in perfectly good order, and had it not been for the patch containing zinc having had its position fixed by careful measurements, its whereabouts could not have been discovered. This is exactly what one would have expected; as long as the varnish remains intact oxide of iron, zinc, or, indeed, any substance which will not damage the varnish, does perfectly well; but had the vessel been allowed to continue until the varnishes had perished, then I venture to say that the patch containing the zinc would have shown better protection than those parts containing the oxide of iron. My ideas have undergone considerable modification during the past two years, but I still consider the views I put forward in my last paper were perfectly sound, and I am every day more and more convinced that the great object the composition-maker has to aim at is the prolongation of the life and effectiveness of compositions, and not the multiplication of short-lived devices, however admirable in their action.

In the fifth class of protectives we have cement coatings; but these, together with such schemes as the covering the hull of the vessels with vitreous glazes, glass, &c., have of late years, as far as I know, entirely been abandoned. The action of cement on iron, however, must later on be discussed in its important bearing on the protection of the interior portions of the hull, for which it is largely employed, its weight and the difficulty of attachment rendering it unfitted for outside work.

In selecting a protective composition for the bottom of a vessel, one of the second or fourth class should be chosen, attention being given to the points I have indicated, which are that in the bituminous and asphaltic compositions all the original acids must be eliminated, and that in the varnishes of the fourth group quickly evaporating solvents should be avoided, and, if possible, zinc substituted for oxide of iron.

The vessel should have her plates as dry as possible during the application of the protective, and, if feasible, days on which the air is fairly dry should be chosen. The protective should not be too thick, as, if it is, it does not readily fill into inequalities in the plates; and, if in this way any air is inclosed, change of temperature will cause it to expand or contract, thus causing a blister to form, which will fill with sea water and set up rapid corrosion. The composition must either be elastic or else have the same rate of expansion and contraction as the iron; for, if not, the change of temperature will cause cracking and tearing of the composition with disastrous results. The vessel, if she has to be scraped down to the bare metal, must be scrubbed free from all traces of rust, and where a well-adhering coating of composition exists, it should be painted over and not disturbed. In the case of a new ship, she must be pickled with dilute acid, to get rid of every trace of mill scale, and then washed down with some slightly alkaline liquid to neutralize every trace of acidity, the alkali in turn being removed by clean water. Under these conditions, and given a composition with good adhering properties, but little apprehension need be felt as to the ravages of corrosion on the metal of a ship's bottom, the chief risk being from abrasion and other mechanical injury to the composition, coupled with improper constituents in the anti-fouling compositions. The protection of the interior portion of the vessels, where the plates are exposed to the corroding action of bilge water, rendered more active by a high temperature, leakage from cargo, acids and sulphates from wet coals, and the presence of such electro-negative factors as coal dust, scale, and rust, is a matter of quite as great importance as the exterior protection; whilst the great chance of mechanical abrasion during coaling and shifting of cargo, as well as the difficulty of getting at the lower portions of the hold to examine the condition of the plates, renders it a question of the gravest consideration. The corrosion found in the portions underneath the engine-seats, the bunkers, and the water-ballast chambers, especially near the engine-room, is often very serious, and needs most careful watching, which, from the position of these parts of the vessel, it is very hard to bestow upon it.

It must also be remembered that the bilge water in a vessel is in constant motion, and that the air in these parts of the vessel may be expected to be exceptionally rich in carbonic acid gas, which, as I have before shown, is the most important factor in corrosion. Under these conditions any abraded portion would probably be continually washed over, and then exposed to the foul air, a condition of things most conducive to rapid rusting. There are three main classes of protectives for the interior of a ship—

(1) Cements.
(2) Bituminous coatings.
(3) Paints.

The first of these, the cement coatings, have many good points to recommend them, but they also have many serious drawbacks.

The rigidity, firmness of adherence and endurance, are all of them points of the greatest importance, and there is no doubt but that the silicates present in the cement in time, not only bind the cement into a mass of wonderful hardness, but also bind that cement to the iron. A point to which I should like to draw your attention, however, is that a thin coating of Portland cement is highly porous, and that it can be permeated by liquids and gases. Suppose, now, that some copper scale from the interior fittings had fallen into the bottom of the vessel, and had been converted into soluble salts of copper by the saline bilge water, this solution would soak through the capillary orifices in the cement, until it came in contact with the iron below, when the copper would be deposited on the iron, and rapid galvanic action set up, the cement being loosened, and to a certain extent lifted, by the formation of rust, whilst corrosion would gradually extend under the cement, giving on the outside of the coating but little sign of damage taking place below it.

Also the hardness and rigidity of the cement gives it a tendency to crack away from the metal when any strain is thrown upon the plates, or during any expansion or contraction of the metal; whilst any repairs on the outside of the ship, such as making a boring to test the thickness of plate, replacement of rivets, &c., would undoubtedly cause a loosening of the cement coating within, and, wherever a loosening takes place, the space between the cement and the plate will quickly be found to become a starting-point for corrosion, which quickly spreads and loosens the cement, and will only be discovered by chance.

It is for this reason that I consider bituminous or asphaltic varnishes, freed from any trace of acid, and applied hot, or sound tough paint, preferable to cement; as, although they are not so hard, yet if serious corrosion should be set up, it is easily discovered and stopped before much damage results, whilst, being impervious to moisture, deleterious solutions, either from the coal bunkers or cargo, would be prevented from acting upon the skin of the ship.

In approaching the subject of fouling, one is impressed with the apparent hopelessness of obtaining any reliable information from the successes or failures registered by the bottoms of the vessels, in the Service, or in the Mercantile Marine. Hundreds of ships may be examined, and their condition and the nature of the compositions used upon them registered, and just as one begins to feel that the key to the mystery is within one's grasp, a whole series of results so abnormal suddenly comes to light that it seems impossible to reconcile them with one's previous experience. A ship may sail half a dozen times to the same waters, coated with the same composition—on four occasions she will come home clean and in good condition, whilst on the other two voyages she may accumulate an amount of weed and animal life sufficient to knock down her speed from nine knots to five. Moreover, if the compositions with which she was coated be examined, and scrapings taken from her on her return, no cause will present itself that

can in any way explain the great difference in her condition. After several years' close observation, however, certain factors begin to make themselves apparent. Ships at sea from March to August show a worse average than those afloat from August to March; one also begins to realize that the amount of fouling increases enormously if the ship has been long at anchor—ships which have been lying at the mouths of rivers, although quite clean in the brackish water, foul much more rapidly on going to sea than the vessels which have been cruising, or even at anchor for the same time in salt water; and finally, certain ports and certain seas seem to exercise a deleterious effect, both as regards corrosion and fouling, which is not to be found elsewhere.

Turning back to the naval history of the past, we find that fouling is no new trouble born with the advent of our present iron monsters; but that it has been the one trouble that the combined engineering and scientific skill of many centuries has been unable to overcome.

With our wooden ships, metallic copper sheathing, if it were of the best kind, answered the purpose fairly well; but then the copper wasted so fast the inferior kinds and alloys were substituted to prevent the rapid loss, and, with the slowing down of the destruction of the copper, at once the trouble of fouling returned.

When iron ships began to replace the wooden ones, as was only natural, attempts were made to utilize the metal which had before given relief; but it was quickly found that the effect of the galvanic action set up by the copper was fatal to the iron plates of the ship, and attempts were then made to sheathe the ship with copper plates in such a way that they should be insulated from the iron of the vessel, a condition almost impossible to attain and attended with great risk, should any accidental injury to the insulation take place.[1] Early in the history of iron shipbuilding the idea was started of using coatings of paint, so prepared as to fulfil the same functions as the copper plates had done; but from 1840, when the first paint of this kind was patented, down to the present day, when there are upwards of thirty-two different compositions in the market, very little progress has been made in their manufacture, and the best of their compounds cannot be relied upon for keeping a ship's bottom even fairly free from fouling for periods extending beyond nine months, and I am personally convinced that the reason of this is to be found in the fact that a start was originally made in the wrong direction.

The idea which originally led to the present class of anti-fouling compositions was that the copper salts formed by the action of the sea water on the metallic sheathing owed a considerable portion of their value as anti-foulers to the poisonous action they exerted upon marine animal and vegetable growths; but, when an observer comes to study the natural history of these lower forms of animal life and vegetation, it is gradually forced upon one that it is only in the early stages of their growth—the germ period—that metallic poisons can affect them. Seaweeds do not take in the constituents they require for their growth by means of their roots, as is, to a certain extent, the case with ordinary plants, but absorb them by means of their pores from the water itself, the root only serving to attach them to the solid they choose for their resting-place; it is also well known that when once a marine plant which has passed the first stages of existence is dislodged or torn from its support, it cannot reattach itself to anything else, whilst most of the mineral poisons have little or no effect upon their life and growth.

In the same way we find that, with the animal life found on a ship's bottom, the under side is used to cling on with only, and not as an extractor of nourishment, and that, therefore, after the seeds and germs have once obtained a foothold on the side of the vessel, no amount of poison which can be put into a composition will have any effect upon them. Metallic poisons undoubtedly do exert an influence upon the germs in their earliest stages; but after that they are perfectly useless as anti-foulers, and only imperil the plates of the vessel.

The germs of both kinds of growth are of necessity more abundant in the surface water near shore than in deep water, and therefore the period when the ship is in port is the time when the germs are most likely to make good their attachment, after which their further development is, unless other methods of getting rid of them are employed, merely a matter of time.

On examining the conditions under which a vessel is placed when coated with a composition which relies for its anti-fouling powers on metallic poisons only, we at once see the reasons which must make such a coating of little or no avail. In the composition we have drastic mineral poisons, probably salts of copper, mercury, or arsenic, which have been worked into a paint by admixture with varnishes of varying composition, and each particle of poison is protected from the action of the sea water by being entirely coated by this vehicle: that this must be so is evident, or the composition would not have sufficient cohesive power to stick on the ship. As a rule, care is taken to select fairly good varnishes, which will resist the action of sea water for, perhaps, two or three months, before they get sufficiently disintegrated to allow the sea water to dissolve any of the poison; whilst, even with the accidental or intentional use of inferior varnishes, three or four weeks will pass before any solution can take place, and any poison be liberated to attack the germs. A ship is dry docked, cleaned, and, her anti-fouling composition having been put on, she goes probably into the basin to take in cargo. Here she is at rest, and, with no skin friction or other disturbing causes to prevent it, a slimy deposit of dirt from the water takes place, and this, as a rule, is rich in the ova and germs of all kinds of growth, whilst the poisons in her coating are locked up in their restraining varnish, and are rendered inactive at the only period during which they could be of any use. After a more or less protracted period, the ship puts to sea, and, the perishing of the varnish being aided by the friction of the water, the poisonous salts begin to dissolve or wash out of the composition; but the germs have already got a foothold, and with a vessel sweeping at a rate of, say 10 to 12 knots through the water, the amount of poison which can come in contact with their breathing and absorbing organs is evidently so infinitesimally minute that it would be impossible to imagine it having any effect whatever upon their growth. If the poison is soluble, it is at once washed away as it dissolves; if it is insoluble, then it is also washed away, but there is just a chance that a grain or two may become entangled in the organs of some of the forms of life, and cause them discomfort. As the surface varnish perishes, the impact of the water during the rapid passage of the vessel through the water quickly dissolves out or washes out the poisonous salts, and leaves a perished and porous, but still cohesive, coating of resinous matter, which forms an admirable lodgment for anything which can cling to it; and by the time the vessel lays-to in foreign waters, teeming with every kind of life, the poison which would now again have been of some use is probably all washed away, and a fresh crop of germs are acquired, to be developed on the homeward voyage, and a "bad ship" is reported by the person who looks after her docking. It is evident that a poison, even if it had the power of killing animal and vegetable life in all stages, could only act with the vessel at rest, unless it were of so actively corrosive a nature as to burn off the roots and attachments of the life rooted to it, and if it did this, what, may I ask, would become of the protective composition and the plates of the vessel? And I think it is also evident that any poison so used must be under conditions in which it is very unlikely to be in a position to act when it might do good.

The lamentable failure of composition after composition of this kind has gradually reduced them in number to some ten or twelve at the present time, and in most cases it is low price alone which keeps them in the market.

The practical proof, given by experience, that poisons alone are unable to secure a clean bottom, soon led many inquirers to the conviction that it was the exfoliation in the case of copper which had acted in giving fairly good results, and in many compositions the attempt has been made to provide a coating which shall slowly wash off, and, by losing its original surface, shall at the same time clear away germs and partly developed growths, and so expose a continually renewed surface, in this way keeping the bottom of the vessel free from life. There is no doubt that, when this is successfully done, a most valuable composition will result, but the practical difficulties which beset this class of anti-foulers must not be overlooked. In order to secure success, the composition must waste at a fairly uniform rate, when the ship is at rest, and also when she is rushing through the water; and this is the more important in the case of Service vessels, as in many cases they spend a large percentage of their existence at anchor, or in the basins of our big dockyards. If a composition is made to waste so rapidly that it will keep a vessel clean for months in a basin, then you have a good composition *for that purpose*; but send the vessel to sea, and under conditions where you have a higher temperature, and the enormous friction caused by her passage through the water exerting its influence upon the composition, and you will find that the coating, which did its work well for six months at rest in the basin, will, in the course of one month under these altered conditions, be all washed

[1] Some copper sheathed vessels still exist, and its revival has been lately warmly advocated in America.

away, and fouling will be set up. Noting this result, the manufacturer renders his composition more insoluble—less wasting—and so obtains a coating which, when the vessel is in motion, scales just fast enough to prevent fouling, and good results at once follow; the composition is then put on the same or other vessels, and they take a spell of rest in the basin, and, bereft of the aid of the higher temperatures and the friction of the water, the composition ceases to waste fast enough, and bad results at once have to be recorded.

There is no doubt that this is the true explanation of the wide discrepancies which are found between the compositions in the Navy and in the Mercantile Marine: take any of the big lines, their steamers are running at a fairly uniform rate of speed, and the periods of inaction are as short as the desire not to waste the charge on the capital they represent can make them, and under these conditions, by varying the constituents in the varnishes used for anti-fouling purposes, it is fairly easy, given the necessary data, to so constitute a composition as to secure admirable results; but when you come to apply this same coating to an ironclad running at various speeds, and as often at rest as in motion, then you at once find that the composition you before imagined to be all that could be desired fails just as lamentably as the tribe of anti-foulers which preceded it. It is not so very long ago that I had the honour to serve on an Admiralty Committee under the able guidance of Admiral Colomb, and, after inspecting many vessels in the Mercantile Marine, and watching all the dockings of Service vessels over a considerable space of time, we were forced to the conviction that it was only in very rare cases that the condition of the bottoms of Her Majesty's ships at all approached the freedom from fouling to be found in the ships belonging to the big companies, with the result that some of the most successful of the compositions in the Mercantile Marine were brought into use in the Navy, and I believe the reports of the dockings since they have been adopted will amply prove the existence of the difficulties I have mentioned.

Another factor which is often overlooked, and which tends to give misleading results, is the action of brackish water, which, in many cases, seems to exert a special action in keeping the bottom of a vessel clean, the fresh water having a tendency to disagree with certain forms of marine growth, whilst the salt water is apparently equally unpalatable to the fresh-water forms of fouling.

In most of the compositions now in use, attempts are made to combine strongly poisonous substances with exfoliating and wasting coatings, and this is done by either using metallic soaps, the basis of which is, as a rule, copper, or else by charging a perishable and easily washed-off varnish with poisonous salts, consisting, as usual, of compounds of either copper, mercury, or arsenic, and in some cases all three.

As I have before pointed out, I do not think the presence of these substances exerts any deterrent action upon the fouling, save perhaps when the vessel is at rest; but they exert undoubtedly an important influence upon the rate of exfoliation, as when the perishing of the varnish exposes them they dissolve, or are washed out, and in this way tend to disintegrate and clear away the surface more rapidly—an important and decidedly useful function, but one which might be more cheaply performed by substances other than high-priced metallic poisons.

The use of metallic poisons of the character indicated throws an increased burden upon the protective composition, as, should the latter become abraded by friction of chain cables, barges alongside, or any other cause, the iron of the vessel will be attacked by the metallic salts, either present in the soluble form in the anti-fouling composition, or rendered so by the solvent action of the saline constituents of the sea water, the action of the metallic salts being to rapidly dissolve portions of the iron, and to deposit the metal which they contain upon the surface of the plates, and these deposits, exciting energetic galvanic action, cause corrosion and pitting to go on with alarming rapidity. Both mercury and copper salts are offenders in this way, but copper is by far the most objectionable, from the fact that the salts formed by the action of the sea water upon the compounds used in the compositions are far more soluble than the corresponding salts of mercury, and are therefore liable to be present in much larger quantity, and so exert comparatively a much more injurious action on the plates.

As an illustration of this, two equal portions of sea water were saturated, the one with copper chloride, the other with mercuric chloride, and into each a piece of steel, planed upon one side, and of about equal weight and size, was placed, and left for four days. At the end of this period the two plates were removed, and, after being cleaned and dried, were again weighed, when it was found that the one exposed to the copper-saturated sea water had lost 22·2 per cent. in weight, while the plate exposed to the mercurial solution had only lost 3·6 per cent., this being due to the much larger amount of the copper salt soluble in the sea water.

On now placing these plates in clean sea water, corrosion went on in each case with extreme rapidity, and after being exposed for a month, they had both wasted to about the same extent—that is to say, when once deposited on the iron, mercury is practically as injurious as copper.

I am quite aware that this experiment is not at all likely to be carried out in practice, and none can have a greater conviction of the inutility of small laboratory experiments than I have, as they lack all the factors of mass of material and atmospheric influence which play so important a part in a question like the present; but such an experiment gives one a definite and fairly correct idea of the relative rate of action of the two poisons upon the plates.

All the time the ship is in motion, the wash of the sea water will prevent the metallic poisons doing the plates or the marine growths much harm, but there is one phase of this question which I think has been overlooked. I need not point out that in certain ports there is a fashion in compositions, and that most of the homes of the Mercantile Marine have some pet local composition which is largely used at the particular port. If, now, many ships are laying in a basin, taking in and discharging cargo, and if the prevalent compositions contain copper, it is evident that a certain quantity will go into solution in the water, which often does not undergo frequent or rapid change, and under these conditions every ship in the basin will be exposed to the same danger, and wherever an abrasion has taken place in the protectives, there copper will be deposited on the iron, causing corrosion and destruction of the plates; and it must be remembered that when the vessel is next docked and coated no amount of scraping will remove the fine particles of copper deposited in the pitted and corroded portions of the plate, and so finely divided as to be invisible to the eye, but that they will remain and carry on the destructive work under the new coatings of protective.

It is, I think, a well-recognized fact that, when a vessel coated with a copper compound has become corroded from failure of her protective, or from abrasion, even an entire change of composition does little or no good in stemming the tide of corrosion, until after some considerable period has elapsed, a result which is due to the same cause; and, inasmuch as copper compositions are a source of danger, not only to the ships coated with them, but to any others which may be at rest in the same basin, I do strongly urge upon the manufacturers to abandon the use of these deleterious compounds, and to use others equally efficacious and free from the grave objections I have enumerated.

At the present time, 15 out of 32 principal compositions rely upon copper in some form or other as the basis of their anti-fouling composition, and in one which has enjoyed considerable favour finely divided metallic copper itself is used, and should vessel coated with it, after the varnishes had commenced to disintegrate, be moored alongside an iron ship by a chain cable, or even by a wet hawser, a big galvanic couple would be formed at the expense of serious damage to any exposed iron.

In the history of anti-fouling many attempts have been made to obtain highly glazed and glass like-surfaces which it was hoped would withstand the action of sea water, and afford no lodgment to marine growths; but even glass itself is slowly acted upon by sea water, and, when once roughened on the surface, will foul, whilst the rigidity of such coatings, and the straining and cracking consequent on unequal expansion and contraction of the plates and their coating, offers a serious obstacle to any such scheme.

In concluding this long paper, I wish to point out that in the present phase of the anti-fouling question, and until some new principle for preventing marine growth has been advanced and successfully adopted, satisfactory results can only be insured by an intelligent use of the existing compositions.

The protective composition is the important composition, and care must be taken to obtain the best in the market, as, if the protection is good, the plates remain uninjured even if fouling take place. The anti-fouling composition to be used with it must either be elastic, or have the same rate of contraction and expansion as the protective, and must—at any rate in the Navy—be chosen to suit the work to be done, such as contain copper compounds being carefully rejected, whilst preference should be given to those which rely on exfoliation rather than mineral poisons.

If a vessel is to remain at rest for a considerable period, an anti-fouling composition which exfoliates rapidly, and which also contains poisons known to act on germ life, must be used, the amount of such poison depending on the seasons and the waters in which the ship is to be; whilst if a vessel is to be continually running, then a slowly exfoliating composition must be employed, and a very small percentage of poison is all that is required, as skin friction and the comparative absence of the germs and spores in deep water will do the rest.

Our ships represent an enormous capital, and any trouble or care which will prolong their existence is well worth taking and will be amply repaid, and at the present time a heavily corroded and foul vessel means either ignorance or negligence on the part of those who have the responsibility of deciding on the compositions to be used; and, finally, it must be clearly borne in mind that there is no anti-fouling composition which ever has been made, or probably ever will be made, that will answer for all cases, and that, until this is clearly recognized, the present unsatisfactory condition of the question will exist.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 28.—"The Diurnal Variation of Terrestrial Magnetism." By Arthur Schuster, F.R.S., Professor of Physics; with an Appendix by H. Lamb, F.R.S., Professor of Mathematics, Owens College, Manchester.

In the year 1839, Gauss published his celebrated memoir on "Terrestrial Magnetism," in which the potential on the earth's surface was calculated to twenty-four terms of a series of surface harmonics. It was proved in this memoir that if the horizontal components of magnetic force were known all over the earth the surface potential could be derived without the help of the vertical forces, and it is well known now how these latter can be used to separate the terms of the potential which depend on internal from those which depend on external sources.

The use of harmonic analysis to separate internal from external causes has never been put to a practical test, but it seems to me to be specially well adapted to inquiries on the causes of the periodic oscillations of the magnetic needle.

If the magnetic effects can be fairly represented by a single term in the series of harmonics as far as the horizontal forces are concerned, there should be no doubt as to the location of the disturbing cause, for the vertical force should be in the opposite direction if the origin is outside from what it should be if the origin is inside the earth.

In any case, the differences between the two results will be of the same order of magnitude as the vertical force itself. If it were then a question simply of deciding whether the cause is outside or inside, without taking into account a possible combination of both causes, the result should not be doubtful even if we have only an approximate knowledge of the vertical forces.

Two years ago I showed that the leading features of the horizontal components for diurnal variation could be approximately represented by the surface harmonic of the second degree and first type, and that the vertical variation agreed in direction and phase with the calculation on the assumption that the seat of the force is outside the earth. The agreement seemed to me to be sufficiently good to justify the conclusion that the greater part of the variation is due to causes outside the earth's surface. Nevertheless, it seemed advisable to enter more fully into the matter, as in the first approximate treatment of the subject a number of important questions had to be left untouched. I now publish the results of an investigation which has been carried out as far as the observations at my disposal have allowed me to do. My original conclusions have been fully confirmed, and some further information has been obtained, which I believe to be of importance.

I have made use of the observations taken at Bombay, Lisbon, Greenwich, and St. Petersburg. The horizontal components of the diurnal variation during the year 1870 were in the first place reduced to the same system of co-ordinates and to the same units. If we remember that experience has shown the diurnal variation to be very nearly the same for places in the same latitude, except near the magnetic pole, and also that it is symmetrical north and south of the equator, we may for a given time of day assume the horizontal components known over eight circles of latitude, four of which are north and four south of the equator.

From the horizontal components, the potential was calculated in terms of a series of surface harmonics. It was found that in order to represent both the summer and the winter effect with sufficient accuracy thirty-eight terms were necessary. In this calculation the vertical forces were not made use of at all.

From the potential, as calculated from the horizontal components, we can deduce the vertical force, either on the assumption that the variation is due to an outside cause, or that it is due to an inside cause; and compare the vertical forces thus found with the vertical forces as actually observed.

If we put both into the form

$$r_n \cos n(t - t_n),$$

we can obtain an idea of the agreement as regards amplitude and phase for each harmonic term. The following tables give the results for $n = 1$ and $n = 2$—that is, for the diurnal and the semi-diurnal variation:—

TABLE I.

Observed and calculated Values of the Coefficients t_1 and t_2 of Vertical Force, when expressed in the form $r_1 \cos (t - t_1) + r_2 \cos 2(t - t_2)$, on the supposition that the Disturbing Force is *inside* the Earth.

In Table I. the comparison of the observed phases is made with the values calculated on the assumption that the disturbing force is inside the earth. In Table II. the same comparison is made on the alternative hypothesis. There is complete disagreement in Table I. between the observed and calculated values, and nearly complete agreement in Table II. It is seen how both at Lisbon and Bombay the time of maximum displacement agrees within three minutes of time for the diurnal variation, and at Lisbon within four minutes of time also for the semi-diurnal variation. Considering that Lisbon is the most important station, not only on account of its geographical position, but also because the observed vertical forces apply to the same year as the calculated ones, the result is strikingly in favour of the outside force. The results for Greenwich argue in the same direction. As regards St. Petersburg, the results for 1870 neither agree with one nor with the other hypothesis. The observations for 1870 are, however, doubtful, but the results for 1878 agree well with the hypothesis of an outside disturbing force.

The observed amplitudes are found in all cases to be considerably smaller than the calculated ones.

If we then take it as proved that the primary cause of this variation comes to us from outside the earth's surface, we are led to consider that a varying magnetic potential must cause induced currents within the earth, if that body is a sufficiently good conductor. These induced currents might be the cause of the apparent reduction in amplitude. As my colleague, Prof. Lamb, has given considerable attention to the problem of currents in a conducting sphere, I consulted him, and he

gave me the formulæ by means of which the induced currents can be calculated. This investigation is given in an appendix to the paper. The result is very interesting. If the earth is treated as a conducting sphere, the observed reduction in amplitude is accounted for, but that reduction should be accompanied by a change of phase which is not given by observation. We can reconcile all facts if we assume, as suggested by Prof. Lamb, the average conductivity of the outer layers of the earth to be very small, so that the reduction in amplitude is chiefly due to currents induced in the inner layers. If the conductivity inside is sufficiently large, a considerable reduction in amplitude would not be accompanied by a sensible change of phase. We have arrived, therefore, at the following result:—

The vertical forces of the diurnal variation can be accounted for if we assume an outside cause of the variation, which induces currents in the earth, and if the earth's conductivity is greater in the lower strata than near the surface.

Prof. Balfour Stewart's suggestion that convection currents in the atmosphere moving across the lines of the earth's magnetic forces are the causes of the daily variation, gains much in probability by this investigation. If the daily variation of the barometer is accompanied by a horizontal current in the atmosphere similar to the tangential motion in waves propagated in shallow canals, and if the conductivity of the air is sufficiently good, the effects on our magnetic needles would be very similar to those actually observed. The difficulty as to the conductivity of the air is partly met by the author's investigation of the behaviour of gases through which electric discharges are passing.

It will be interesting to follow out the investigation, especially with a view of examining the influence of sun-spot variation. The question of magnetic disturbances is more complicated, but as magnetic observatories are being established in many countries, the time may not be far distant when we shall be able to bring the irregular disturbances within the reach of calculation.

The author acknowledges the help he has received from Mr. William Ellis in some of the reductions; he has also to thank his assistant, Mr. A. Stanton, for much labour bestowed on making and checking numerical calculations.

Royal Meteorological Society, April 17.—Dr. W. Marcet, F.R.S., President, in the chair.—The following papers were read:—On the deaths caused by lightning in England and Wales from 1852 to 1880, as recorded in the returns of the Registrar-General, by Inspector-General R. Lawson. The total number of deaths from lightning during the twenty-nine years amounted to 546, of which 442 were of males, and 104 of females. In consequence of their greater exposure, the inhabitants of rural districts suffer more from lightning than those of towns. It appears also that vicinity to the west and south coasts reduces the chances of injury by lightning, and that distance from the coast and highland seems to increase them.—The diurnal range of the barometer in Great Britain and Ireland, by Mr. F. C. Bayard. The author has reduced the hourly records of the barometer at the nine Observatories, Aberdeen, Armagh, Bidston, Falmouth, Glasgow, Greenwich, Kew, Stonyhurst, and Valencia, during the years 1876–80. The curves of inland places are smoother than those of places on the sea-coast, and the curves of places to the westward are more irregular than those of places to the eastward. As we go from south to north the general tendency of the curve is to get flatter with a lessened diurnal range.—Note on a working model of the Gulf Stream, by Mr. A. W. Clayden. The author showed this interesting model at work; it has been constructed to illustrate the formation of ocean currents in general and of the Gulf Stream in particular.—On the rime-frost of January 6 and 7, 1889, by Mr. C. B. Plowright. The author gives an account of the very heavy rime which occurred in the neighbourhood of King's Lynn on these days, when the fringe of crystals upon twigs and branches of trees was about 2 inches in length. The weight was so great that nearly all the telegraph wires were snapped and an immense number of branches of trees broken off.

Zoological Society, April 16.—Dr. A. Günther, F.R.S., Vice-President, in the chair.—The Secretary exhibited a pair of a fine large Buprestine Beetle of the genus *Julodis* (*Julodis ffinchi*), obtained by Mr. B. T. Ffinch near Karachi; and a Mole-cricket (*Gryllotalpa vulgaris*), sent by Mrs. Talbot from Bagdad.—Mr. Sclater made some remarks on the animals he had noticed during a recent visit to the Zoological Gardens of Rotterdam, Amsterdam, and Antwerp.—A communication was read from Mr. A. H. Everett, containing remarks on the zoo-geographical relationships of the Island of Palawan and some adjacent islands. In this paper it was contended that Palawan and the other islands intervening between Borneo and Mindoro form an integral portion of the Bornean group, and do not naturally belong to the Philippine Archipelago, with which they have hitherto been treated. The writer founded his contention upon the grounds (1) that the islands in question are connected with Borneo by a shallow submarine bank, while they are separated from the Philippines by a sea of over 500 feet depth; and (2) that a comparison of the Bornean and Philippine elements in the fauna of Palawan, so far as it is known, shows a marked preponderance of the former over the latter element; while the Philippine forms are also more largely and more profoundly modified than the Bornean species. This fact indicated that they had been longer isolated, and consequently that the fauna of Palawan was originally derived from Borneo, and not from the Philippines, though a considerable subsequent invasion of species from the latter group had taken place.—A communication was read from Mr. Oldfield Thomas, containing an account of the mammals of Kina Balu, North Borneo, from the collections made on that mountain by Mr. John Whitehead in 1887 and 1888. The species represented in Mr. Whitehead's collection were 21 in number, of which six had proved to be new to science.—Mr. G. A. Boulenger read the second of his communications on the fishes obtained by Surgeon-Major A. S. G. Jayakar at Muscat, on the east coast of Arabia. The two collections recently received from Mr. Jayakar contained examples of 80 species not included in Mr. Boulenger's former list.

PARIS.

Academy of Sciences, April 8.—M. Des Cloizeaux, President, in the chair.—Fixation of nitrogen by vegetable soil with or without the aid of leguminous plants, by M. Berthelot. The paper deals with a fresh series of sixty-four methodic experiments carried out during the year 1888, and fully described in the April number of the *Annales de Chimie et de Physique*. They form a sequel to the systematic researches begun by the author in 1883, and tend fully to confirm the views already announced by him on the fixation of free nitrogen in the ground effected either with or without the co-operation of luzern, vetches, and other leguminous plants. He considers the fixation now fully established, and finds in this fact the true interpretation of a multitude of phenomena highly important to agriculture.—Experiments on putrefaction and the formation of manures, by M. J. Reiset. The more recent experiments here described fully confirm the results of those undertaken by the author so far back as 1854, and show that, in the process of organic decomposition, nitrogen is not fixed, but liberated.—On the identity of erysipelas and acute lymphangitis, by MM. Verneuil and Clado. The researches of the authors in the Hospital de la Pitié show that these are not two distinct disorders, as is often assumed, but merely two forms of the same contagious, infectious, and parasitic disease, due to a special microbe easily recognized, isolated, cultivated, and inoculated in animals. This microbe, hitherto discovered in erysipelas alone, has now also been detected in acute lymphangitis with all its characters and biological properties.—On the influence of refraction in the reduction of the observations of a meridian transit, by M. G. Rayet. The conditions already described by the author in his communication on the influence of refraction in the reduction of the observations of the circumpolar stars (*Comptes rendus*, March 11, 1889), are here shown to be equally applicable to the reduction of the observations of transits at any declination.—Direct determination of the compressibility of glass, crystal, and metals, up to 2000 atmospheres, by M. E. H. Amagat. By direct determination is here meant a determination effected without employing any formula. The results already communicated in recent notes were for slight pressures only; hence these further experiments have been undertaken for the purpose of ascertaining whether, under very high pressures, the compressibility of glass, crystal, &c., undergoes any considerable diminution. The process employed is that adopted by Mr. Buchanan, and afterwards by Prof. Tait in their researches.—On the intensity of telephonic effects, by M. E. Mercadier. During his researches on the theory of the telephone, the author has been led to study the causes to which is due the varying intensity of the effects produced by this instrument. Here he studies more particularly the influence of the thickness of the diaphragm for a telephone of well-defined form, and for a like variation of the magnetic

field. Some experiments are described with iron diaphragms, and it is generally inferred that for all telephones of a given magnetic field there is a given thickness of the iron diaphragm which yields a maximum effect.—On the solubility of salts, by M. H. W. Bakhuis Roozeboom. This is a reply to M. Le Chatelier's critical remarks (*Comptes rendus*, March 18, 1889) on the work recently published by the author on the conditions of equilibrium between the solid and liquid combinations of water with salts, more particularly with calcium chloride.—On methylacetanilide, by M. H. Giraud. It is pointed out that the scientific name of ortho-methylacetanilide given to the *exalgine* recently prepared by M. Brigonnet, can only be applied to the substance described by Beilstein and Kuhlberg under the name of aceto-orthotoluide. It is further shown that M. Brigonnet's preparation is not new, that it was described by Hofmann in 1874, and that its true name is methylacetanilide.

Berlin.

Physiological Society, March 27.—Prof. du Bois-Reymond, President, in the chair.—Dr. Klemperer spoke on the proteid needs of the animal economy in health and in certain pathological conditions. Voit's teaching, that the human body in health requires daily from 100 to 120 grammes of proteid in order to supply its nitrogenous needs, has been recently contested from many sides; and even if the experiments on which the attacks were based were not altogether free from some defects, they still sufficed to cast a good deal of doubt on Voit's theory. The speaker had endeavoured, working from the clinical point of view, to decide the question whether an increased proteid metabolism can be prevented or diminished by an increased ingestion of carbohydrates or fats. He carried out experiments on the nutrition of two healthy persons, in which the daily dose of proteids was very considerably diminished, even down to 40 grammes, while in compensation for the lessened proteids larger quantities of fats, sugar, and easily absorbed and oxidizable alcohol were administered. The nitrogen excreted in the urine was constantly less in amount than that taken in the food, thus showing that healthy, active men can be fed with largely diminished amounts of proteid without the occurrence of any destructive metabolism of their tissue-proteids. He next proceeded to investigate whether, in diseases which are characterized by an abnormally large breaking down of tissue-proteids, this increased nitrogenous metabolism could be lessened by the ingestion of an increased quantity of non-nitrogenous food. An increased nitrogenous metabolism occurs in dyspnœa, fever, anæmia, cancer, tuberculosis, diabetes, and Addison's disease. For dyspnœa, experiments were made on animals; while for anæmia, cancer, diabetes, and Addison's disease, observations were made on the human subject, and results were obtained which corresponded to the supposition under which the experiments were started. A very considerable reduction of the nitrogen excreted in the urine was observed when only moderate quantities of proteid were given, while at the same time increased amounts of carbohydrates, fats, and alcohol, were administered. It is impossible to enter here into the interesting details of these experiments, which were all carried out by very precise methods, or into a discussion of the hypotheses which were advanced in explanation of the phenomena which had been observed.—Prof. Rosenthal, of Erlangen, gave an account of calorimetric experiments with which he had been busied for the last few years. He employed in these an air-calorimeter of special construction. It consisted of a copper vessel, of easy ventilation, in which the animal was placed; this was surrounded by an air-tight envelope, filled with air and constituting the reservoir of an air-thermometer; external to this was a covering to shield the whole apparatus from any changes in the temperature of the surrounding atmosphere. When the animal gives up to the envelope of air, per unit of time, exactly the same amount of heat as the whole apparatus radiates into the surroundings, the temperature of the air in the envelope remains constant, as also its *pressure*: hence the heat produced and given off by the animal during any known time could be measured by means of a manometer. Notwithstanding that the dog used in the experiments was fed in exactly the same way at each meal, the quantities of heat produced varied very largely, and any considerable uniformity is only obtained by taking the mean of a long series of observations. Up to about the third hour after the meal the heat-production diminishes, then rises rapidly to a maximum, and from this point, at about the eighth hour, it begins to fall again slowly and with irregularities, until the next meal. Over the whole twenty-four hours the heat-production is more uniform during the second period of twelve hours than in the first; about 20 per cent. more heat is produced during the first than during the second half of the whole day. When an excess of food was given the heat produced was always less than that calculated out from the oxidation of the food itself; but with a uniformly constant diet the mean value of the heat produced corresponded to the heat calculated for the oxidation of the food. The amount of carbonic acid gas given off by the animal was found to correspond to the heat given off during the same period only in cases where prolonged intervals of time were taken into account. When the surrounding temperature varied between 5° and 25° C., all other conditions remaining the same, a minimal production of heat was observed at 15° C.: from this point it increased uniformly in both directions, not only when the temperature fell to 5° C., but also when it rose to 25° C.—Prof. Schweigger demonstrated several pieces of apparatus, which by the use of small incandescent electric lamps, could take the place of the ophthalmoscope, and even render a binocular examination possible. They also made the measurement of refraction in the eye both simple and exact.
